The primary function of the respiratory system is to remove appropriate amounts of carbon dioxide (CO₂) from the blood entering the pulmonary circulation and to add adequate amounts of oxygen (O₂) to the blood leaving the pulmonary circulation. This section of the chapter provides a broad overview of the causes and manifestations of the hypoxemia and hypercapnia that develop as the result of the impaired ventilation and gas exchange occurring with many of the disorders discussed in the chapter.

Ventilation involves the movement of atmospheric air to the alveoli for provision of O₂ and removal of CO₂. Minute ventilation is the volume of air exchanged per minute and is determined by both the amount of air exchanged with each breath (tidal volume) and the respiratory rate (breaths per minute).

Gas exchange takes place within the lungs and involves the exchange of O₂ and CO₂ between air in the alveoli and the blood in the pulmonary capillaries. The process involves the diffusion or movement of O₂ from the air in the alveoli (which is rich in O₂ and low in CO₂) to the blood in the pulmonary capillaries. It also involves the transfer of CO₂ from the blood in the pulmonary capillaries (which has low amounts of O₂ and high amounts of CO₂) to the alveoli. Adequate oxygenation of the blood and removal of CO₂ also depend on adequate circulation of blood through the pulmonary blood vessels (perfusion) and appropriate contact between ventilated alveoli and perfused capillaries of the pulmonary circulation (ventilation and perfusion matching) (Fig. 37.1).

As a general rule, oxygenation of the blood depends primarily on factors that promote diffusion of O₂ from the alveoli into the pulmonary capillaries. Removal of CO₂ depends primarily on the minute ventilation (respiratory rate × tidal volume) and elimination of CO₂ from the alveoli (Fig. 37.2).

**Hypoxemia**

Hypoxemia refers to a reduction in arterial blood O₂ levels, which is considered a PaO₂ less than 95 mm Hg.

**Etiology and Pathogenesis**

Hypoxemia can result from an inadequate amount of O₂ in the air, a disorder of the respiratory system, dysfunction of the neurologic system, or alterations in circulatory function. The mechanisms whereby respiratory disorders lead to a significant reduction in PO₂ are hypoventilation, impaired diffusion of gases, inadequate circulation of blood through the pulmonary capillaries, and mismatching of ventilation and perfusion. Often, more than one mechanism contributes to hypoxemia in a person with respiratory or cardiac disease.

**Clinical Manifestations**

Hypoxemia produces its effects through tissue hypoxia and the compensatory mechanisms that the body uses to adapt to the lowered oxygen level. Body tissues vary considerably in their vulnerability to hypoxia. Tissues with the greatest need are the brain, lungs, and heart. If the PO₂ of the tissues falls below a critical level, aerobic metabolism ceases and anaerobic metabolism takes over, with formation and release of lactic acid. This results in increased serum lactate levels and metabolic acidosis. The normal range of serum lactate levels is 1 to 0.5 mmol/L in nonacutely ill people.

Mild hypoxemia produces few manifestations. Recruitment of sympathetic nervous system compensatory mechanisms produces an increase in heart rate, peripheral vasoconstriction, diaphoresis, and a mild increase in blood pressure. There may be slight impairment of mental performance and visual acuity and sometimes hyperventilation. This is because hemoglobin saturation still is approximately 90% when the PO₂ is only 60 mm Hg. More pronounced hypoxemia may produce confusion, personality changes,
restlessness, agitation or combative behavior, uncoordinated muscle movements, euphoria, impaired judgment, delirium, and, eventually, stupor and coma.

The manifestations of chronic hypoxemia may be insidious in onset and attributed to other causes, particularly in people with chronic lung disease. The body compensates for chronic hypoxemia by increased ventilation, pulmonary vasoconstriction, and increased production of red blood cells. Pulmonary vasoconstriction occurs as a local response to alveolar hypoxia. It increases pulmonary arterial pressure and improves the matching of ventilation and blood flow. Increased production of red blood cells results from the release of erythropoietin from the kidneys in response to hypoxia. Polycythemia increases the red blood cell concentration and the oxygen-carrying capacity of the blood. Other adaptive mechanisms include a shift to the right in the oxygen dissociation curve, which increases O2 release to the tissues.

Cyanosis refers to the bluish discoloration of the skin and mucous membranes that results from an excessive concentration of reduced or deoxygenated hemoglobin in the small blood vessels. It usually is most marked in the lips, nail beds, ears, and cheeks. The degree of cyanosis is modified by the amount of cutaneous pigment, skin thickness, and the state of the cutaneous capillaries. Cyanosis is more difficult to distinguish in people with dark skin and in areas of the body with increased skin thickness. Inspect the buccal tissue of the oral mucosa of dark-skinned people because this is the most accurate location to assess for cyanosis. Although cyanosis may be evident in people with respiratory failure, it often is a late sign.

A concentration of approximately 5 g/dL of deoxygenated hemoglobin is required in the circulating blood for cyanosis to occur. The absolute quantity of reduced hemoglobin, rather than the relative quantity, is important in producing cyanosis.

People with anemia and low hemoglobin levels are less likely than people with high hemoglobin concentrations to exhibit cyanosis (because they have less hemoglobin to deoxygenate), even though they may be relatively hypoxic because of their decreased ability to transport oxygen. A person with a high hemoglobin level due to polycythemia may be cyanotic without being hypoxic.

Cyanosis can be divided into two types: central and peripheral. Central cyanosis is evident in the tongue and lips. It is caused by an increased amount of deoxygenated hemoglobin or an abnormal hemoglobin derivative in the arterial blood. Abnormal hemoglobin derivatives include methemoglobin, in which the nitrite ion reacts with hemoglobin. Because methemoglobin has a low affinity for O₂, large doses of nitrites can result in cyanosis and tissue hypoxia. Although nitrites are used in treating angina, the therapeutic dose is too small to cause cyanosis. Peripheral cyanosis occurs in the extremities and on the tip of the nose or ears. It is caused by slowing of blood flow to an area of the body, with increased extraction of oxygen from the blood. It results from vasoconstriction and diminished peripheral blood flow, as occurs with cold exposure, shock, heart failure, or peripheral vascular disease. Clubbing may also be evident in people with COPD since there is long-term hypoxia. This is readily seen during a peripheral cardiovascular inspection when the provider assesses peripheral oxygenation/perfusion since the angle of the nail is 180 degrees or greater (Fig. 37.3).

Diagnosis
Diagnosis of hypoxemia is based on clinical observation and diagnostic measures of PO₂ levels. The analysis of arterial blood gases provides a direct measure of the O₂ content of the blood and is the best indicator of the ability of the lungs to oxygenate the blood. Venous oxygen saturation (SvO₂) reflects the body’s extraction and utilization of O₂ at the tissue levels. Venous blood samples can be obtained through either a pulmonary artery catheter or a central line. The latter is less invasive but slightly less accurate because the blood has not yet been mixed in the right ventricle.

Noninvasive measurements of arterial O₂ saturation of hemoglobin can be obtained using an instrument called the pulse oximeter (Fig. 37.4). The pulse oximeter uses light-emitting diodes and combines plethysmography (i.e., changes in light absorbance and vasodilation) with spectrophotometry to measure oxygen saturation. The normal SpO₂ ranges from 90 to 100. Spectrophotometry uses a red-wavelength light that passes through oxygenated hemoglobin and is absorbed by deoxygenated hemoglobin and an infrared-wavelength light that is absorbed by oxygenated hemoglobin and passes through deoxygenated hemoglobin. Sensors that can be placed on the ear, finger, toe, or forehead are available. Sensors can be placed on the palm, penis, foot, and arm of infants. The pulse oximeter cannot distinguish between oxygen-carrying hemoglobin and carbon monoxide–carrying hemoglobin. In addition, the pulse oximeter cannot detect elevated levels of methemoglobin. Although pulse oximetry is not as accurate as arterial blood gas measurements, it provides the means for noninvasive and continuous monitoring of O₂ saturation. This is a useful trend indicator of respiratory and circulatory status. However, its reliability is questionable when used with people who are acutely ill. Using a formula that identifies arterial values of pH, PCO₂, and PO₂ from the person’s venous values and pulse oximetry has also been effective. Using blood from a central venous line with pulse oximetry may offer more information than arterial specimens in people acutely ill with respiratory disorders.

The ratio between the arterial PO₂ and the fraction of inspired oxygen (FiO₂), termed the PF ratio, is an additional indicator of alterations in diffusion of O₂ at the lung level. In determining this ratio, the PO₂ is divided by the FiO₂ of a person breathing room air. For example, the FiO₂ of a person breathing room air is 0.21 because
21% of atmospheric air is \( \text{O}_2 \). Whereas for the person receiving 40% \( \text{O}_2 \), the \( \text{FiO}_2 \) is 0.40. The normal value of the PF ratio is greater than 300. The PF ratio is useful for evaluating improvements or deteriorations in oxygen diffusion regardless of the percentage of supplemental oxygen that is being administered. In addition, the PF ratio is a diagnostic indicator of acute lung injury and acute respiratory distress syndrome (ARDS).

**Treatment**

Treatment of hypoxemia is directed toward correcting the cause of the disorder and increasing the gradient for diffusion through the administration of supplemental oxygen. Oxygen may be delivered by nasal cannula, mask, or administered directly via an endotracheal or tracheostomy tube in people who are mechanically ventilated. A high-flow administration system is one in which the flow rate and reserve capacity are sufficient to provide all the inspired air. A low-flow administration system is based on the \( \text{PO}_2 \) being administered (usually determined by the flow rate) is based on the \( \text{PO}_2 \). A high flow rate must be carefully monitored in people with chronic lung disease because increases in \( \text{PO}_2 \) above 60 mm Hg may depress the ventilatory drive. There also is the danger of oxygen toxicity with high concentrations of oxygen. Continuous breathing of oxygen at high concentrations can lead to diffuse parenchymal lung injury. People with healthy lungs begin to experience respiratory symptoms such as cough, sore throat, substernal tightness, nasal congestion, and painful inspiration after breathing pure oxygen for 24 hours.

**Hypercapnia**

Hypercapnia refers to an increase in the carbon dioxide content of the arterial blood. The carbon dioxide level in the arterial blood, or \( \text{PCO}_2 \), is proportional to carbon dioxide production and inversely related to alveolar ventilation.

**Etiology and Pathogenesis**

Hypercapnia can occur in a number of disorders that cause hypoventilation or mismatching of ventilation and perfusion. The diffusing capacity of carbon dioxide is 20 times that of oxygen. Therefore, hypercapnia without hypoxemia is usually observed only in situations of hypoventilation. In cases of ventilation–perfusion mismatching, hypercapnia is usually accompanied by a decrease in arterial \( \text{PO}_2 \) levels.

Conditions that increase carbon dioxide production, such as an increase in metabolic rate or a high-carbohydrate diet, can contribute to the degree of hypercapnia that occurs in people with impaired respiratory function. Changes in the metabolic rate resulting from an increase in activity, fever, or disease can have profound effects on carbon dioxide production. Alveolar ventilation usually rises proportionally with these changes, and hypercapnia occurs only when this increase is inappropriate.

The respiratory quotient (RQ), which is the ratio of carbon dioxide production to oxygen consumption (RQ = \( \text{CO}_2 \) production/\( \text{O}_2 \) consumption), varies with the type of food metabolized. A characteristic of carbohydrate metabolism is an RQ of 1.0, with equal amounts of carbon dioxide being produced and oxygen being consumed. Because fats contain less oxygen than carbohydrates, their oxidation produces less carbon dioxide (RQ = 0.7). The metabolism of pure proteins (RQ = 0.81) results in the production of more carbon dioxide than the metabolism of fat, but less than the metabolism of carbohydrates. The type of food that is eaten or the types of nutrients that are delivered through enteral feedings (i.e., through a tube placed in the small intestine) or parenteral nutrition (i.e., through a central venous catheter) may influence \( \text{PCO}_2 \) levels.

**Clinical Manifestations and Diagnosis**

Hypercapnia affects a number of body functions, including acid–base balance and renal, neurological, and cardiovascular function. Elevated levels of \( \text{PCO}_2 \) produce a decrease in pH and respiratory acidosis. The body normally compensates for an increase in \( \text{PCO}_2 \) by increasing renal bicarbonate (HCO\(_3^-\)) retention, which results in an increase in serum HCO\(_3^-\) and pH levels. As long as the pH is within normal range, the main complications of hypercapnia are those resulting from the accompanying hypoxia. Because the body adapts to chronic increases in blood levels of carbon dioxide, people with chronic hypercapnia may not have symptoms until the \( \text{PCO}_2 \) becomes markedly elevated. At this point, they will display symptoms of increased work of breathing since they will also be experiencing hypoxemia (Chart 37.1).

The diagnosis of hypercapnia is based on physiologic manifestations, arterial pH, and arterial blood gas levels. PACO\(_2\) can also be measured on individuals receiving...
mechanical ventilation via end-tidal carbon dioxide (ETCO₂) measuring at the end of exhalation. Samples of the carbon dioxide at the end of the exhaled breath can be used to identify an estimated PACO₂.

**Treatment**

The treatment of hypercapnia is directed at decreasing the work of breathing and improving the ventilation-perfusion balance. The use of intermittent rest therapy, such as nocturnal negative-pressure ventilation or continuous positive airway pressure, in people with chronic obstructive disease or chest wall disease may be effective in increasing the strength and endurance of the respiratory muscles and improving the PCO₂. Respiratory muscle retraining aimed at improving respiratory muscle strength and their endurance, or both, has been used to improve exercise tolerance and diminish the likelihood of respiratory fatigue. Use of a ventilator may become necessary in situations of acute hypercapnia.

**IN SUMMARY**

The primary function of the respiratory system is to remove appropriate amounts of CO₂ from the blood entering the pulmonary circulation and provide adequate O₂ to blood leaving the pulmonary circulation. This is accomplished through the process of ventilation, in which air moves into and out of the lungs, and diffusion, in which gases move between the alveoli and the pulmonary capillaries. Although both diffusion and ventilation affect gas exchange, oxygenation of the blood largely depends on diffusion and removal of carbon dioxide on ventilation.

Hypoxemia refers to a decrease in arterial blood oxygen levels that results in a decrease in tissue oxygenation. Hypoxemia can occur as the result of hypoventilation, diffusion impairment, shunt, and ventilation-perfusion impairment. Acute hypoxemia is manifested by increased respiratory effort (increased respiratory and heart rates, use of accessory muscles, pursed-lip breathing, diaphoresis), cyanosis, and impaired sensory and neurologic function, which is also referred to as work of breathing. The body compensates for chronic hypoxemia by increased ventilation, pulmonary vasoconstriction, and increased production of red blood cells.

Hypercapnia refers to an increase in carbon dioxide levels. In the clinical setting, four factors contribute to hypercapnia: alterations in carbon dioxide production, disturbance in the gas exchange function of the lungs, abnormalities in function of the chest wall and respiratory muscles, and changes in neural control of respiration. Alterations in respiratory function or the rate decrease minute volume, which is the most common cause of hypercapnia. The manifestations of hypercapnia consist of those associated with a decreased pH (respiratory acidosis); vasodilation of blood vessels, including those in the brain; and depression of central nervous system (CNS) function.

Air entering through the airways inflates the lung, and the negative pressure in the pleural cavity keeps the lung from collapsing. Disorders of lung inflation are caused by conditions that obstruct the airways, cause lung compression, or produce lung collapse. There can be compression of the lung by an accumulation of fluid in the intrapleural space; complete collapse of an entire lung, as in pneumothorax; or collapse of a segment of the lung due to airway obstruction, as in atelectasis.

**Disorders of the Pleura**

The pleura is a thin, double-layered serous membrane that encases the lungs (Fig. 37.5). The outer parietal layer lines the thoracic wall and superior aspect of the diaphragm. It continues around the heart and between the lungs, forming the lateral walls of the mediastinum. The inner visceral layer covers the lung and is adherent to all its surfaces. The pleural cavity or space between the two layers contains a thin layer of serous fluid that lubricates the pleural surfaces and allows the parietal and visceral pleurae to slide smoothly over each other during breathing movements. The pressure in the pleural cavity, which is negative in relation to atmospheric pressure, holds the lungs against the chest wall and keeps them from collapsing. Disorders of the pleura include pleural effusion, hemothorax, pneumothorax, and pleural inflammation.

**Pleural Effusion**

Pleural effusion refers to an abnormal collection of fluid in the pleural cavity. Like fluid developing in other transcellular spaces in the body, pleural effusion occurs when the rate of fluid formation exceeds the rate of its removal.

**Etiology and Pathogenesis.** Normally, fluid enters the pleural space from capillaries in the parietal pleura and is removed by the lymphatics situated in the parietal pleura. Fluid can also enter from the interstitial spaces of the lung through the visceral pleura or from small holes in the diaphragm. Accordingly, fluid may accumulate when there is excess fluid formation (from the interstitium of the lung, the parietal pleura,
or peritoneal cavity) or when there is decreased removal by the lymphatics.

The fluid that accumulates in a pleural effusion may be a transudate or exudate, purulent (containing pus), chyle, or sanguineous (bloody). The accumulation of a serous transudate (clear fluid) in the pleural cavity often is referred to as hydrothorax. The condition may be unilateral or bilateral. The most common cause of hydrothorax is congestive heart failure. Other causes are renal failure, nephrosis, liver failure, and malignancy. An exudate is a pleural fluid that has a specific gravity greater than 1.020 and often contains inflammatory cells.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. LDH is an enzyme that is released from inflamed and injured pleural tissue. Because measurements of LDH are easily obtained from a sample of pleural fluid, it is a useful marker for diagnosis of exudative pleural disorders. Exudative pleural effusion meets at least one of the following criteria:

1. A pleural fluid protein/serum protein ratio greater than 0.5
2. A pleural fluid LDH/serum LDH ratio greater than 0.6
3. A pleural fluid LDH greater than two thirds the upper limit of normal serum LDH

Conditions that produce exudative pleural effusions are bacterial pneumonia, viral infection, pulmonary infarction, and malignancies. These conditions make up approximately 70% of all pleural effusions.

**Empyema** refers to an infection in the pleural cavity that results in exudate containing glucose, proteins, leukocytes, and debris from dead cells and tissue. It is caused by an adjacent bacterial pneumonia, rupture of a lung abscess into the pleural space, invasion from a subdiaphragmatic infection, or infection associated with trauma.

Chylothorax is the effusion of lymph in the thoracic cavity. Chyle, a milky fluid containing chylomicrons, is found in the lymph fluid originating in the gastrointestinal tract. The thoracic duct transports chyle to the central circulation. Chylothorax also results from trauma, inflammation, or malignant infiltration obstructing chyle transport from the thoracic duct into the central circulation. It is the most common cause of pleural effusion in the fetus and neonate, resulting from congenital malformation of the thoracic duct or lymph channels. Chylothorax also can occur as a complication of intrathoracic surgical procedures and use of the great veins for total parenteral nutrition and hemodynamic monitoring.

**Clinical Manifestations.** The manifestations of pleural effusion vary with the cause. Empyema may be accompanied by fever, increased white blood cell count, and other signs of inflammation. Fluid in the pleural cavity acts as a space-occupying mass; it causes a decrease in lung expansion on the affected side that is proportional to the amount of fluid collected. Characteristic signs of pleural effusion are dullness or flatness to percussion and diminished breath sounds. Hypoxemia may occur due to the decreased surface area and usualy is corrected with supplemental oxygen. Dyspnea, the most common symptom, occurs when fluid compresses the lung, resulting in increased effort or rate of breathing. Pleuritic pain usually occurs only when inflammation is present. However, constant discomfort may be felt with large effusions.

**Diagnosis and Treatment.** Diagnosis of pleural effusion is based on chest radiographs, chest ultrasonography, and computed tomography (CT). Thoracentesis (aspiration of fluid from the pleural space) can be used to obtain a sample of pleural fluid for diagnosis. The treatment of pleural effusion is directed at the cause of the disorder. With large effusions, thoracentesis may be used to remove fluid from the intrapleural space and allow for reexpansion of the lung. A palliative method used for treatment of pleural effusions caused by a malignancy is the injection of a sclerosing agent into the pleural cavity. This method of treatment causes obliteration of the pleural space and prevents the reaccumulation of fluid. Chest tube drainage may be necessary in cases of continued effusion.

**Hemothorax**

Hemothorax is a specific type of pleural effusion in which there is blood in the pleural cavity.

**Etiology and Pathogenesis.** Bleeding may be the result of chest injury, a complication of chest surgery, malignancies, or rupture of a great vessel such as an aortic aneurysm. Hemothorax may be classified as minimal, moderate, or large. A minimal hemothorax involves the presence of at least 250 mL of blood in the pleural space. Small amounts of blood usually are absorbed from the pleural space, and the hemothorax usually clears in 10 to 14 days without complication. A moderate hemothorax fills approximately one third of the pleural cavity.
pleural space and may produce signs of lung compression and loss of intravascular volume. It requires immediate drainage and replacement of intravascular fluids. A large hemothorax fills one half or more of one side of the chest and is usually caused by bleeding from a high-pressure vessel such as an intercostal or mammary artery. It requires immediate drainage and, if the bleeding continues, surgery to control the bleeding.

**Clinical Manifestations.** In addition to alterations in oxygenation, ventilation, respiration effort, and breath sounds, signs of blood loss, including increased heart rate, may accompany hemothorax. Because hemothorax is abrupt in onset, the manifestations are usually sudden and distressing. One of the complications of untreated moderate or large hemothorax is fibrothorax—the fusion of the pleural surfaces by fibrin, hyaline, and connective tissue—and, in some cases, calcification of the fibrous tissue, which restricts lung expansion.

**Diagnosis and Treatment.** Diagnosis of hemothorax is based on chest radiographs and decreased arterial saturation, which is indicative of decreased oxygen exchange. If the person is symptomatic or oxygen exchange is compromised, chest tube drainage is indicated.

**Pneumothorax**

Pneumothorax refers to the presence of air in the pleural space. Pneumothorax causes partial or complete collapse of the affected lung.

**Etiology and Pathogenesis.** Pneumothorax can occur without an obvious cause or injury (i.e., spontaneous pneumothorax) or as a result of direct injury to the chest or major airways (i.e., traumatic pneumothorax). Tension pneumothorax describes a life-threatening condition in which increased pressure within the pleural cavity impedes both respiratory and cardiac function.

**Spontaneous Pneumothorax.** Spontaneous pneumothorax is hypothesized to occur due to the rupture of an air-filled bleb, or blister, on the surface of the lung. Rupture of these blebs allows atmospheric air from the airways to enter the pleural cavity (Fig. 37.6). Because alveolar pressure normally is greater than pleural pressure, air flows from the alveoli into the pleural space, causing the involved portion of the lung to collapse as a result of its own recoil. Air continues to flow into the pleural space until a pressure gradient no longer exists or until the decline in lung size causes the leak to seal. Spontaneous pneumothoraces can be divided into primary and secondary pneumothoraces. Primary pneumothorax occurs in otherwise healthy people, whereas secondary pneumothorax occurs in persons with underlying lung disease.

In primary spontaneous pneumothorax, the blebs usually are located at the top of the lungs. The condition is seen most often in tall boys and young men between 10 and 30 years of age. It has been suggested that the difference in pleural pressure from the top to the bottom of the lung is greater in tall people and that this difference in pressure may contribute to the development of blebs. Smoking and family history are factors associated with primary spontaneous pneumothorax.

**Disorders of Ventilation and Gas Exchange**

![FIGURE 37.6](image)

**FIGURE 37.6** Mechanism for development of spontaneous pneumothorax, in which an air-filled bleb on the surface of the lung ruptures, allowing atmospheric air from the airways to enter the pleural space.
require chest surgery. Medical procedures such as transthoracic needle aspirations, central line insertion, intubation, and positive-pressure ventilation occasionally may cause pneumothorax. Traumatic pneumothorax also can occur as a complication of cardiopulmonary resuscitation.

**Tension Pneumothorax.** Tension pneumothorax occurs when the intrapleural pressure exceeds atmospheric pressure. It is a life-threatening condition and occurs when injury to the chest or respiratory structures permits air to enter but not leave the pleural space (Fig. 37.7). This results in a rapid increase in pressure within the chest that causes compression atelectasis of the unaffected lung, a shift in the mediastinum to the opposite side of the chest, and compression of the vena cava, which results in a decrease in venous return to the heart and reduced cardiac output. Although tension pneumothorax can develop in people with spontaneous pneumothoraces, it is seen most often in people with traumatic pneumothoraces. It also may result from barotrauma caused by mechanical ventilation.

**Clinical Manifestations.** The manifestations of pneumothorax depend on its size and the integrity of the underlying lung. In spontaneous pneumothorax, manifestations of the disorder sometimes include development of ipsilateral chest pain. There is an almost immediate increase in respiratory rate, often accompanied by dyspnea that occurs as a result of the activation of receptors that monitor lung volume. Asymmetry of the chest may occur because of the air being trapped in the pleural cavity on the affected side. This asymmetry may be evidenced during inspiration as a lag in the movement of the affected side, with inspiration delayed until the unaffected lung reaches the same level of pressure as the lung with the air trapped in the pleural space. Percussion of the chest produces a more hyperresonant sound, and breath sounds are decreased or absent over the area of the pneumothorax.

With tension pneumothorax, the structures in the mediastinal space shift toward the opposite side of the chest (see Fig. 37.7). When this occurs, the position of the trachea, normally located in the midline of the neck, deviates with the mediastinum. The position of the trachea can be used as a means of assessing for a mediastinal shift. Because of the increase in intrathoracic pressure, stroke volume is impaired to such an extent that cardiac output is decreased despite an increase in heart rate. There may be jugular neck vein distention, subcutaneous emphysema (i.e., presence of air in the subcutaneous tissues of the chest and neck), and clinical signs of shock due to impaired cardiac function.

**FIGURE 37.7** • Open or communicating pneumothorax (top) and tension pneumothorax (bottom). In an open pneumothorax, air enters the chest during inspiration and exits during expiration. There may be slight inflation of the affected lung because of a decrease in pressure as air moves out of the chest. In tension pneumothorax, air can enter but not leave the chest. As the pressure in the chest increases, the heart and great vessels are compressed and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed.

Hypoxemia usually develops immediately after a large pneumothorax, followed by vasoconstriction of the blood vessels in the affected lung, causing the blood flow to shift to the unaffected lung. In people with primary spontaneous pneumothorax, this mechanism usually returns oxygen saturation to normal within 24 hours. Hypoxemia usually is more serious in persons with underlying lung disease in whom secondary spontaneous pneumothorax develops or in people with underlying heart disease who are unable to compensate with an increase in heart rate and stroke volumes. Regardless of etiology, the hypoxemia caused by the partial or total loss of lung function can be life-threatening. Without immediate intervention, the increased thoracic pressure will further impair both cardiac and pulmonary function, resulting in severe hypoxemia and hypotension, which often leads to respiratory and cardiac arrest.

**Diagnosis and Treatment.** Chest radiograph or CT scan confirms diagnosis of pneumothorax. Perform pulse oximetry and blood gas analysis to determine the effect on blood oxygen levels. Treatment of pneumothorax varies with the cause and extent of the disorder. In small spontaneous pneumothoraces, the air usually reabsorbs spontaneously. Therefore, only observation and follow-up chest radiographs are required. Supplemental oxygen may be used to correct the hypoxemia until the air is reabsorbed. In larger pneumothoraces, the air is removed by needle aspiration or a closed drainage system used with or without suction. This type of drainage system uses a one-way valve or a water-seal chamber to allow air to exit the pleural space and prevent it from reentering the chest.

Emergency treatment of tension pneumothorax involves the prompt insertion of a large-bore needle or chest tube into the affected side of the chest along with one-way valve
Porth9781451146004-ch037.indd   967

should be advised against cigarette smoking, exposure to high
recurrence, people with primary spontaneous pneumothorax
gauze, firm piece of plastic). Chest tubes are inserted as soon
as possible to reexpand the lung. Because of the risk for
recurrence, people with primary spontaneous pneumothorax
should be advised against cigarette smoking, exposure to high
altitudes, flying in nonpressurized aircraft, and scuba diving.

**KEY POINTS**

**Disorders of Lung Inflation**
- The pleura encases the lungs and is made up of
two layers, which create the pleural cavity where
pathology is often caused by air getting into the
space, which is called a pneumothorax, or blood
in the pleural space, which would cause a hemo-
thora.
- Atelectasis is a partial expansion of the lung,
which is caused by obstruction or compression of
lung tissue.

**Pleuritis**

Pleuritis (also called pleurisy) refers to inflammation of the
pleura. Pleuritis is common in infectious processes such as
respiratory infections that extend to involve the pleura. Pain
is a frequent symptom and most commonly is unilateral
and abrupt in onset. When the central part of the diaphragm
is irritated, the pain may be referred to the shoulder. Chest
movements such as deep breathing and coughing that exag-
gerate pressure changes in the pleural cavity and increase
movement of the inflamed or injured pleural surfaces usually
make the pain worse. Because deep breathing is painful, tidal
volumes usually are kept small, and breathing becomes more
rapid to maintain minute volume. Reflex splinting of the chest
muscles may occur, causing a lesser respiratory expansion on
the affected side.

It is important to differentiate pleural pain from pain pro-
duced by other conditions, such as musculoskeletal strain of
chest muscles, bronchial irritation, and myocardial disease.
Musculoskeletal pain may occur as the result of frequent, force-
ful coughing. This type of pain usually is bilateral and located
in the inferior portions of the rib cage, where the abdominal
muscles insert into the anterior rib cage. Movements associ-
ated with contraction of the abdominal muscles make it worse.
The pain associated with irritation of the bronchi usually is
substantial and dull in character rather than sharp; it is often
described as tightening. This type of pain is made worse with
coughing but is not affected by deep breathing. Myocardial
discomfort or pain usually is located in the substernal area and
is not affected by respiratory movements.

Treatment of pleuritis consists of treating the underlying
disease and inflammation. Analgesics and nonsteroidal anti-
inflammatory drugs (NSAIDs; e.g., ibuprofen, indomethacin)
may be used for pleural pain. Although these agents reduce
inflammation, they may not entirely relieve the discomfort
associated with deep breathing and coughing.

**Atelectasis**

Atelectasis refers to an incomplete expansion of a lung or por-
tion of a lung. It can be caused by airway obstruction, lung
compression such as occurs in pneumothorax or pleural effu-
sion, or increased recoil of the lung due to loss of pulmonary
surfactant. The disorder may be present at birth (i.e., primary
atelectasis) or develop during the neonatal period or later in
life (i.e., acquired or secondary atelectasis).

**Etiology and Pathogenesis**

Primary atelectasis of the newborn implies that the lung has
never been inflated. It is seen most frequently in premature
and high-risk infants. A secondary form of atelectasis can
occur in infants who established respiration and subsequently
experienced impairment of lung expansion. Among the causes
of secondary atelectasis in the newborn is respiratory distress
syndrome associated with lack of surfactant, airway obstruc-
tion due to aspiration of amniotic fluid or blood, and broncho-
pulmonary dysplasia.

Acquired atelectasis occurs mainly in adults. It is caused
most commonly by airway obstruction and lung compression
(Fig. 37.8). A mucus plug in the airway or external compres-
sion by fluid, tumor mass, exudate, or other matter in the area
surrounding the airway can cause obstruction. Portions of
alveoli, a small segment of lung, or an entire lung lobe may be
involved in obstructive atelectasis. Complete obstruction of an
airway is followed by the absorption of air from the dependent
alveoli and collapse of that portion of the lung. Breathing high
concentrations of oxygen increases the rate at which gases
are absorbed from the alveoli and predisposes to atelectasis.

![Obstructed airway](image)

**FIGURE 37.8** Atelectasis caused by airway obstruction and
absorption of air from the involved lung area (**left**) and by compression
of lung tissue (**right**).
The danger of obstructive atelectasis increases after surgery. Administration of narcotics or anesthesia, pain, and immobility tend to promote retention of viscid bronchial secretions and can cause airway obstruction. The encouragement of coughing and deep breathing, frequent change of position, adequate hydration, and early ambulation decrease the likelihood of atelectasis developing.

Another cause of atelectasis is compression of lung tissue. It occurs when the pleural cavity is partially or completely filled with fluid, exudate, blood, a tumor mass, or air. It is observed most commonly in people with pleural effusion from congestive heart failure or cancer.

Clinical Manifestations

The clinical manifestations of atelectasis include tachypnea, tachycardia, dyspnea, cyanosis, signs of hypoxemia, diminished chest expansion, decreased breath sounds, and intercostal retractions. There may be intercostal retraction (pulling in of the intercostal spaces) over the involved area during inspiration. Signs of respiratory distress are proportional to the extent of lung collapse. If the collapsed area is large, the mediastinum and trachea shift to the affected side. In compression atelectasis, the mediastinum shifts away from the affected lung.

Diagnosis and Treatment

The diagnosis of atelectasis is based on signs and symptoms. Chest radiographs are used to confirm the diagnosis. CT scans may be used to show the exact location of the obstruction.

Treatment depends on the cause and extent of lung involvement. It is directed at reducing the airway obstruction or lung compression and at reinflating the collapsed area of the lung. Ambulation, deep breathing, and body positions that favor increased lung expansion are used when appropriate. Administration of oxygen may be needed to correct the hypoxemia. There are new minimally invasive bronchoscopic procedures that may be used as both a diagnostic and treatment method.

IN SUMMARY

Disorders of the pleura include pleural effusion, hemothorax, pneumothorax, and pleuritis. Pleural effusion refers to the abnormal accumulation of fluid in the pleural cavity. The fluid may be a transudate (i.e., hydrothorax), exudate (i.e., empyema), or chyle (i.e., chylothorax). Hemothorax refers to the presence of blood in the pleural cavity. Pain is a common symptom of conditions that produce pleuritis or inflammation of the pleura. Characteristically, the pain is unilateral, abrupt in onset, and exaggerated by respiratory movements. Pneumothorax refers to an accumulation of air in the pleural cavity that causes partial or complete collapse of the lung. Pneumothorax can result from rupture of an air-filled bleb on the lung surface or from penetrating or nonpenetrating injuries. A tension pneumothorax is a life-threatening event in which air progressively accumulates in the thorax, collapsing the lung on the injured side and progressively shifting the mediastinum to the opposite side of the thorax, producing severe cardiac and respiratory impairment.

Atelectasis refers to an incomplete expansion of the lung. Primary atelectasis occurs most often in premature and high-risk infants. Acquired atelectasis occurs mainly in adults and is caused most commonly by a mucus plug in the airway or by external compression by fluid, tumor mass, exudate, or other matter in the area surrounding the airway.

OBSTRUCTIVE AIRWAY DISORDERS

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the interaction between one’s genetics, alteration of immune response, and environmental agents in the pathogenesis of asthma or reactive airway disease.
- Differentiate between chronic bronchitis and emphysema in terms of pathology and clinical manifestations.
- Describe the genetic abnormality responsible for the manifestations of cystic fibrosis.

Obstructive airway disorders are caused by disorders that limit expiratory airflow. Asthma represents an acute and reversible form of airway disease caused by narrowing of airways due to bronchospasm, inflammation, and increased airway secretions. Chronic obstructive disorders include a variety of airway diseases, such as chronic bronchitis, emphysema, bronchiectasis, and CF.

Physiology of Airway Disease

Air moves through the upper airways (i.e., trachea and major bronchi) into the lower or pulmonary airways (i.e., bronchi and alveoli). In the pulmonary airways, the cartilaginous layer that provides support for the trachea and major bronchi gradually disappears and is replaced with crisscrossing strips of smooth muscle. The contraction and relaxation of the smooth muscle layer, which is innervated by the autonomic nervous system, controls the diameter of the bronchial airways and consequent resistance to airflow. Parasympathetic stimulation, through the vagus nerve and cholinergic receptors, produces bronchial constriction, whereas sympathetic stimulation, through β2-adrenergic receptors, increases bronchial dilation. At rest, a slight vagal-mediated bronchoconstrictor tone predominates. When there is need for increased airflow, as during exercise, the bronchodilator effects of the sympathetic nervous system are stimulated and the bronchoconstrictor effects of the parasympathetic nervous system are inhibited. Bronchial smooth muscle also responds to inflammatory mediators, such as histamine, that act directly on bronchial smooth muscle cells to produce constriction.
Chapter 37  Disorders of Ventilation and Gas Exchange  969

KEY POINTS

AIRWAY DISORDERS

• Changes in airway patency involve changes in airway diameter due to bronchial smooth muscle hyperreactivity or changes in bronchial wall structure, injury to the mucosal lining of the airways, or excess respiratory tract secretions.

• Bronchial asthma is a chronic disorder of the airways that causes episodes of airway obstruction due to bronchial smooth muscle hyperreactivity and airway inflammation. The episodes usually are reversible.

• COPD represents a group of disorders that cause chronic and recurrent obstruction of the pulmonary airways. These disorders can affect patency of the bronchial structures (chronic bronchitis), the gas-diffusing airspaces distal to the terminal bronchioles (emphysema), or a combination of both.

Asthma

Asthma is a chronic disorder of the airways that causes episodes of airway obstruction, bronchial hyperresponsiveness, airway inflammation, and, in some, airway remodeling. According to 2009 data, an estimated 7.1 million American children, which is 9.6% of all American children, have asthma. An estimated 17.5 million American adults have asthma, which is approximately 7.7% of all adults. Even though many diseases have decreased mortality rates in the United States, the mortality rate for asthma has increased, especially with older adults (>85 years) and African Americans.

The strongest risk factor for developing asthma is a genetic predisposition for the development of an immunoglobulin E (IgE)-mediated response to common allergens. IgE is the antibody involved in causing allergic reactions and inflammation. Other risk factors for childhood asthma include family history of asthma, allergies, antenatal exposure to tobacco smoke and pollution, and multiple potentially overlapping genetic predispositions. Asthma severity is impacted by several factors including genetics, age of onset, pollution exposure, atopy, degree of exposure to triggers, environmental triggers such as tobacco smoke and dust mites, and the presence of gastroesophageal reflux disease or respiratory infections (see “Severe or Refractory Asthma”). Reflux during sleep can also contribute to nocturnal asthma.

Etiology and Pathogenesis

The common denominator underlying asthma is an exaggerated hyperresponsiveness to a variety of stimuli. Airway inflammation manifested by the presence of inflammatory cells (particularly eosinophils, lymphocytes, and mast cells) and by damage to the bronchial epithelium contributes to the pathogenesis of the disease. There are two subsets of T-helper cells (T1H and T2H) that develop from the same precursor CD4+ T lymphocyte. T1H cells differentiate in response to microbes and stimulate the differentiation of B cells into immunoglobulin (Ig)M– and IgG-producing plasma cells. T2H cells, on the other hand, respond to allergens and helminths (intestinal parasites) by stimulating B cells to differentiate into IgE-producing plasma cells, produce growth factors for mast cells, and recruit and activate eosinophils. In people with allergic asthma, T-cell differentiation appears to be skewed toward a proinflammatory T1H response. Although the molecular basis for this preferential differentiation is unclear, it seems likely that both genetic and environmental factors play a role.

Cytokines also have an apparent role in the chronic inflammatory response and complications of asthma. Tumor necrosis factor (TNF-α) and interleukins 4 and 5 (IL-4, IL-5) participate in the pathogenesis of bronchial asthma through their effects on the bronchial epithelial and smooth muscle cells. Studies suggest that TNF-α, an inflammatory cytokine that is stored and released from mast cells, plays a critical role in the initiation and amplification of airway inflammation in persons with asthma. TNF-α is credited with increasing the migration and activation of inflammatory cells (i.e., eosinophils and neutrophils) and contributing to all aspects of airway remodeling, including proliferation and activation of fibroblasts, increased production of extracellular matrix glycoproteins, and mucous cell hyperplasia.

It has been determined that frequent viral respiratory infections predispose people with asthma to experience an exacerbation of their disease. In fact, frequent viral respiratory infections may also cause the development of asthma in some people. When these respiratory infections are frequent at an early age, there is evidence that the T-helper 2 (T1H) response is exaggerated. When the CD4 T1H cytokines IL-4, IL-5, and IL-13 are released, the airways are predisposed for an allergic response, which favors the production of IgE.
on the loss of heat and water from the tracheobronchial tree because of the need for warming and humidifying large volumes of air.\textsuperscript{21} The response commonly is exaggerated when the person exercises in a cold environment. The second theory supporting EIA is the airway rewarming hypothesis, which states that airways cool and then warm during any exercise.\textsuperscript{21} This causes congestion in the bronchiolar vessels that surround the bronchial tree and allows fluid exudates to move into the mucosa of the airway, which triggers the inflammatory cascade. It is important to assess the type of air (polluted, cold, or warm), level of exercise, presence/absence of respiratory infectious process, and individual’s asthma stability when identifying if a person has EIA.\textsuperscript{19}

Eosinophils tend to be present in airways of people with asthma and generate inflammatory enzymes and release leukotrienes and many proinflammatory enzymes.\textsuperscript{14,22} It is common to have increased neutrophils in sputum and airways of people experiencing asthma exacerbations.\textsuperscript{22} The release of leukotrienes causes more mucus secretion, which often obstructs the airway further and causes more histamine release from the mast cells.\textsuperscript{21}

This inflammatory process produces recurrent episodes of airway obstruction, characterized by wheezing, breathlessness, chest tightness, and a cough that often is worse at night and in the early morning. These episodes, which usually are reversible either spontaneously or with treatment, also cause an associated increase in bronchial responsiveness to a variety of stimuli.\textsuperscript{17} Chronic inflammation can lead to airway remodeling, in which case airflow limitations may be only partially reversible.\textsuperscript{14} This may be due to the long-term effects of the inflammation on the airway structures.\textsuperscript{14}

There is a small group of people with the clinical triad of asthma, chronic rhinosinusitis with nasal polyps, and precipitation of asthma and rhinitis attacks in response to aspirin and other NSAIDs.\textsuperscript{22} The mechanism of the hypersensitivity reaction is complex and not fully understood, but most evidence points toward an abnormality in arachidonic acid (AA) metabolism. Cyclooxygenase (COX), the rate-limiting enzyme in AA metabolism, exists in two main forms: COX-1 and COX-2. COX-1 is responsible for the synthesis of protective prostaglandins and COX-2 for the synthesis of mediators of inflammation and bronchoconstriction. It has been hypothesized that in people with aspirin-induced asthma, the inhibition of COX-1 shunts the metabolism of AA away from the production of protective prostaglandins and toward the generation of COX-2 and other mediators of inflammation and bronchoconstriction.\textsuperscript{23} Avoidance of aspirin and all NSAIDs is a necessary part of the treatment program.

In addition, both emotional factors and changes in hormone levels are thought to contribute to an increase in asthma symptoms. Emotional factors produce bronchospasm by way of vagal pathways. They can act as a bronchospastic trigger, or they can increase airway responsiveness to other triggers through noninflammatory mechanisms. The role of sex hormones in asthma is unclear, although there is much circumstantial evidence to suggest that they may be important. In fact, research shows girls with an early menarche (<11.5 years) had twice the chance of developing asthma in their twenties than girls with average menarche.\textsuperscript{23} Up to 40% of women with asthma report a premenstrual increase in asthma symptoms.\textsuperscript{24} Female sex hormones have a regulatory role on \(\beta_2\)-adrenergic function, and it has been suggested that abnormal regulation may be a possible mechanism for premenstrual asthma.\textsuperscript{24} A study comparing premenopausal women with asthma, menopausal women with asthma, and a control group found that menopausal women with asthma had decreased estradiol concentrations, had high sputum neutrophils, and exhaled IL-6, which is indicative of a neutrophilic inflammation. Women with premenopausal asthma had an eosinophilic inflammatory phenotype.\textsuperscript{24}

Clinical Manifestations

Asthma attacks may occur spontaneously or in response to various triggers, respiratory infections, emotional stress, or weather changes. Asthma is often worse at night, referred to as nocturnal asthma. Studies of nocturnal asthma suggest that there is a circadian and sleep-related variation in hormones and respiratory function.\textsuperscript{25,26} The greatest decrease in respiratory function occurs at about 4:00 AM, at which time cortisol levels are low, melatonin levels high, and eosinophil activity increased.

People with asthma exhibit a wide range of signs and symptoms, from episodic wheezing and feelings of chest tightness to an acute, immobilizing attack. The attacks differ from person to person, and between attacks, many people are symptom-free. A mild attack may produce a feeling of chest tightness, a slight increase in respiratory rate with prolonged expiration, and mild wheezing. A cough may accompany the wheezing. More severe attacks are accompanied by use of the accessory muscles, distant breath sounds due to air trapping, and loud wheezing. As the condition progresses, fatigue develops, the skin becomes moist, and anxiety and apprehension are obvious. Sensations of shortness of breath may be severe, and often the person is able to speak only one or two words before taking a breath. At the point at which airflow is markedly decreased, breath sounds become inaudible with diminished wheezing, and the cough becomes ineffective despite being repetitive and hacking.\textsuperscript{17} This point often marks the onset of respiratory failure.

During an asthmatic attack, the airways narrow because of bronchospasm, edema of the bronchial mucosa, and mucus plugging. Expiration becomes prolonged because of progressive airway obstruction. The amount of air that can be forcibly expired in 1 second (forced expiratory volume in 1 second [FEV\textsubscript{1.0}]) and the peak expiratory flow (PEF) rate, measured in liters per second, are decreased. A fall in the PEF to levels below 50% of the predicted value during an acute asthmatic attack indicates a severe exacerbation and the need for emergency department treatment.\textsuperscript{17}

During a prolonged attack, air becomes trapped behind the occluded and narrowed airways, causing hyperinflation of the lungs. This produces an increase in the residual volume (RV) along with a decrease in the inspiratory reserve capacity (tidal volume + inspiratory reserve volume [IRV]) and forced vital capacity (FVC), such that the person breathes close to his or
her functional residual capacity (residual volume + expiratory reserve volume). As a result, more energy is needed to overcome the tension already present in the lungs, and the accessory muscles (e.g., sternocleidomastoid muscles) are required to maintain ventilation and gas exchange. This increased work of breathing further increases oxygen demands and causes dyspnea and fatigue. Because air is trapped in the alveoli and inspiration is occurring at higher residual lung volumes, the cough becomes less effective. As the condition progresses, the effectiveness of alveolar ventilation declines, and mismatching of ventilation and perfusion occurs, causing hypoxemia and hypercapnia. Pulmonary vascular resistance may increase as a result of the hypoxemia and hyperinflation, leading to a rise in pulmonary arterial pressure and increased work demands on the right heart.

Diagnosis

The diagnosis of asthma is based on a careful history and physical examination, laboratory findings, and pulmonary function studies. Spirometry provides a means for measuring FVC, FEV$_{1.0}$, PEF, tidal volume, expiratory reserve capacity, and inspiratory reserve capacity. The FEV$_{1.0}$/FVC ratio can then be calculated. The level of airway responsiveness can be measured by inhalation challenge tests using methacholine (a cholinergic agonist), histamine, or exposure to a nonpharmacologic agent such as cold air.

Small, inexpensive, portable meters that measure PEF are available. Although not intended for use in the diagnosis of asthma, they can be used in clinics and primary care providers’ offices and in the home to provide frequent measures of flow rates. Day–night (circadian) variations in asthma symptoms and PEF variability can be used to indicate the severity of bronchial hyperresponsiveness. The person’s best performance is established from readings taken over several weeks. This often is referred to as the individual’s personal best and is used as a reference to indicate changes in respiratory function.$^{14}$

Treatment

The NHLBI EPR 3 classifies four stages of asthma for children greater than 12 years and adults, including intermittent, mild persistent, moderate persistent, and severe persistent.$^{17}$ The Expert Panel developed these classification systems in order to direct asthma treatment and to assist in identifying people at high risk for development of life-threatening asthma attacks$^{14,15}$ (Table 37.1). Asthma treatment consists of prevention measures, nonpharmacological measures, desensitization, and pharmacologic management.

Prevention measures to control factors contributing to asthma severity are aimed at limiting exposure to irritants and factors that increase asthma symptoms and precipitate asthma exacerbations. They include education of the person and family regarding measures used in avoiding exposure to irritants and allergens that are known to induce or trigger an attack. A careful history often is needed to identify all the contributory factors. Factors such as nasal polyps, a history of aspirin sensitivity, and gastroesophageal reflux should be considered. Annual influenza vaccination is recommended for people with persistent asthma.

Nonpharmacological management includes relaxation techniques and controlled breathing, which often help to allay the panic and anxiety that aggravate breathing difficulties. The hyperventilation that often accompanies anxiety and panic is known to act as an asthmatic trigger. In a child, measures to encourage independence as it relates to symptom control, along with those directed at helping to develop a positive self-concept, are essential.

FEV$_{1.0}$, forced expiratory volume in 1 second; PEF, peak expiratory flow rate.

A program of desensitization may be undertaken in people with persistent asthma who react to allergens, such as house dust mites, that cannot be avoided. This involves the injection of selected antigens (based on skin tests) to stimulate the production of IgG antibodies that block the IgE response. A course of allergen immunotherapy is typically of 3 to 5 years’ duration.14

The Expert Panel recommends a stepwise approach to pharmacologic therapy based on the classification systems discussed previously.14 The first line of treatment with any of the persistent forms of asthma includes an inflammatory controller drug that would include inhaled corticosteroids (ICS), mast cell stabilizers, and leukotriene modifiers. ICS are considered the most effective in preventing airway inflammation and generally the drug used.

The quick-relief medications such as the short-acting β₂-adrenergic agonists (SABA) (e.g., albuterol, levalbuterol, pirbuterol) relax bronchial smooth muscle and provide prompt relief of symptoms, usually within 30 minutes. They are administered by inhalation (i.e., metered-dose inhaler [MDI] or nebulizer), and their recommended use is in alleviating acute attacks of asthma because regular use does not produce beneficial effects.14 The anticholinergic medications (e.g., ipratropium) block the postganglionic efferent vagal pathways that cause bronchoconstriction. These medications, which are administered by inhalation, produce bronchodilation by direct action on the large airways and do not change the composition or viscosity of the bronchial mucus. It is thought that they may provide some additive benefit for treatment of asthma exacerbations when administered with inhaled β₂-adrenergic agonists.14 A short course of systemic corticosteroids, administered orally or parenterally, may be used for treating an acute flare. Although their onset of action is slow (>4 hours), systemic corticosteroids may be used in the treatment of moderate to severe exacerbations because of their action in preventing the progression of the exacerbation, speeding recovery, and preventing early relapses.14

The anti-inflammatory agents sodium cromolyn and nedocromil are also used to prevent an asthmatic attack. These agents act by stabilizing mast cells, thereby preventing release of the inflammatory mediators that cause an asthmatic attack. They are used prophylactically to prevent early and late responses but are of no benefit when taken during an attack. Due to the immunomodulatory properties of vitamin D and its abilities to modify proinflammatory and anti-inflammatory responses in the immunological system, there have been studies suggesting a correlation of vitamin D and more effective management of childhood and asthma exacerbations as well as with steroid-resistant asthma.27

Severe or Refractory Asthma
Severe or refractory asthma represents a subgroup of approximately 5% of people with asthma who have more troublesome disease as evidenced by high medication requirements to maintain good symptom control or those who continue to have persistent symptoms despite high medication use.30 These people are at increased risk for fatal or near-fatal asthma.

Little is known about the causes of severe asthma. Among the proposed risk factors are genetic predisposition, continued allergen or tobacco exposure, infection, intercurrent sinusitis or gastroesophageal reflux disease, and lack of compliance or adherence with treatment measures.30 It has been proposed that because asthma is a disease involving multiple genes, mutations in genes regulating cytokines, growth factors, or receptors for medications used in treatment of asthma (β₂-adrenergic agonist or glucocorticoid) could be involved. Environmental factors include both allergen and tobacco exposure, with the strongest response occurring in response to house dust, cockroach allergen, and Alternaria exposure. Infections may also play a role. Respiratory syncytial virus infections are implicated in children, and pathogens such as mycoplasma and chlamydiae may play a role in adults. Gastroesophageal reflux and chronic sinusitis may also play a role. Although the cause of death during an acute asthmatic attack is largely unknown, both cardiac arrhythmias and asphyxia due to severe airway obstruction have been implicated. It has been suggested that an underestimation of the severity of the attack may be a contributing factor. Deterioration often occurs rapidly during an acute attack, and underestimation of its severity may lead to a life-threatening delay in seeking medical attention. Frequent and repetitive use of β₂-adrenergic agonist inhalers far in excess of the recommended doses may temporarily blunt symptoms and mask the severity of the condition. It has been suggested that people who have a fatal or near-fatal asthmatic attack may not perceive its severity.31 That is, they may not perceive the severity of their condition and consequently not take appropriate measures in terms of seeking medical or emergency treatment.

The long-acting β₂-agonists (LABA) such as salmeterol and formoterol are used to treat severe refractory asthma only if no other treatment is effective. The long-acting β₂-adrenergic agonists have durations of action of at least 12 hours and should not be used to treat acute symptoms or exacerbations. These drugs have a black box warning from the U.S. Food and Drug Administration due to their possibility of causing asthma death, especially if they are used as a monotherapy. Research is also focusing on the use of allergen immunotherapy treatment aimed at Th2 cytokines in specific groups of people with severe asthma. However, only one is currently available.28,29 The only licensed anti-IgE therapy for severe asthma is omalizumab, which has severe potential systemic side effects.29

Asthma in Older Adults
For older adults with asthma, who already have a decreased immunological function due to aging, it is important to be aware of how this lowered immunity impacts their airway inflammation. Studies demonstrate these changes in immune function can seriously affect their conditions.32

Asthma in Children
Asthma is a leading cause of chronic illness in children and is responsible for approximately 14.4 million number of lost school days/year. It is the most frequent admitting diagnosis
in children’s hospitals. Based on information collected by the Centers for Disease Control and Prevention, asthma may have its onset at any age. In addition, asthma is more prevalent in black than white children and results in more frequent disability and more frequent hospitalizations in black children. As with adults, asthma in children commonly is associated with an IgE-related reaction. It has been suggested that IgE directed against respiratory viruses in particular may be important in the pathogenesis of wheezing illnesses in infants (i.e., bronchiolitis), which often precede the onset of asthma. Other contributing factors include exposure to environmental allergens such as pet dander, dust mite antigens, and cockroach allergens. Exposure to environmental tobacco smoke also contributes to asthma in children.

The signs and symptoms of asthma in infants and small children vary with the stage and severity of an attack. Because airway patency decreases at night, many children have acute signs of asthma at this time. Often, previously well infants and children develop what may seem to be a cold with rhinorrhea, rapidly followed by irritability, a tight and nonproductive cough, wheezing, tachypnea, dyspnea with prolonged expiration, and use of accessory muscles of respiration. Cyanosis, hyperinflation of the chest, and tachycardia indicate increasing severity of the attack. Wheezing may be absent in children with extreme respiratory distress. The symptoms may progress rapidly and require a trip to the emergency department or hospitalization.

The Expert Panel of the NAEPP has developed guidelines for management of asthma in infants and children from 0 to 4 years, 5 to 11 years, and for adults and children older than 12 years of age. As with adults and older children, the Expert Panel recommends a stepwise approach to diagnosing and managing asthma in infants and children from 0 to 4 years and from 5 to 11 years.

Chronic Obstructive Pulmonary Disease

COPD is characterized by chronic and recurrent obstruction of airflow in the pulmonary airways. Airflow obstruction usually is progressive and is accompanied by inflammatory responses to noxious particles or gases. COPD is a leading cause of morbidity and mortality worldwide. It has been estimated that approximately 24 million Americans have some degree of COPD and 12.1 million are diagnosed with COPD. COPD is the fourth leading cause of death in the United States. In 2006, COPD claimed the lives of more than 120,970 people in the United States, with the number of women dying from COPD surpassing that of men. According to the National Heart, Lung, and Blood Institute, the national projected annual cost for COPD in 2010 was $49.9 billion.

The most common cause of COPD is smoking, as evidenced by the fact that 80% to 85% of people with COPD have a history of smoking. A second, less common factor is a hereditary deficiency in α1-antitrypsin. Other predisposing factors are asthma and airway hyperresponsiveness. Unfortunately, clinical findings are almost always absent during the early stages of COPD, and as many as 50% of smokers may have undiagnosed COPD. By the time symptoms appear or are recognized, the disease is usually far advanced. For smokers with early signs of airway disease, there is hope that early recognition, combined with appropriate treatment and smoking cessation, may prevent or delay the usually relentless progression of the disease.

Etiology and Pathogenesis

The mechanisms involved in the pathogenesis of COPD usually are multiple and include inflammation and fibrosis of the bronchial wall, hypertrophy of the submucosal glands and hypersecretion of mucus, and loss of elastic lung fibers and alveolar tissue. Inflammation and fibrosis of the bronchial wall, along with excess mucus secretion, obstruct airflow and cause mismatching of ventilation and perfusion. Destruction of alveolar tissue decreases the surface area for gas exchange, and loss of elastic fibers impairs the expiratory flow rate, increases air trapping, and predisposes to airway collapse.

The term chronic obstructive pulmonary disease encompasses two types of obstructive airway disease: emphysema, with enlargement of airspaces and destruction of lung tissue, and chronic obstructive bronchitis, with increased mucus production, obstruction of small airways, and a chronic productive cough. People with COPD often have overlapping features of both disorders.

Emphysema. Emphysema is characterized by a loss of lung elasticity and abnormal enlargement of the airspaces distal to the terminal bronchioles, with destruction of the alveolar walls and capillary beds (Fig. 37.9). Enlargement of the airspaces leads to hyperinflation of the lungs and produces an increase in total lung capacity (TLC). Two of the recognized causes of emphysema are smoking, which incites lung injury, and an inherited deficiency of α1-antitrypsin, an antiprotease enzyme that protects the lung from injury. AAT deficiency is the second most severe genetic problem affecting the lungs and is a result of a mutated ATT gene at gene locus 14. AAT is a protease inhibitor that helps to protect the lung from protease enzymes such as neutrophil elastase, which damages healthy lung tissue as well as assists in removing bacteria during acute respiratory dysfunction.

Emphysema is thought to result from the breakdown of elastin and other alveolar wall components by enzymes, called proteases, which digest proteins. Normally, antiprotease enzymes, including α1-antitrypsin, protect the lung. Cigarette smoke and other irritants stimulate the movement of inflammatory cells into the lungs, resulting in increased release of elastase and other proteases. In smokers in whom COPD develops, antiprotease production and release may be inadequate to neutralize the excess protease production such that the process of elastic tissue destruction goes unchecked (Fig. 37.10).

The type and amount of α1-antitrypsin that a person has is determined by a pair of codominant genes referred to as...
UNIT IX Disorders of Respiratory Function

FIGURE 37.9 • Panacinar emphysema. (A) A whole mount of the left lung from a person with severe emphysema reveals widespread destruction of pulmonary parenchyma that in some areas leaves behind a lacy network of supporting tissue. (B) The lung from a person with α₁-antitrypsin deficiency shows a panacinar pattern of emphysema. The loss of alveolar walls has resulted in markedly enlarged airspaces. (From Rubin R., Strayer D. (Eds.). (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 569). Philadelphia, PA: Lippincott Williams & Wilkins.)

FIGURE 37.10 • Protease (elastase)-antiprotease (antitrypsin) mechanisms of emphysema. The effects of smoking and an inherited α₁-antitrypsin deficiency on the destruction of elastic fibers in the lung and development of emphysema are shown.

PI (protein inhibitor) genes. An α₁-antitrypsin deficiency is inherited as an autosomal recessive disorder. There are more than 75 mutations of the gene. ATT deficiency is most common in people of Scandinavian descent. Most people with clinically diagnosed emphysema before the age of 40 years have an α₁-antitrypsin deficiency. Smoking and repeated respiratory tract infections, which also decrease α₁-antitrypsin levels, contribute to the risk for emphysema in persons with α₁-antitrypsin deficiency. Laboratory methods are available for measuring α₁-antitrypsin levels. Human α₁-antitrypsin is available for replacement therapy in people with a hereditary deficiency of the enzyme.

There are two commonly recognized types of emphysema: centriacinar or centrilobular, and panacinar (Fig. 37.11). The centriacinar type affects the bronchioles in the central part of the respiratory lobule, with initial preservation of the alveolar ducts and sacs. It is the most common type of emphysema and is seen predominantly in male smokers. The panacinar type produces initial involvement of the peripheral alveoli and later extends to involve the more central bronchioles. This type of emphysema is more common in people with α₁-antitrypsin deficiency. It also is found in smokers in association with centriacinar emphysema. In such cases, the panacinar pattern tends to occur in the lower parts of the lung and centriacinar emphysema is seen in the upper parts of the lung.
**Chapter 37 Disorders of Ventilation and Gas Exchange**

**Chronic Bronchitis.** Chronic bronchitis represents airway obstruction of the major and small airways. The condition is seen most commonly in middle-aged men and is associated with chronic irritation from smoking and recurrent infections. A clinical diagnosis of chronic bronchitis requires the history of a chronic productive cough for at least 3 consecutive months in at least 2 consecutive years. Typically, the cough has been present for many years, with a gradual increase in acute exacerbations that produce frankly purulent sputum.

The earliest feature of chronic bronchitis is hypersecretion of mucus in the large airways, associated with hypertrophy of the submucosal glands in the trachea and bronchi. Although mucus hypersecretion in the large airways is the cause of sputum overproduction, it is now thought that accompanying changes in the small airways (small bronchi and bronchioles) are physiologically important in the airway obstruction that develops in chronic bronchitis. Histologically, these changes include a marked increase in goblet cells and excess mucus production with plugging of the airway lumen, inflammatory infiltration, and fibrosis of the bronchiolar wall. It is thought that both the submucosal hypertrophy in the larger airways and the increase in goblet cells in the smaller airways are a protective reaction against tobacco smoke and other pollutants. Viral and bacterial infections are common in people with chronic bronchitis and are thought to be a result rather than a cause of the problem.

**Clinical Manifestations**

The clinical manifestations of COPD usually have an insidious onset. People characteristically seek medical attention in the fifth or sixth decade of life, with manifestations such as fatigue, exercise intolerance, cough, sputum production, or shortness of breath. The productive cough usually occurs in the morning and the dyspnea becomes more severe as the disease progresses. Frequent exacerbations of infection and respiratory insufficiency are common, causing absence from work and eventual disability. The late stages of COPD are characterized by recurrent respiratory infections and chronic respiratory failure. Death usually occurs during an exacerbation of illness associated with infection and respiratory failure.

The mnemonics “pink puffer” and “blue bloater” have been used to differentiate the clinical manifestations of emphysema and chronic obstructive bronchitis. People with predominant emphysema are classically referred to as *pink puffers*, a reference to the lack of cyanosis, the use of accessory muscles, and pursed-lip (“puffer”) breathing. With loss of lung elasticity and hyperinflation of the lungs, the airways often collapse during expiration because pressure in surrounding lung tissues exceeds airway pressure. Air becomes trapped...
obstruction may also exhibit use of the accessory muscles, sitting in the characteristic “tripod” position to facilitate use of the sternocleidomastoid, scalene, and intercostal muscles. Pursed-lip breathing enhances airflow because it increases the resistance to the outflow of air and helps to prevent airway collapse by increasing airway pressure. Eventually, people with COPD are unable to maintain normal blood gases by increasing their breathing effort. Hypoxemia, hypercapnia, and cyanosis develop, reflecting an imbalance between ventilation and perfusion.

Severe hypoxemia, in which arterial PO2 levels fall below 55 mm Hg, causes reflex vasoconstriction of the pulmonary vessels and further impairment of gas exchange in the lung. It is more common in people with the chronic bronchitis form of COPD. Hypoxemia also stimulates red blood cell production, causing polycythemia. The increase in pulmonary vasoconstriction and subsequent elevation in pulmonary artery pressure further increase the work of the right ventricle. As a result, people with COPD may develop right-sided heart failure with peripheral edema (i.e., cor pulmonale). However, signs of overt right-sided heart failure are seen less frequently since the advent of supplemental oxygen therapy.

**Diagnosis**

The diagnosis of COPD is based on a careful history and physical examination, pulmonary function studies, chest radiographs, and laboratory tests. Airway obstruction prolongs the expiratory phase of respiration and affords the in the alveoli and lungs, producing an increase in the anteroposterior dimensions of the chest, the so-called barrel chest that is typical of people with emphysema (Fig. 37.12). Such people have a dramatic decrease in breath sounds throughout the chest. Because the diaphragm may be functioning near its maximum ability, the person is vulnerable to diaphragmatic fatigue and acute respiratory failure.

People with a clinical syndrome of chronic bronchitis are classically labeled blue bloaters, a reference to cyanosis and fluid retention associated with right-sided heart failure. In practice, differentiation between the two types of COPD is often difficult. This is because people with COPD often have some degree of both emphysema and chronic bronchitis.

The manifestations of COPD represent a progressive change in respiratory function. There is moderate to severe respiratory impairment due to obstruction of airflow, which is greater on expiration than inspiration, resulting in increased work of breathing but decreased effectiveness. The development of exertional dyspnea, often described as increased effort to breathe, heaviness, air hunger, or gasping, can be insidious and is often reported in the sixth decade. Activities involving significant arm work, particularly above the shoulders, are particularly difficult for persons with COPD. Activities that allow the person to brace the arms and use the accessory muscles are better tolerated. As the disease progresses, breathing becomes increasingly more labored, even at rest. The expiratory phase of respiration is prolonged, and expiratory wheezes and crackles can be heard on auscultation. People with severe airflow obstruction may also exhibit use of the accessory muscles, sitting in the characteristic “tripod” position to facilitate use of the sternocleidomastoid, scalene, and intercostal muscles. Pursed-lip breathing enhances airflow because it increases the resistance to the outflow of air and helps to prevent airway collapse by increasing airway pressure. Eventually, people with COPD are unable to maintain normal blood gases by increasing their breathing effort. Hypoxemia, hypercapnia, and cyanosis develop, reflecting an imbalance between ventilation and perfusion.

Severe hypoxemia, in which arterial PO2 levels fall below 55 mm Hg, causes reflex vasoconstriction of the pulmonary vessels and further impairment of gas exchange in the lung. It is more common in people with the chronic bronchitis form of COPD. Hypoxemia also stimulates red blood cell production, causing polycythemia. The increase in pulmonary vasoconstriction and subsequent elevation in pulmonary artery pressure further increase the work of the right ventricle. As a result, people with COPD may develop right-sided heart failure with peripheral edema (i.e., cor pulmonale). However, signs of overt right-sided heart failure are seen less frequently since the advent of supplemental oxygen therapy.
Potential for impaired gas exchange because of mismatching of ventilation and perfusion. The FVC is the amount of air that can be forcibly exhaled after maximal inspiration. In an adult with normal respiratory function, this should be achieved in 4 to 6 seconds. In people with chronic lung disease, the time required for FVC is increased, the FEV_{1.0} is decreased, and the ratio of FEV_{1.0} to FVC is decreased. In severe disease, the FVC is markedly reduced. Lung volume measurements reveal a marked increase in RV, an increase in TLC, and elevation of the RV-to-TLC ratio. These and other measurements of expiratory flow are determined by spirometry and are used in the diagnosis of COPD. Spirometry measurements can be used in staging disease severity. For example, an FEV_{1.0}-to-FVC ratio of less than 70% with an FEV_{1.0} of 80% or more, with or without symptoms, indicates mild disease, and an FEV_{1.0}-to-FVC ratio of less than 70% with an FEV_{1.0} of less than 50%, with or without symptoms, indicates severe disease. Other diagnostic measures become important as the disease advances. Measures of exercise tolerance, nutritional status, hemoglobin saturation, and arterial blood gases can be used to assess the overall impact of COPD on health status and to direct treatment.

**Treatment**

The treatment of COPD depends on the stage of the disease and often requires an interdisciplinary approach. Smoking cessation is the only measure that slows the progression of the disease. Education of people with COPD and their families is a key to successful management of the disease. Psychosocial rehabilitation must be individualized to meet the specific needs of people with COPD and their families. These needs vary with age, occupation, financial resources, social and recreational interests, and interpersonal and family relationships.

People in more advanced stages of the disease often require measures to maintain and improve physical and psychosocial functioning, pharmacologic interventions, and oxygen therapy. Avoidance of cigarette smoke and other environmental airway irritants is imperative. Wearing a cold-weather mask often prevents dyspnea and bronchospasm due to cold air and wind exposure.

Respiratory tract infections can prove life-threatening to people with severe COPD. A person with COPD should avoid exposure to others with known respiratory tract infections and should avoid attending large gatherings during periods of the year when influenza or respiratory tract infections are prevalent. Immunization for influenza and pneumococcal infections decreases the likelihood of their occurrence.

Maintaining and improving physical and psychosocial functioning is an important part of the treatment program for people with COPD. A long-term pulmonary rehabilitation program can significantly reduce episodes of hospitalization and add measurably to a person’s ability to manage and cope with his or her impairment in a positive way. This program includes breathing exercises that focus on restoring the function of the diaphragm, reducing the work of breathing, and improving gas exchange. Physical conditioning with appropriate exercise training increases maximal oxygen consumption and reduces ventilatory effort and heart rate for a given workload. Work simplification and energy conservation strategies may be needed when impairment is severe.

The pharmacologic treatment of COPD includes the use of bronchodilators, including inhaled adrenergic and anticholinergic agents. Inhaled β_2-adrenergic agonists have been the mainstay of treatment of COPD. It has been suggested that long-acting inhaled β_2-adrenergic agonists may be even more effective than the short-acting forms of the drug. The anticholinergic drugs (e.g., ipratropium bromide, tiotropium bromide), which are administered by inhalation, produce bronchodilation by blocking parasympathetic cholinergic receptors that produce contraction of bronchial smooth muscle. These medications, which are administered by inhalation, produce bronchodilation by direct action on the large airways and do not change the composition or viscosity of the bronchial mucus. They also reduce the volume of sputum without altering its viscosity. Because these drugs have a slower onset and longer duration of action, they usually are used on a regular basis rather than on an as-needed basis. Inhaled irreversibly anticholinergic drug with a β_2-adrenergic agonist is available.

Inhaled corticosteroids often are used in treatment of COPD; there is controversy regarding their usefulness. An explanation for this lack of effect may be related to the fact that corticosteroids prolong the action of neutrophils and hence do not suppress the neutrophilic inflammation seen in COPD. Because corticosteroids are useful in relieving asthma symptoms, they may benefit people with asthma concomitant with COPD. Inhaled corticosteroids also may be beneficial in treating acute exacerbations of COPD, minimizing the undesirable effects that often accompany systemic use.

Oxygen therapy is prescribed for selected people with significant hypoxemia (arterial PO_2 < 55 mm Hg). Administration of continuous low-flow (1 to 2 L/minute) oxygen to maintain arterial PO_2 levels between 55 and 65 mm Hg decreases dyspnea and pulmonary hypertension and improves neuropsychological function and activity tolerance. The overall goal of oxygen therapy is to maintain a hemoglobin oxygen saturation of at least 90%. Because the ventilatory drive associated with hypoxic stimulation of the peripheral chemoreceptors does not occur until the arterial PO_2 has been reduced to about 60 mm Hg or less, increasing the arterial PO_2 above 60 mm Hg tends to depress the hypoxic stimulus for ventilation and often leads to hypoventilation and carbon dioxide retention.

**Bronchiectasis**

Bronchiectasis is an uncommon type of COPD characterized by a permanent dilation of the bronchi and bronchioles caused by destruction of the muscle and elastic supporting tissue as the result of a continuous cycle of infection and inflammation (Fig. 37.13). It is not a primary disease but is considered secondary to acquiring frequent infections. In the past, bronchiectasis often followed a necrotizing bacterial pneumonia that frequently complicated measles, pertussis, or influenza.
Bronchiectasis can present in either of two forms: a local obstructive process involving a lobe or segment of a lung or a diffuse process involving much of both lungs. Localized bronchiectasis is most commonly caused by conditions such as tumors, foreign bodies, and mucus plugs that produce atelectasis and infection due to obstructed drainage of bronchial secretions. It can affect any area of the lung, the area being determined by the site of obstruction or infection. Generalized bronchiectasis usually is bilateral and most commonly affects the lower lobes. It is due largely to inherited impairments of host mechanisms or acquired disorders that permit introduction of infectious organisms into the airways. They include inherited conditions such as CF, in which airway obstruction is caused by impairment of normal mucociliary function; congenital and acquired immunodeficiency states, which predispose to respiratory tract infections; lung infection (e.g., tuberculosis, fungal infections, lung abscess); and exposure to toxic gases that cause airway obstruction.

Clinical Manifestations
Bronchiectasis is associated with a number of abnormalities that profoundly affect respiratory function, including atelectasis, obstruction of the smaller airways, and diffuse bronchitis. People with bronchiectasis have recurrent bronchopulmonary infection; coughing; production of copious amounts of foul-smelling, purulent sputum; and hemoptysis. Weight loss and anemia are common.

In addition, the manifestations of bronchiectasis are similar to those seen in chronic bronchitis and emphysema. As in the latter two conditions, chronic bronchial obstruction leads to marked dyspnea and cyanosis. Clubbing of the fingers, which is not usually seen in other types of obstructive lung diseases, is more common in moderate to advanced bronchiectasis.

Diagnosis and Treatment
Diagnosis is based on history and imaging studies. The condition often is evident on chest radiographs. High-resolution CT scanning of the chest allows for definitive diagnosis. Accuracy of diagnosis is important because interventional bronchoscopy or surgery may be palliative or curative in some types of obstructive disease.

Treatment consists of early recognition and treatment of infection along with regular postural drainage and chest physical therapy. Persons with this disorder benefit from many of the rehabilitation and treatment measures used for chronic bronchitis and emphysema.

Cystic Fibrosis
CF, which is the major cause of severe chronic respiratory disease in children, is an autosomal recessive disorder involving the exocrine glands in the epithelial lining of the respiratory, gastrointestinal, and reproductive tracts. CF affects about 30,000 children and adults in the United States and more than varicose veins. Bronchiolar obliteration is not as severe and various symptoms can occur.
There are greater than 1000 possible CFTR changes that can occur. However, 70% of CF individuals have F 508, which is a deletion of 3 bases that cause the loss of phenylalanine and a more severe phenotype. Others have a partial loss of CFTR so their phenotype is less severe and often goes unnoticed until they have an acute injury such as pneumonia and may need intubation and mechanical ventilation.

The impact on impaired Cl− transport is relatively tissue specific. In the sweat glands, the concentration of sodium (Na+) and Cl− secreted into the lumen of the gland remains unaffected, whereas the reabsorption of Cl− through the CFTR and accompanying reabsorption of Na+ in the ducts of the gland fail to occur. This defect accounts for the high concentration of NaCl in the sweat of persons with CF. In the normal airway epithelium, Cl− is secreted into airway lumen through the CFTR. The impaired transport of Cl− ultimately leads to a series of secondary events, including increased absorption of Na+ and water from the airways into the blood. This lowers the water content of the mucociliary blanket coating the respiratory epithelium, causing it to become more viscid. The resulting dehydration of the mucous layer leads to defective mucociliary function and accumulation of viscid secretions that obstruct the airways and predispose to recurrent pulmonary infections. Similar transport abnormalities and pathophysiologic events take place in the pancreatic and biliary ducts and in the vas deferens in boys.

**Clinical Manifestations**

Respiratory manifestations of CF are caused by an accumulation of viscid mucus in the bronchi, impaired mucociliary clearance, and lung infections. Chronic bronchiolitis and bronchitis are the initial lung manifestations. However, after months and years, structural changes in the bronchial wall lead to bronchiectasis. In addition to airway obstruction, the basic genetic defect that occurs with CF predisposes to chronic infection with a surprisingly limited number of organisms, the most common being *Pseudomonas aeruginosa*. Soon after birth, initial infection with bacterial pathogens occurs and is associated with an excessive neutrophilic inflammatory response that appears to be independent of the infection itself. There is evidence that the CF airway epithelial cells or surface liquids provide a favorable environment for harboring these organisms. *P. aeruginosa*, in particular, has a propensity to undergo mucoid transformation in this environment. The complex polysaccharide produced by these organisms provides a hypoxic environment and generates a biofilm that protects *Pseudomonas* against antimicrobial agents. Pulmonary inflammation is another cause of decline in respiratory function in people with CF and may precede the onset of chronic infection.

Pancreatic function is often abnormal to some degree with individuals with CF. Steatorrhea, diarrhea, and abdominal pain and discomfort are common. In the newborn, meconium ileus may cause intestinal obstruction, a fatal condition if left untreated. The degree of pancreatic involvement is highly variable. In some children, the defect is relatively mild,
and in others, the involvement is severe and impairs intestinal absorption. In addition to exocrine pancreatic insufficiency, hyperglycemia may occur, especially after 10 years of age, when many people with CF develop diabetes mellitus.39

**Diagnosis and Treatment**

Early diagnosis and treatment are important in delaying the onset and severity of chronic illness in children with CF. Diagnosis is based on the presence of respiratory and gastrointestinal manifestations typical of CF, a history of CF in a sibling, or a positive newborn screening test result. Confirmatory laboratory tests include the sweat test, assessment of bioelectrical properties of respiratory epithelia in the nasal membrane, and genetic tests for CFTR gene mutations. The sweat test, using pilocarpine iontophoresis to collect the sweat followed by chemical analysis of its chloride content, remains the standard approach to diagnosis. Newborns with CF have elevated blood levels of immunoreactive trypsinogen, presumably because of secretory obstruction in the pancreas. **Newborn screening** consists of a test for determination of immunoreactive trypsinogen.

Twenty years after cloning the CFTR gene, there are still no approved treatments for correcting the genetic defects in CF or to reverse the ion transport abnormalities associated with the dysfunctional CFTR. Drugs focused at the CFTR gene are known as protein repair therapy and are being trialed and predicted to be of use in the future.41 Thus, treatment measures are directed toward slowing the progression of secondary organ dysfunction and sequelae such as chronic lung infection and pancreatic insufficiency.41 They include the use of antibiotics to prevent and manage infections, the use of chest physical therapy (chest percussion and postural drainage) and mucolytic agents to prevent airway obstruction, and pancreatic enzyme replacement, and nutritional therapy.

Appropriate antibiotic therapy directed against bacterial pathogens isolated from the respiratory tract is an essential component in the management of CF lung disease. Indications for oral antibiotics include the presence of respiratory tract symptoms and identification of pathogenic organisms in respiratory tract cultures. Intravenous antibiotics are used for progressive and unrelenting symptoms.

People with CF who have complete loss of exocrine pancreas function and have inadequate digestion of fats and proteins require diet adjustment, pancreatic enzyme replacement, and supplemental vitamins and minerals. Many people with CF have a higher-than-normal caloric need because of the increased work of breathing and perhaps because of the increased metabolic activity related to the basic defect. Pancreatic enzyme dosage and product type are individualized for each person.

Progress of the disease is variable. Improved medical management has led to longer survival. Today, many people with the disease can expect to live into their 30s, 40s, and beyond.39 Lung transplantation is being used as a treatment for people with end-stage lung disease. Current hopes reside in research that would make gene therapy a feasible alternative for people with the disease.

**IN SUMMARY**

Obstructive ventilatory disorders are characterized by airflow obstruction and limitation in expiratory airflow. Asthma is a chronic inflammatory disorder of the airways characterized by airway hyperreactivity, airway narrowing, and airway remodeling. T-H cells differentiate in response to microbes and stimulate the differentiation of B cells into immunoglobulin (Ig)M- and IgG-producing plasma cells. Whereas, T-H cells respond to allergens by stimulating B cells to differentiate into IgE-producing plasma cells, produce growth factors for mast cells, and recruit and activate eosinophils. In people with allergic asthma, T-cell differentiation appears to be skewed toward a pro-inflammatory T-H response. It appears that both genetic and environmental factors play a role in the development of asthma or reactive airway disease.

COPD describes a group of conditions characterized by obstruction to airflow in the lungs. Among the conditions associated with COPD are emphysema, chronic bronchitis, and bronchiectasis. Emphysema is characterized by a loss of lung elasticity, abnormal, permanent enlargement of the airspaces distal to the terminal bronchioles, and hyperinflation of the lungs. Chronic bronchitis is caused by inflammation of major and small airways and is characterized by edema and hyperplasia of submucosal glands and excess mucus secretion into the bronchial tree. A history of a chronic productive cough that has persisted for at least 3 months and for at least 2 consecutive years in the absence of other disease is necessary for the diagnosis of chronic bronchitis. Emphysema and chronic bronchitis are manifested by eventual mismatching of ventilation and perfusion. As the condition advances, signs of respiratory distress and impaired gas exchange become evident, with development of hypercapnia and hypoxemia. Bronchiectasis is a less common form of COPD that is characterized by an abnormal dilation of the large bronchi associated with infection and destruction of the bronchial walls.

CF is an autosomal recessive genetic disorder manifested by chronic lung disease, pancreatic exocrine deficiency, and elevation of sodium chloride in the sweat. The disorder is caused by a mutation of a single gene on the long arm of chromosome 7 that codes for the CFTR, which functions in the transepithelial transport of the chloride ion. The defect causes exocrine gland secretions to become exceedingly viscid, and it promotes colonization of the respiratory tract with P. aeruginosa and other organisms such as Staphylococcus aureus. Accumulation of viscid mucus in the bronchi, impaired mucociliary function, and infection contribute to the development of chronic lung disease and a decreased life expectancy.
After completing this section of the chapter, you should be able to meet the following objectives:

- State the difference between chronic obstructive pulmonary diseases and interstitial lung diseases in terms of their pathology and manifestations.
- Cite the characteristics of occupational dusts that determine their pathogenicity in terms of the production of pneumoconiosis.
- Describe the pathophysiology of idiopathic pulmonary fibrosis.
- Describe the causes of hypersensitivity pneumonitis.
- Describe the systemic pathophysiology of organ involvement in sarcoidosis.

### CHRONIC INTERSTITIAL (RESTRICTIVE) LUNG DISEASES

The diffuse interstitial lung diseases (ILDs) are a diverse group of lung disorders that produce similar inflammatory and fibrotic changes in the interstitium or interalveolar septa of the lung. Because the ILDs result in a stiff and noncompliant lung, they are commonly classified as restrictive lung disorders. In contrast to obstructive lung diseases, the lungs are stiff and difficult to expand, despite normally functioning airways.

### Etiology and Pathogenesis of Interstitial Lung Diseases

The ILDs may be acute or insidious in onset. They may be rapidly progressive, slowly progressive, or static in their course. They include occupational lung diseases such as the pneumoconioses, which are caused by the inhalation of inorganic dusts such as silica, coal dust, and asbestos; hypersensitivity pneumonitis; lung diseases caused by exposure to toxic drugs (e.g., methotrexate, bleomycin, phenytoin, amiodarone); and granulomatous disorders such as sarcoidosis (Chart 37.2). Some of the most common ILDs are caused by exposure to inhaled dust and particles and, in others, no specific cause can be found.

In contrast to the obstructive lung diseases, which primarily involve the airways of the lung, the interstitial lung disorders exert their effects on the collagen and elastic connective tissue found in the delicate interstitium of the alveolar walls. Certain ILDs affect the distal part of the alveoli and this causes physiologic restrictions and decreased lung volumes. Other ILDs impact the interstitium closer to the proximal aspect of the acinus near the bronchioles, which causes physiologic obstruction but does not impact the lung volumes. Many of these diseases also involve the airways, arteries, and veins. In general, these lung diseases share a pattern of lung dysfunction that includes diminished lung volumes, reduced diffusing capacity of the lung, and varying degrees of hypoxemia.

It is thought that these disorders are initiated by some inflammatory process that involves the alveoli and interstitium of the lung. An accumulation of inflammatory and immune cells causes continued damage to lung tissue and replacement of normally functioning lung tissue with fibrous scar tissue.

### Clinical Manifestations

In general, the ILDs are characterized by clinical changes consistent with restrictive rather than obstructive changes in the lung, although some people have both components. People with ILDs have dyspnea, tachypnea, and eventual cyanosis, without evidence of wheezing or signs of airway obstruction. Usually, there is an insidious onset of breathlessness that initially occurs during exercise and may progress to the point at which the person is totally incapacitated. Typically, a person with a restrictive lung disease breathes with a tachypneic pattern of breathing, in which the respiratory rate is increased and the tidal volume is decreased. This pattern of breathing serves to maintain minute volume yet reduces the work of breathing because it takes less work to move air through the airways at an increased rate than it does to stretch a stiff lung to accommodate a larger tidal volume. A nonproductive cough may develop, particularly with continued exposure to the inhaled irritant, along with clubbing of the fingers and toes.

Lung volumes, including vital capacity and TLC, are reduced in ILD. In contrast to COPD, in which expiratory flow rates are reduced, the FEV\(_{1.0}\) usually is preserved, even though the ratio of FEV\(_{1.0}\) to FVC may increase. Although resting

*This list is not intended to be inclusive.
arterial blood gases usually are normal early in the course of the disease, arterial PO₂ levels may fall during exercise. In persons with advanced disease, hypoxemia often is present, even at rest. In the late stages of the disease, hypercapnia and respiratory acidosis develop. Alterations in the alveolar–capillary membrane, as well as an increase in shunt resulting from unventilated regions of the lung, are thought to cause the impaired diffusion of gases in people with ILD.

### Diagnosis and Treatment

The diagnosis of ILD requires a comprehensive personal and family history, with particular emphasis on exposure to environmental, occupational, and other injurious agents. Chest radiographs and other imaging may be used as an initial diagnostic method, and serial chest films often are used to follow the progress of the disease. A surgical lung biopsy specimen for histologic study and culture is the preferred diagnostic examination.

The treatment goals for people with ILD focus on identifying and removing the injurious agent, suppressing the inflammatory response, preventing progression of the disease, and providing supportive therapy for people with advanced disease. In general, the treatment measures vary with the type of lung disease. Immunosuppressants and corticosteroid drugs frequently are used. Many of the supportive treatment measures used in the late stages of the disease, such as oxygen therapy and measures to prevent infection, are similar to those discussed for people with COPD. For some people a lung transplant may be the only potentially effective treatment.

### KEY POINTS

**INTERSTITIAL LUNG DISEASES**

- ILDs result from inflammatory conditions that affect the interalveolar structures of the lung and produce lung fibrosis and a stiff lung.
- A stiff and noncompliant lung is difficult to inflate, increasing the work of breathing and causing decreased exercise tolerance due to hypoxemia.
- Because of the increased effort needed for lung expansion, people with ILD tend to take small but more frequent breaths.

### Occupational and Environmental Interstitial Lung Diseases

The occupational and environmental ILDs include the pneumoconioses, drug-induced ILD, and the hypersensitivity diseases. The pneumoconioses are caused by the inhalation of inorganic dusts and particulate matter. The hypersensitivity diseases result from the inhalation of organic dusts and related occupational antigens. A third type of occupational lung disease, byssinosis, a disease that affects cotton workers, has characteristics of the pneumoconioses and hypersensitivity lung diseases.

Among the pneumoconioses are silicosis, found in hard-rock miners, foundry workers, sandblasters, pottery makers, and workers in the slate industry; coal miner’s pneumoconiosis; asbestosis, found in asbestos miners, manufacturers of asbestos products, and installers and removers of asbestos insulation; talcosis, found in talc miners, millers, or drug abusers and in infants or small children who accidentally inhale powder containing talc; and berylliosis, found in ore extraction workers and alloy production workers. The danger of exposure to asbestos dust is not confined to the workplace. The dust pervades the general environment because it was used in the construction of buildings and in other applications before its health hazards were realized. It has been mixed into paints and plaster, wrapped around water and heating pipes, used to insulate hair dryers, and woven into theater curtains, hot pads, and ironing board covers.

Important etiologic determinants in the development of the pneumoconioses are the size of the dust particle, its chemical nature and ability to incite lung destruction, and the concentration of dust and the length of exposure to it. The most dangerous particles are those in the range of 1 to 5 μm. These small particles are carried through the inspired air into the alveolar structures, whereas larger particles are trapped in the nose or mucous linings of the airways and removed by the mucociliary blanket. Exceptions are asbestos and talc particles, which range in size from 30 to 60 μm but find their way into the alveoli because of their density.

All particles in the alveoli must be cleared by the lung macrophages. Macrophages are thought to transport engulfed particles from the small bronchioles and the alveoli, which have neither cilia nor mucus-secreting cells, to the mucociliary escalator or to the lymphatic channels for removal from the lung. This clearing function is hampered when the function of the macrophage is impaired by factors such as cigarette smoking, consumption of alcohol, and hypersensitivity reactions. This helps to explain the increased incidence of lung disease among smokers exposed to asbestos. In silicosis, the ingestion of silica particles leads to the destruction of the lung macrophages and the release of substances resulting in inflammation and fibrosis. Tuberculosis and other diseases caused by mycobacteria are common in people with silicosis. Because the macrophages are responsible for protecting the lungs from tuberculosis, the destruction of macrophages accounts for an increased susceptibility to tuberculosis in people with silicosis.

The concentration of some dusts in the environment strongly influences their effects on the lung. For example, acute silicosis is seen only in people whose occupations entail intense exposure to silica dust over a short period. It is seen in sandblasters, who use a high-speed jet of sand to clean and polish bricks and the insides of corroded tanks; in tunnelers; and in rock drillers, particularly if they drill through sandstone. Acute silicosis is a rapidly progressive disease, usually leading to severe disability and death within 5 years of diagnosis. In contrast to acute silicosis, which is caused by exposure to extremely high concentrations of silica dust, the symptoms related to chronic, low-level exposure to silica dust usually do not begin to develop until after many years of exposure, and then the symptoms often are insidious in onset and slow to progress.
**Drug-Induced Interstitial Lung Disease**

Drugs can cause a variety of both acute and chronic alterations in lung function. For example, some of the cytotoxic drugs (e.g., bleomycin, busulfan, methotrexate, cyclophosphamide) used in treatment of cancer cause pulmonary damage as a result of direct toxicity of the drug and by stimulating the influx of inflammatory cells into the alveoli. Amiodarone, a drug used to treat resistant cardiac arrhythmias, is preferentially sequestered in the lung and causes significant pneumonitis in 5% to 15% of people receiving it.

**Hypersensitivity Pneumonitis**

The hypersensitivity occupational lung disorders (e.g., hypersensitivity pneumonitis or also termed extrinsic allergic alveolitis) are caused by intense and often prolonged exposure to inhaled organic dusts and related occupational antigens. Those affected have a heightened sensitivity to the antigen. The most common forms of hypersensitivity pneumonitis are farmer’s lung, which results from exposure to moldy hay; pigeon breeder’s lung, provoked by exposure to the serum, excreta, or feathers of birds; bagassosis, from contaminated sugar cane; and humidifier or air conditioner lung, caused by mold in the water reservoirs of these appliances. Unlike asthma, this type of hypersensitivity reaction involves primarily the alveoli. These disorders cause progressive fibrotic lung disease, which can be prevented by the removal of the environmental agent.

**Sarcoidosis**

Sarcoidosis is a systemic disorder in which granulomas are found in affected tissues and organ systems, particularly the lung and lymphatic system. An important qualification is that these granulomas occur in the absence of exogenous (infection or environmental) agents known to cause granulomatous inflammation. The disorder predominantly affects people between 10 and 40 years of age, although it can occur in older people. The incidence of sarcoidosis in the United States is approximately 10.9 of 100,000 persons per year for whites and 35.5 of 100,000 persons per year for blacks.

**Etiology and Pathogenesis**

The characteristic lesion of sarcoidosis is the noncaseating granuloma. Unlike the granulomatous lesions that develop in tuberculosis and histoplasmosis, the collection of tissue macrophages composing the granulomas in sarcoidosis do not show evidence of necrosis or caseation. In addition to granulomas, in which multinuclear giant cells are frequently seen, there is often alveolitis or inflammation of the alveoli.

The cause of sarcoidosis remains obscure. It is thought that the disorder may result from exposure of genetically predisposed persons to specific environmental agents. Support for a genetic influence comes from epidemiologic studies that have demonstrated the higher incidence in American Blacks and Scandinavian populations. Additional evidence comes from familial clustering of the disease. Analysis of human leukocyte antigen (HLA) genes located in the major histocompatibility complex also suggests that unique HLA genes can be linked to disease susceptibility and prognosis. Despite advances, including the identification of sarcoidosis genetic factors, a specific etiologic agent has yet to be identified.

**Clinical Manifestations**

Sarcoidosis has variable manifestations and an unpredictable course of progression in which any organ system can be affected. The organs that most commonly manifest symptoms are the lungs, lymph nodes, skin, and eyes. People with sarcoidosis frequently seek health care either as a result of abnormalities detected on an incidental chest film or because of insidious onset of respiratory symptoms (shortness of breath, nonproductive cough, chest pain) or constitutional signs and symptoms (e.g., fever, sweating, anorexia, weight loss, fatigue, myalgia). Eye involvement (anterior uveitis) and skin involvement (skin papules and plaques) are particularly common extrathoracic manifestations, but there may be cardiac, neuromuscular, hematologic, hepatic, endocrine, and lymph node findings.

Sarcoidosis follows an unpredictable course characterized by either progressive chronicity or periods of activity interspersed with remissions, sometimes permanent, that may be spontaneous or induced by corticosteroid therapy. The disease is thought to be connected to abnormal immunological function since there is an increase in ratio of CD4+ and CD8+ lymphocytes and increased proinflammatory cytokines. Approximately 65% to 75% of people recover with minimal clinical and radiographic abnormalities.

**Diagnosis and Treatment**

The diagnosis of sarcoidosis is based on history and physical examination, tests to exclude other diseases, chest radiography, and biopsy to obtain confirmation of noncaseating granulomas. The use of CT scans and magnetic resonance imaging (MRI) as routine methods for diagnosis of sarcoidosis remains controversial. For example, increased angiotensin-converting enzyme (ACE) is commonly seen with sarcoidosis; however, it is not specific so is deemed controversial.

Treatment is directed at interrupting the granulomatous inflammatory process that is characteristic of the disease and managing the associated complications. When treatment is indicated, corticosteroid drugs are used. These agents produce clearing of the lung, as seen on the chest radiograph, and improve pulmonary function, but it is not known whether they affect the long-term outcome of the disease.

**IN SUMMARY**

The ILDs are characterized by fibrosis and decreased compliance of the lung. They include the occupational and environmental lung diseases and granulomatous disorders, such as sarcoidosis. These disorders are thought to result from an inflammatory process that begins in the alveoli.
and extends to involve the interstitial tissues of the lung. Unlike COPD, which affects the airways, ILDs affect the supporting collagen and elastic tissues that lie between the airways and blood vessels. These lung diseases generally decrease lung volumes, reduce the diffusing capacity of the lung, and cause various degrees of hypoxemia. Because lung compliance is reduced, people with this form of lung disease tend to maintain their minute volume by a rapid, shallow breathing pattern.

**DISORDERS OF THE PULMONARY CIRCULATION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the cause of pulmonary embolism and the clinical manifestations of the disorder.
- Describe the pathophysiology of pulmonary hypertensive disorders.
- Describe the rationale for right ventricular hypertrophy with cor pulmonale.

As blood moves through the pulmonary capillaries, oxygen content increases and carbon dioxide decreases. These processes depend on the matching of ventilation (i.e., gas exchange) and perfusion (i.e., blood flow). This section discusses two major problems of the pulmonary circulation: pulmonary embolism and pulmonary hypertension.

**Pulmonary Embolism**

Pulmonary embolism develops when a blood-borne substance lodges in a branch of the pulmonary artery and obstructs blood flow. The embolism may consist of a thrombus (Fig. 37.15), air that has accidentally been injected during intravenous infusion, fat that has been mobilized from the bone marrow after a fracture or from a traumatized fat depot, or amniotic fluid that has entered the maternal circulation after rupture of the membranes at the time of delivery. Approximately 50,000 deaths/year in the United States are a result of a pulmonary embolism.42

**Etiology and Pathogenesis**

Almost all pulmonary emboli are thrombi that arise in the systemic venous system and become lodged in a pulmonary blood vessel as they move from the right heart into and through the pulmonary circulation. It may arise as a primary disorder of the pulmonary arteries in which an abnormal thickening of the vessel wall increases the resistance to blood flow, or as a secondary disorder due to chronic lung disorders or environmental conditions that produce hypoxemia and a resultant constriction of small pulmonary arteries, cardiac disorders that increase pulmonary venous pressure, or thromboembolic disorders that occlude pulmonary blood vessels.
because of a large embolus. Although small areas of infarction may occur, frank pulmonary infarction is uncommon.

Among the physiologic factors that contribute to venous thrombosis is Virchow triad, which consists of venous stasis, venous endothelial injury, and hypercoagulability states. The thrombophilias (e.g., antithrombin III deficiency, protein C and S deficiencies, factor V Leiden mutation) are a group of inherited disorders affecting coagulation that make an individual prone to development of venous thromboemboli. Venous stasis and venous endothelial injury can result from prolonged bed rest, trauma, surgery, childbirth, fractures of the hip and femur, myocardial infarction and congestive heart failure, and spinal cord injury. People undergoing orthopedic surgery and gynecologic cancer surgery are at particular risk, as are immobilized persons. Hypercoagulability is related to various factors. Cancer cells can produce thrombin and synthesize procoagulation factors, increasing the risk for thromboembolism. Use of oral contraceptives, pregnancy, and hormone replacement therapy are thought to increase the resistance to endogenous anticoagulants.

Refer back to Ms. French in discussion about pulmonary embolism etiology. Ms. French, who you met at the beginning of the unit, presented to the emergency department with soreness in her right calf. This was because the embolus originated in the saphenous vein of her right leg and then broke free and traveled to the pulmonary circulation. Ms. French’s history of cigarette smoking and use of estrogen-based oral contraceptives increased her risk for thrombus development, because these agents cause vasoconstriction and inflammation.

Clinical Manifestations

The manifestations of pulmonary embolism depend on the size and location of the obstruction. Chest pain, dyspnea, and increased respiratory rate are the most frequent signs and symptoms of pulmonary embolism. Pulmonary infarction often causes pleuritic pain that changes with respiration; it is more severe on inspiration and less severe on expiration. Moderate hypoxemia without carbon dioxide retention occurs as a result of impaired gas exchange. Small emboli that become lodged in the peripheral branches of the pulmonary artery may go unrecognized unless the person is compromised, such as occurs in the elderly or acutely ill. Repeated small emboli gradually reduce the size of the pulmonary capillary bed, resulting in pulmonary hypertension. People with moderate-sized emboli often present with breathlessness accompanied by pleuritic pain, apprehension, slight fever, and cough productive of blood-streaked sputum. Tachycardia often occurs to compensate for decreased oxygenation, and the breathing pattern is rapid and shallow. People with massive emboli usually present with sudden collapse, crushing substernal chest pain, shock, and sometimes loss of consciousness. The pulse is rapid and weak, the blood pressure is low, the neck veins are distended, and the skin is cyanotic and diaphoretic. Massive pulmonary emboli often are fatal.

Refer to Ms. French in discussion about pulmonary embolism clinical features. On presentation, Ms. French’s heart rate was elevated (132 beats/minute) and the electrocardiogram (ECG) showed sinus tachycardia. Her breathing was rapid and shallow. In a person with pulmonary embolism, tachycardia and tachypnea often occur to compensate for decreased oxygenation.

Diagnosis

The diagnosis of pulmonary embolism is based on clinical signs and symptoms, blood gas determinations, venous thrombosis studies, troponin, d-dimer testing, lung scans, and helical CT scans of the chest. Laboratory studies and radiologic films are useful in ruling out other conditions that might give rise to similar symptoms. Because emboli can cause an increase in pulmonary vascular resistance, the ECG may be used to detect signs of right heart strain.

Because most pulmonary emboli originate from DVT, venous studies such as lower limb compression ultrasonography, impedance plethysmography, and contrast venography are often used as initial diagnostic procedures. Of these, lower limb compression ultrasonography has become an important noninvasive means for detecting DVT. D-dimer testing involves the measurement of plasma d-dimer, a degradation product of coagulation factors that have been activated as the result of a thromboembolic event. Troponin levels may be increased due to stretching of the right ventricle by a large pulmonary infarction. The ventilation–perfusion scan uses radionuclide albumin, which is injected intravenously, and a radiolabeled gas, which is inhaled. A scintillation (gamma) camera is used to scan the various lung segments for blood flow and distribution of the radiolabeled gas. Ventilation–perfusion scans are useful only when their results are either normal or indicate a high probability of pulmonary embolism. Helical (spiral) CT angiography requires administration of an intravenous radiocontrast medium. It is sensitive for the detection of emboli in the proximal pulmonary arteries and provides another method of diagnosis. Pulmonary angiography involves the passage of a venous catheter through the right heart and into the pulmonary artery under fluoroscopy. Although it remains the most accurate method of diagnosis, it is infrequently done since it is such an invasive procedure. An embolectomy sometimes is performed during this procedure.

Refer back to Ms. French in discussion about pulmonary embolism diagnostics. D-dimer testing involves the measurement of plasma D-dimer, a degradation product of coagulation factors that have been activated as the result of a thromboembolic event. Recall that Ms. French’s D-dimer levels were elevated.
Treatment

The treatment goals for pulmonary emboli focus on preventing DVT and the development of thromboemboli; protecting the lungs from exposure to thromboemboli when they occur; and, in the case of large and life-threatening pulmonary emboli, sustaining life and restoring pulmonary blood flow. Thrombolytic therapy using recombinant tissue plasminogen activator may be indicated in people with multiple or large emboli.

Prevention focuses on identifying people at risk, avoidance of venous stasis and hypercoagulability states, and early detection of venous thrombosis. It is important that people start to become mobile as soon as possible after surgery or illness. For people at risk, graded compression elastic stockings and intermittent pneumatic compression (IPC) boots can be used to prevent venous stasis. Surgical interruption of the vena cava may be indicated when pulmonary embolism poses a life-threatening risk.

Pharmacologic prophylaxis involves the use of anticoagulant drugs. Anticoagulant therapy may be used to decrease the likelihood of DVT, thromboembolism, and fatal pulmonary embolism after major surgical procedures. Low molecular weight heparin, which can be administered subcutaneously on an outpatient basis, is often used. Warfarin, an oral anticoagulation drug, may be used for people with a long-term risk for development of thromboemboli.

Pulmonary Hypertension

The pulmonary circulation is a low-pressure system designed to accommodate varying amounts of blood delivered from the right heart and to facilitate gas exchange. The main pulmonary artery and major branches are relatively thin-walled, compliant vessels. The distal pulmonary arterioles also are thin walled and have the capacity to dilate, collapse, or constrict depending on the presence of vasoactive substances released from the endothelial cells of the vessel, neurohumoral influences, flow velocity, oxygen tension, and alveolar ventilation.

Pulmonary hypertension is a disorder characterized by an elevation of pressure within the pulmonary circulation, namely, the pulmonary arterial system. The elevation in pressure may be acute or chronic, depending on the causative factors.

Etiology and Pathogenesis

A number of factors can contribute to the pathogenesis of pulmonary arterial hypertension (PAH), including a decrease in the cross-sectional area of the pulmonary arteries, a loss of blood vessels from either scarring or destructive processes affecting the alveolar walls, vasoconstriction in response to hypoxia, the need to accommodate excessive inflow of blood flow without any anatomic changes in the pulmonary arteries or arterioles, or the occlusion of outflow from the pulmonary circulation due to elevated pressures within the left atrium or ventricle.

The disorder may be due to changes in the arterial wall, often referred to as pulmonary arterial hypertension, or it may occur as a secondary condition related to the occlusion of the pulmonary circulation by pulmonary emboli or to disruption of the pulmonary circulation due to heart or lung disease.

Pulmonary Arterial Hypertension

The term pulmonary arterial hypertension (PAH) is used to describe a type of pulmonary hypertension that has its origin in the pulmonary arteries. The World Health Organization (WHO) categorized pulmonary hypertension into five groups related to their disease mechanism.

- Group I is pulmonary arterial or idiopathic hypertension.
- Group II is pulmonary venous hypertension.
- Group III is pulmonary hypertension associated with hypoxemia.
- Group IV is pulmonary hypertension due to chronic thrombotic or embolic disease or both.
- Group V comprises miscellaneous disorders that cause PAH.

PAH is a rare and debilitating disorder characterized by abnormal proliferation and contraction of vascular smooth muscle, coagulation abnormalities, and marked intimal fibrosis leading to obliteration or obstruction of the pulmonary arteries and arterioles (Fig. 37.16). The resulting increase in pressure results in progressive right heart failure, low cardiac output, and death if left untreated. The past decade has witnessed dramatic advances in the treatment of PAH, with medical therapies targeting specific pathways that are believed to play pathogenetic roles in development of the disorder. Despite these achievements, PAH remains a serious, life-threatening condition.

Etiology and Pathogenesis. The familial form of PAH appears to be inherited as an autosomal dominant trait with a variable but low penetrance, with some people inheriting the trait without exhibiting the disease. The bone morphogenetic protein receptor type II gene (BMPR2), which codes for a member of the transforming growth factor-β (TGF-β) superfamily of receptors, was identified as causative of familial PAH. Mutations in these receptors are thought to prevent TGF-β and related molecules from exerting an inhibitory effect on smooth muscle and endothelial cell proliferation. Other conditions associated with PAH include collagen vascular disorders (e.g., scleroderma), drugs and toxins, human immunodeficiency virus (HIV) infection, portal hypertension, and persistent pulmonary hypertension in the newborn.

Although the specific mechanisms responsible for the vascular changes that occur in PAH remain unknown, a number of mechanisms have been proposed. These include enhanced expression of the serotonin transporter, diminished levels of nitric oxide and prostacyclin, and increased levels of several growth factors, including endothelin, vascular endothelial growth factor, and platelet-derived growth factor.
effects on vascular smooth muscle. The endothelium also produces prostacyclin (PGI2), an inhibitor of platelet aggregation and potent vasodilator. Results of studies relating these mechanisms to the structure and function of the pulmonary arterial circulation have already been translated into targeted therapies for PAH, with the probability that more will be investigated in the future.

**Clinical Manifestations.** PAH is defined by persistent elevation in pulmonary artery pressure with normal left ventricular pressures, differentiating it from left-sided heart failure. Symptoms typically progress from shortness of breath and decreasing exercise tolerance to right heart failure, with marked peripheral edema and functional limitations. Other common symptoms include fatigue, angina, and syncope (fainting) or near-syncope.

**Diagnosis and Treatment.** The diagnosis of primary pulmonary hypertension is based on an absence of disorders that cause secondary hypertension and mean pulmonary artery pressures greater than 25 mm Hg at rest or 30 mm Hg with exercise.

Treatment consists of measures to improve right heart function as a means of reducing fatigue and peripheral edema. Supplemental oxygen may be used to increase exercise tolerance. This agent often improves symptoms, sometimes dramatically, in people who have not responded to other vasodilators. Sildenafil (e.g., Viagra) a highly selective phosphodiesterase-5 inhibitor, which acts in a manner similar to nitric oxide to produce vasodilation, is another treatment of pulmonary hypertension. Lung transplantation may be an alternative for people who do not respond to other forms of treatment.

**Secondary Pulmonary Hypertension**

Although pulmonary hypertension can develop as a primary disorder, most cases develop secondary to conditions such as chronic hypoxemia due to COPD, ILD, or sleep-disordered breathing; increased resistance to pulmonary venous drainage due to conditions such as diastolic dysfunction of the left heart or disorders of mitral or aortic valves; or chronic thromboembolic disorders.

**Etiology and Pathogenesis.** Continued exposure of the pulmonary vessels to hypoxemia is a common cause of pulmonary hypertension. Unlike blood vessels in the systemic circulation, most of which dilate in response to hypoxemia and hypercapnia, the pulmonary vessels constrict. The stimulus for constriction seems to originate in the airspaces near the smaller branches of the pulmonary arteries. In regions of the lung that are poorly ventilated, the response is adaptive in that it diverts blood flow away from the poorly ventilated areas to those areas that are more adequately ventilated. This effect, however, becomes less beneficial as more and more areas of the lung become poorly ventilated. Pulmonary hypertension is a common problem in people with advanced COPD or ILD. It also may develop at high altitudes in people with normal lungs.
People who experience marked hypoxemia during sleep (such as those with sleep apnea) often experience marked elevations in pulmonary arterial pressure.

Elevation of pulmonary venous pressure is common in conditions such as mitral valve disorders or left ventricular diastolic dysfunction. In each of these alterations, the elevated left atrial pressure is transmitted to the pulmonary circulation. Continued increases in left atrial pressure can lead to medial hypertrophy and intimal thickening of the small pulmonary arteries, causing sustained hypertension. Another cause of secondary pulmonary hypertension is obstruction of pulmonary blood flow due to pulmonary thromboemboli. People who are promptly treated for acute pulmonary thromboembolism with anticoagulants rarely develop pulmonary hypertension. However, in some people, chronic obstruction of the pulmonary vascular bed develops because of impaired resolution of the thromboemboli.

**Clinical Manifestations, Diagnosis, and Treatment.** The signs and symptoms of secondary pulmonary hypertension reflect both the elevated pulmonary arterial pressure and the underlying heart or lung disease. As with primary pulmonary hypertension, diagnosis is based on radiographic findings, echocardiography, and Doppler ultrasonography. Treatment measures are directed toward the underlying disorder. Vasodilator therapy may be indicated for some people.

**Cor Pulmonale**
The term *cor pulmonale* refers to right heart failure resulting from primary lung disease or pulmonary hypertension. The increased pressures and work result in hypertrophy and eventual failure of the right ventricle. The manifestations of cor pulmonale include the signs and symptoms of the primary lung disease and the signs of right-sided heart failure. Signs of right-sided heart failure include venous congestion, peripheral edema, shortness of breath, and a productive cough, which becomes worse during periods of heart failure. Plethora (i.e., redness), cyanosis, and warm, moist skin may result from the compensatory polycythemia and desaturation of arterial blood that accompany chronic lung disease. Drowsiness and altered consciousness may occur as the result of carbon dioxide retention. Management of cor pulmonale focuses on the treatment of the lung disease and heart failure (Fig. 37.17). Low-flow oxygen therapy may be used to reduce the pulmonary hypertension and polycythemia associated with severe hypoxemia caused by chronic lung disease.

**IN SUMMARY**
Pulmonary vascular disorders include pulmonary embolism and pulmonary hypertension. Pulmonary embolism develops when a blood-borne substance lodges in a branch of the pulmonary artery and obstructs blood flow. The embolus can consist of a thrombus, air, fat, or amniotic fluid. The most common form is thromboemboli arising from the deep venous channels of the lower extremities. Pulmonary hypertension is the elevation of pulmonary arterial pressure. It has been categorized into five groups. *Cor pulmonale* describes right heart failure caused by primary pulmonary disease and long-standing pulmonary hypertension.

**ACUTE RESPIRATORY DISORDERS**

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the pathologic lung changes that occur in acute respiratory distress syndrome.
- Describe the clinical manifestations of acute respiratory failure.
- Differentiate between the causes and manifestations of hypoxic and hypoxic/acidemic respiratory failure.
- Describe the treatment of respiratory failure.

The function of the respiratory system is to add oxygen to the blood and remove carbon dioxide. Disruptions in this function occur with ALI/respiratory distress syndrome and acute
respiratory failure. Although the mechanisms that disrupt gas exchange may vary, both conditions represent a life-threatening situation with high risks of morbidity and mortality.

**Acute Lung Injury/Acute Respiratory Distress Syndrome**

Acute respiratory distress syndrome (ARDS) was first described in 1967 in adults and initially called *adult respiratory distress syndrome*. It later was renamed *acute respiratory distress syndrome* because it also affects children. After a consensus conference in 1994, ALI and ARDS were differentiated by the extent of hypoxemia, as evaluated by the PF (PO$_2$ to FiO$_2$) ratio.$^47$ ARDS is a more severe aspect of ALI and is differentiated primarily for early intervention, prevention, and research purposes.

ARDS may result from a number of conditions, including aspiration of gastric contents, major trauma (with or without fat emboli), sepsis secondary to pulmonary or nonpulmonary infections, acute pancreatitis, hematologic disorders, metabolic events, and reactions to drugs and toxins (Chart 37.3).

**Etiology and Pathogenesis**

Although a number of conditions may lead to ALI/ARDS, they all produce similar pathologic lung changes that include diffuse epithelial cell injury with increased permeability of the alveolar–capillary membrane (Fig. 37.18). The increased permeability permits fluid, plasma proteins, and blood cells to move out of the vascular compartment into the interstitium and alveoli of the lung.$^48$ Diffuse alveolar cell damage leads to accumulation of fluid, surfactant inactivation, and formation of a hyaline membrane that is impervious to gas exchange. As the disease progresses, the work of breathing becomes greatly increased as the lung stiffens and becomes more difficult to inflate.

There is increased intrapulmonary shunting of blood, impaired gas exchange, and refractory hypoxemia despite high supplemental oxygen therapy. Gas exchange is further compromised by alveolar collapse resulting from abnormalities in surfactant production. When injury to the alveolar epithelium is severe, disorganized epithelial repair may lead to fibrosis (Fig. 37.19).

**Chart 37.3** Conditions in Which ARDS Can Develop*

- **Aspiration**
  - Near drowning
  - Aspiration gastric contents

- **Drugs, Toxins, and Therapeutic Agents**
  - Free-base cocaine smoking
  - Heroin
  - Inhaled gases (e.g., smoke, ammonia)
  - Breathing high concentrations of oxygen
  - Radiation

- **Infections**
  - Septicemia

- **Trauma and Shock**
  - Burns
  - Fat embolism
  - Chest trauma

- **Disseminated Intravascular Coagulation**

- **Multiple Blood Transfusions**

*This list is not intended to be inclusive.
The pathogenesis of ALI/ARDS is unclear, although both local and systemic inflammatory responses occur so often when a person has been diagnosed with ARDS they already have leaky capillary syndrome in other organs such as the pancreas. Neutrophils accumulate early in the course of the disorder and are considered to play a role in the pathogenesis of ALI/ARDS. Activated neutrophils synthesize and release a variety of products, including proteolytic enzymes, toxic oxygen species, and phospholipid products that increase the inflammatory response and cause further injury to the capillary endothelium and alveolar epithelium.
Clinical Manifestations and Diagnosis

Clinically, ALI/ARDS is marked by a rapid onset of respiratory distress, usually within 12 to 18 hours of the initiating event, an increase in respiratory rate, and signs of respiratory failure. Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen therapy, which results in a decrease in the PF ratio. Many people with ARDS have a systemic response that results in multiple organ failure, particularly of the renal, gastrointestinal, cardiovascular, and central nervous systems. Chest radiography shows diffuse bilateral infiltrates of the lung tissue in the absence of cardiac dysfunction.

Treatment

The treatment goals in ARDS are to supply oxygen to vital organs and provide supportive care until the condition causing the pathologic process has been reversed and the lungs have had a chance to heal. Assisted ventilation using high concentrations of oxygen may be required to correct the hypoxemia. Extensive study has been conducted to determine optimal pressures and volumes to correct the hypoxemia yet prevent further lung injury due to the barotrauma often seen with mechanics of ventilation. Also specific nutritional formulas to be used with these people with ARDS and ARF have been found to increase outcomes.

Acute Respiratory Failure

Respiratory failure can be viewed as a failure in gas exchange due to either heart or lung failure, or both. It is not a specific disease but can occur in the course of a number of conditions that impair ventilation, compromise the matching of ventilation and perfusion, or impair gas diffusion. Acute respiratory failure may occur in previously healthy people as the result of acute disease or trauma involving the respiratory system, or it may develop in the course of a chronic neuromuscular or lung disease.

Respiratory failure is a condition in which the respiratory system fails in one or both of its gas exchange functions—oxygenation of mixed venous blood and elimination of carbon dioxide. The function of the respiratory system can be said to consist of two aspects: gas exchange (movement of gases across the alveolar–capillary membrane) and ventilation (movement of gases into and out of the alveoli due to the action of the respiratory muscles, respiratory center in the CNS, and the pathways that connect the centers in the CNS with the respiratory muscles). Thus, respiratory failure is commonly divided into two types:

1. Hypoxemic respiratory failure due to failure of the gas exchange function of the lung
2. Hypercapnic/hypoxemic respiratory failure due to ventilatory failure

The classification should not be viewed as rigid since lung disorders that cause impaired gas exchange can be complicated by ventilatory failure. In addition, ventilatory failure can be accompanied by lung disorders that impair gas diffusion. Causes of respiratory failure are summarized in Chart 37.4.

Hypoxemic Respiratory Failure

In people with hypoxemic respiratory failure, two major pathophysiologic factors contribute to the lowering of arterial PO₂—ventilation–perfusion mismatching or impaired diffusion.

Mismatching of Ventilation and Perfusion. The mismatching of ventilation and perfusion occurs when areas of the lung are ventilated but not perfused or when areas are perfused but not ventilated. Usually the hypoxemia seen in situations of ventilation–perfusion mismatching is more severe in relation to hypercapnia than that seen in hypoventilation. Severe mismatching of ventilation and perfusion often is seen in people with advanced COPD. These disorders contribute to the retention of carbon dioxide by reducing the effective alveolar ventilation, even when total ventilation is maintained. This occurs because a region of the lung is not perfused and gas exchange cannot take place or because an area of the lung is not being ventilated. Maintaining a high ventilation rate effectively prevents hypercapnia but also increases the work of breathing.

The hypoxemia associated with ventilation–perfusion disorders often is exaggerated by conditions such as hypoventilation and decreased cardiac output. For example, sedation can cause hypoventilation in people with severe COPD, resulting in further impairment of ventilation. Likewise, a
increase in cardiac output because of myocardial infarction can exaggerate the ventilation–perfusion impairment in a person with mild pulmonary edema or COPD.

The beneficial effect of oxygen administration on PO2 levels in ventilation–perfusion disorders depends on the degree of mismatching that is present. Because oxygen administration increases the diffusion gradient in ventilated portions of the lung, it usually is effective in raising arterial PO2 levels. However, high-flow oxygen may decrease the respiratory drive and produce an increase in PCO2.

**Impaired Diffusion.** Impaired diffusion describes a condition in which gas exchange between the alveolar air and pulmonary blood is impeded because of an increase in the distance for diffusion or a decrease in the permeability or surface area of the respiratory membranes to the movement of gases. It most commonly occurs in conditions such as ILD, ALI/ARDS, pulmonary edema, and pneumonia.

Conditions that impair diffusion may produce severe hypoxemia but no hypercapnia because of the increase in ventilation and greater diffusion rate of carbon dioxide. Hypoxemia resulting from impaired diffusion can be partially or completely corrected by the administration of high concentrations of oxygen. In this case, the high concentration of oxygen serves to overcome the decrease in diffusion by establishing a larger alveolar-to-capillary diffusion gradient.

**Hypercapnic/Hypoxemic Respiratory Failure**

In the hypercapnic form of respiratory failure, people are unable to maintain a level of alveolar ventilation sufficient to eliminate CO2 and keep arterial O2 levels within normal range. Because ventilation is determined by a sequence of events ranging from generation of impulses in the CNS to movement of air through the conducting airways, there are several stages at which problems can adversely affect the total minute ventilation.

Hypoventilation or ventilatory failure occurs when the volume of “fresh” air moving into and out of the lung is significantly reduced. It is commonly caused by conditions outside the lung such as depression of the respiratory center (e.g., drug overdose, brain injury), diseases of the nerves supplying the respiratory muscles (e.g., Guillain-Barré syndrome, spinal cord injury), disorders of the respiratory muscles (e.g., muscular dystrophy), exacerbation of chronic lung disease (e.g., COPD), or thoracic cage disorders (e.g., severe scoliosis or crushed chest).

Hypoventilation has two important effects on arterial blood gases. First, it almost always causes an increase in PCO2. The rise in PCO2 is directly related to the level of ventilation; reducing the ventilation by one half causes a doubling of the PCO2. Thus, the PCO2 level is a good diagnostic measure for hypoventilation. Second, it may cause hypoxemia, although the hypoxemia that is caused by hypoventilation can be readily abolished by the administration of supplemental oxygen.

**Clinical Manifestations**

Acute respiratory failure is usually manifested by varying degrees of hypoxemia and hypercapnia. There is no absolute definition of the levels of PO2 and PCO2 that indicate respiratory failure. Respiratory failure is conventionally defined by an arterial PO2 of less than 50 mm Hg, an arterial PCO2 of more than 50 mm Hg, or both when prior blood values have been normal. It is important to emphasize that these cutoff values are not rigid but simply serve as a general guide in combination with history and physical assessment information. The signs and symptoms of acute respiratory failure are those of the underlying disease combined with signs of hypoxemia and hypercapnia/hypoxemia. Respiratory acidosis is usually present because the retention of CO2 results in increased production of acids.

Hypoxemia is accompanied by increased respiratory drive and increased sympathetic tone. Potential signs of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, fatigue, tachypnea, hypertension, cardiac arrhythmias, and tremor. The initial cardiovascular effects are tachycardia with increased cardiac output and increased blood pressure. Serious arrhythmias may be triggered. The pulmonary vasculature constricts in response to low alveolar PO2. If severe, the pulmonary vasoconstriction may result in acute right ventricular failure with manifestations such as jugular vein distention and dependent edema. Profound acute hypoxemia can cause convulsions, retinal hemorrhages, and permanent brain damage. Hypotension and bradycardia often are preterminal events in people with hypoxemic respiratory failure, indicating the failure of compensatory mechanisms.

Many of the adverse consequences of hypercapnia are the result of respiratory acidosis. Direct effects of acidosis include depression of cardiac contractility, decreased respiratory muscle contractility, and arterial vasodilation. Raised levels of PCO2 greatly increase cerebral blood flow, which may result in headache, increased cerebrospinal fluid pressure, and sometimes papilledema. The headache is due to dilation of the cerebral vessels. Additional indicators of hypercapnia are warm and flushed skin and hyperemic conjunctivae. Hypercapnia has nervous system effects similar to those of an anesthetic—hence the term carbon dioxide narcosis. There is progressive somnolence, disorientation, and, if the condition is untreated, coma. Mild to moderate increases in blood pressure are common. Air hunger and rapid breathing occur when alveolar PCO2 levels rise to approximately 60 to 75 mm Hg; as PCO2 levels reach 80 to 100 mm Hg, the person becomes lethargic and sometimes semicomatose.

**Treatment**

The treatment of the person with acute respiratory failure consists of specific therapy directed toward the underlying disease, respiratory supportive care directed toward maintenance of adequate gas exchange, and general supportive care. A number of treatment modalities are available, including the establishment of an airway and the use of anti-inflammatory bronchodilators, mucolytics, and antibiotics for respiratory infections. The main therapeutic goal in acute hypoxemic respiratory failure is to ensure adequate oxygenation of vital organs, which is generally accomplished by mechanical ventilation.
IN SUMMARY

The hallmark of ALI and ARDS is a pronounced inflammatory response that affects the lung and may or may have already resulted in systemic organ failure. In fact, the damage to the lung in ARDS may not be the initial manifestation but part of a multiorgan shutdown due to leaky capillary syndrome. The acute inflammatory response results in damage and dysfunction of the alveolar–capillary membrane of the lung. Classically, there is interstitial edema of lung tissue, an increase in surface tension caused by inactivation of surfactant, collapse of the alveolar structures, a stiff and noncompliant lung that is difficult to inflate, and impaired diffusion of the respiratory gases with severe hypoxia that is totally refractory to oxygen therapy.

Acute respiratory failure is a condition in which the lungs fail to oxygenate the blood adequately (hypoxemic respiratory failure) or prevent undue retention of carbon dioxide (hypercapnic/hypoxemic respiratory failure). The causes of respiratory failure are many. It may arise acutely in people with previously healthy lungs, or it may be superimposed on chronic lung disease. Treatment of acute respiratory failure is directed toward treatment of the underlying disease, maintenance of adequate gas exchange and tissue oxygenation, and general supportive care. When alveolar ventilation is inadequate to maintain PO$_2$ or PCO$_2$ levels because of impaired respiratory function or neurologic failure, mechanical ventilation may be necessary. There are multiple problems that can result from the barotraumas caused by the mechanical ventilation to the lung parenchyma. This condition is caused by ventilator-induced lung injury (VILI), which needs to be prevented if at all possible. Lung protective strategies are focused on increasing compliance and decreasing shear stresses, which occur with the frequent alveolar collapse secondary to the high pressure needed to ventilate the lungs.

2. A 10-year-old boy who is having an acute asthmatic attack is brought to the emergency department by his parents. The boy is observed to be sitting up and struggling to breathe. His breathing is accompanied by use of the accessory muscles, a weak cough, and audible wheezing sounds. His pulse is rapid and weak and both heart and breath sounds are distant on auscultation. His parents relate that his asthma began to worsen after he developed a “cold,” and now he doesn’t even get relief from his “albuterol” inhaler.
   A. Explain the changes in physiologic function underlying this boy’s signs and symptoms.
   B. The boy is treated with a systemic corticosteroid and inhaled anticholinergic and $\beta_2$-adrenergic agonist and then transferred to the intensive care unit. Explain the action of each of these medications in terms of relieving this boy’s symptoms.

3. A 62-year-old man with an 8-year history of chronic bronchitis reports to his health care provider with complaints of increasing shortness of breath, ankle swelling, and a feeling of fullness in his upper abdomen. The expiratory phase of his respirations is prolonged and expiratory wheezes and crackles are heard on auscultation. His blood pressure is 160/90 mm Hg, his red blood cell count is $6.0 \times 10^6$ m$^{-3}$ (normal 4.2 to 5.4 $\times 10^6$ m$^{-3}$), his hematocrit is 65% (normal male value 40% to 50%), his arterial PO$_2$ is 55 mm Hg, and his O$_2$ saturation, which is 85% while he is resting, drops to 55% during walking exercise.
   A. Explain the physiologic mechanisms responsible for his edema, hypertension, and elevated red blood cell count.
   B. His arterial PO$_2$ and O$_2$ saturation indicate that he is a candidate for continuous low-flow oxygen. Explain the benefits of this treatment in terms of his activity tolerance, blood pressure, and red blood cell count.
   C. Explain why the oxygen flow rate for persons with COPD is normally titrated to maintain the arterial PO$_2$ between 60 and 65 mm Hg.

REVIEW EXERCISES

1. A 30-year-old man is brought to the emergency department with a knife wound to the chest. On visual inspection, asymmetry of chest movement during inspiration, displacement of the trachea, and absence of breath sounds on the side of the wound are noted. His neck veins are distended, and his pulse is rapid and thready. A rapid diagnosis of tension pneumothorax is made.
   A. Explain the observed respiratory and cardiovascular function in terms of the impaired lung expansion and the air that has entered the chest as a result of the injury.
   B. What type of emergent treatment is necessary to save this man’s life?

4. An 18-year-old woman is admitted to the emergency department with a suspected drug overdose. Her respiratory rate is slow (4 to 6 breaths/minute) and shallow. Arterial blood gases reveal a PCO$_2$ of 80 mm Hg and a PO$_2$ of 60 mm Hg.
   A. What is the cause of this woman’s high PCO$_2$ and low PO$_2$?
   B. Hypoventilation almost always causes an increase in PCO$_2$. Explain.
   C. Even though her PO$_2$ increases to 90 mm Hg with institution of oxygen therapy, her PCO$_2$ remains elevated. Explain.

Joseph Reterez, 45 years old, is admitted to the Emergency Department with abdominal and flank discomfort, distension of the abdomen, anorexia, fatigue, and nausea. He says that his urine is really cloudy and he thinks there is some blood visible in the urine. His mother, his maternal grandfather, and two maternal uncles died in their late 40s from renal disease, but no one in his family has had genetic testing. His assessment shows an increased abdominal girth, enlarged kidneys, mild (1+) pedal edema, and bilateral flank pain. His vital signs are as follows: temperature, 100.1°F; blood pressure, 145/92 mm Hg (indicative of hypertension); pulse, 92/minute; and respiratory rate, 14/minute. Significant (abnormal) blood chemistry values include the following: blood urea nitrogen (BUN), 45 mg/dL (normal, 8 to 20 mg/dL); creatinine, 2.0 mg/dL (normal, 0.3 to 1.2 mg/dL); and serum sodium, 147 mEq/L (normal, 135 to 145 mEq/L). His urine specimen shows mildly elevated (+1) protein and the presence of RBCs. Genetic testing reveals a mutation in the PKD1 gene, a common cause of adult polycystic kidney disease. Mr. Reterez’s diagnosis is discussed in Chapter 41.
The kidneys are remarkable organs. Each is smaller than a person’s fist, but in a single day, the two organs process approximately 22% to 25% of cardiac output or 1100 mL/minute.\(^1,2\) As part of their function, the kidneys filter physiologically essential substances, such as sodium (Na\(^+\)) and potassium (K\(^+\)) ions, from the blood and selectively reabsorb those substances that are needed to maintain the normal composition of internal body fluids. Substances that are not needed, or are in excess of those needed, pass into the urine. In regulating the volume and composition of body fluids, the kidneys perform excretory and endocrine functions. The renin–angiotensin mechanism participates in the regulation of blood pressure and the maintenance of circulating blood volume, and erythropoietin stimulates red blood cell production.\(^2\) The discussion in this chapter focuses on the structure and function of the kidneys and tests of renal function.

**Gross Structure and Location**

The kidneys are paired, bean-shaped organs that lie outside the peritoneal cavity in the back of the upper abdomen, one on each side of the vertebral column at the level of the

hilus. It is here that blood vessels and nerves enter and leave the kidney. The ureters, which connect the kidneys with the bladder, also enter the kidney at the hilus.2

The kidney is a multilobular structure, composed of between 8 and 18 lobes.2 Each lobe is composed of nephrons, which are the functional units of the kidney. Each kidney contains approximately 800,000 to 1,000,000 nephrons.2 Each nephron has a glomerulus that filters the blood and a system of tubular structures that selectively reabsorb material from the filtrate back into the blood and secrete materials from the blood into the filtrate as urine is being formed. On longitudinal section, a kidney can be divided into an outer cortex and an inner medulla (Fig. 38.2). The cortex, which is reddish-brown, contains the glomeruli and convoluted tubules of the nephron and blood vessels. The medulla consists of light-colored, cone-shaped masses—the renal pyramids. The columns of cortex that extend into the medulla divide the renal pyramids. Each pyramid, topped by a region of cortex, forms a lobe of the kidney. The apices of the pyramids form the papillae (i.e., 8 to 18 per kidney, corresponding to the number of lobes), which are perforated by the openings of the collecting ducts.2 The renal pelvis is a wide, funnel-shaped structure at the upper end of the ureter. It is made up of the calyces or cuplike structures that drain the upper and lower halves of the kidney.1,2

The kidney is sheathed in a fibrous external capsule and surrounded by a mass of fatty connective tissue, especially at its ends and borders. The adipose tissue protects the kidney from mechanical blows and assists, together with the attached blood vessels and fascia, in holding the kidney in place. Although the kidneys are relatively well protected, they may be bruised by blows to the loin or by compression between the lower ribs and the ileum. The kidneys are located outside the peritoneal cavity. Therefore, injury and rupture do not produce the same threat of peritoneal involvement as that of other organs such as the liver or spleen.
Renal Blood Supply
A single renal artery that arises on either side of the aorta supplies each kidney. As the renal artery approaches the kidney, it divides into five segmental arteries that enter the hilus of the kidney. In the kidney, each segmental artery branches into several lobular arteries that supply the upper, middle, and lower parts of the kidney. The lobular arteries further subdivide to form the interlobular arteries at the level of the corticomedullary junction (Fig. 38.3). These arteries give off branches, the arcuate arteries, which arch across the top of the pyramids. Small intralobular arteries radiate from the arcuate arteries to supply the cortex of the kidney. The afferent arterioles that supply the glomeruli arise from the intralobular arteries.

Although nearly all the blood flow to the kidneys passes through the cortex, less than 10% is directed to the medulla and only approximately 1% goes to the papillae. Under conditions of decreased perfusion or increased sympathetic nervous system stimulation, blood flow is redistributed away from the cortex toward the medulla. This redistribution of blood flow decreases glomerular filtration while maintaining the urine-concentrating ability of the kidneys, a factor that is important during conditions such as shock.

The Nephron
Each kidney is composed of more than approximately 1 million tiny, closely packed functional units called nephrons (Fig. 38.4A). The kidney has no ability to regenerate nephrons. Therefore, with aging, there is a generalized decrease in functioning nephrons. In fact, adults tend to lose approximately 10% of their nephrons each decade beginning at 40 years of age.

Each nephron consists of a glomerulus, a proximal convoluted tubule, a loop of Henle, a distal convoluted tubule, and a collecting duct. Blood is filtered in the glomerulus. In the proximal tubule, loop of Henle, distal tubule, and collecting duct, water, electrolytes, and other substances needed to maintain the constancy of the internal environment are reabsorbed into the bloodstream, while other unneeded materials are secreted into the tubular filtrate for elimination.

Nephrons can be roughly grouped into two categories—cortical nephrons and juxtamedullary nephrons. Cortical nephrons make up approximately 85% of the nephrons and originate in the superficial part of the cortex (see Fig. 38.4B). Cortical nephrons have short, thick loops of Henle that penetrate only a short distance into the medulla. The remaining 15% are juxtamedullary nephrons. These nephrons originate deeper in the cortex and have longer and thinner loops of Henle that penetrate the entire length of the medulla. The juxtamedullary nephrons are largely concerned with urine concentration.

Two capillary systems supply the nephrons—the glomerulus and the peritubular capillary network (see Fig. 38.4A). The glomerulus is a unique, high-pressure capillary filtration
system located between two arterioles, the afferent and the efferent arterioles. Because the arterioles are high-resistance vessels and the afferent arteriole has a larger diameter than the efferent arteriole, the blood pressure in the glomerulus is extraordinarily high for a capillary bed and easily forces fluid and solutes out of the blood into the glomerular capillary along its entire length. The peritubular capillaries originate from the efferent arteriole. They are low-pressure vessels that are adapted for reabsorption rather than filtration. These capillaries surround all portions of the tubules, an arrangement that permits rapid movement of solutes and water between the fluid in the tubular lumen and the blood in the capillaries. In the deepest part of the renal cortex, the efferent arterioles serving the juxtaglomerular glomeruli also continue into long, thin-walled looping vessels called the vasa recta. The vasa recta accompany the long loops of Henle in the medullary portion of the kidney to assist in exchange of substances flowing in and out of that portion of the kidney. The peritubular capillaries rejoin to form the venous channels by which blood leaves the kidneys and empties into the inferior vena cava.

**KEY POINTS**

**THE NEPHRON**

- The nephron, which is the functional unit of the kidney, is composed of a vascular component, which connects to the circulatory system, and a tubular component, which has connections to both the circulatory system and the elimination functions of the kidney.
- The tubular portion of the nephron processes the glomerular filtrate (urine), facilitating the reabsorption of substances from the tubular fluid into the peritubular capillaries and the secretion of substances from the peritubular capillaries into the urine filtrate.

**The Glomerulus**

The glomerulus consists of a compact tuft of capillaries encased in a thin, double-walled capsule called Bowman capsule. Blood flows into the glomerular capillaries from the afferent arteriole and flows out of the glomerular capillaries.

**FIGURE 38.4**

(B) Comparison of differences in location of tubular structures of the cortical and juxtamedullary nephrons.
into the efferent arteriole, which leads into the peritubular capillaries. Fluid and particles from the blood are filtered through the capillary membrane into a fluid-filled space in Bowman capsule, called Bowman space. The portion of the blood that is filtered into the capsule space is called the filtrate.\textsuperscript{2} The mass of capillaries and its surrounding epithelial capsule are collectively referred to as the renal corpuscle (Fig. 38.5A).\textsuperscript{2}

The glomerular capillary membrane is composed of three layers:

1. Capillary endothelial layer
2. Basement membrane
3. Single-celled capsular epithelial layer (see Fig. 38.5B)

The endothelial layer lines the glomerulus and interfaces with blood as it moves through the capillary. This layer contains many small perforations called fenestrations.\textsuperscript{4}

The epithelial layer that covers the glomerulus is continuous with the epithelium that lines Bowman capsule. The cells of the epithelial layer have unusual octopus-like structures that possess a large number of extensions, or foot processes (i.e., podocytes), which are embedded in the basement membrane (see Fig. 38.5B). These foot processes form slit pores through which the glomerular filtrate passes.\textsuperscript{4}

The basement membrane consists of a homogeneous acellular meshwork of collagen fibers, glycoproteins, and mucopolysaccharides (see Fig. 38.5C). The endothelial and epithelial layers of the glomerular capillary have porous structures, and thus the basement membrane determines the permeability of the glomerular capillary membrane. The spaces between the fibers that make up the basement membrane represent the pores of a filter and determine the size-dependent permeability barrier of the glomerulus. The size of the pores in the basement membrane normally prevents red blood cells and plasma proteins from passing through the glomerular membrane into the filtrate. There is evidence that the epithelium plays a major role in producing the basement membrane components, and the epithelial cells probably are active in forming new basement membrane material throughout life. Alterations in the structure and function of the glomerular basement membrane are responsible for the leakage of proteins and blood cells into the filtrate that occurs in many forms of glomerular disease.\textsuperscript{2}

Another important component of the glomerulus is the mesangium.\textsuperscript{4} In some areas, the capillary endothelium and the basement membrane do not completely surround each capillary. Instead, the mesangial cells, which lie between the capillary tufts, provide support for the glomerulus in these areas (see Fig. 38.5B).\textsuperscript{4} The mesangial cells produce an intercellular substance similar to that of the basement membrane. This substance covers the endothelial cells where they are not covered by basement membrane.\textsuperscript{4} The mesangial cells possess phagocytic properties and remove macromolecular materials that enter the intercapillary spaces. Mesangial cells also exhibit contractile properties in response to neurohumoral substances and are thought to contribute to the regulation of blood flow through the glomerulus. In normal glomeruli, the mesangial area is narrow and contains only a small number of cells. Mesangial hyperplasia and increased mesangial matrix occur in a number of glomerular diseases.\textsuperscript{4}
**Tubular Components of the Nephron**

As stated above, the nephron tubule is divided into four segments:

1. A highly coiled segment called the **proximal convoluted tubule**, which drains Bowman capsule
2. A thin, looped structure called the **loop of Henle**
3. A distal coiled portion called the **distal convoluted tubule**
4. A **collecting tubule**, which joins with several tubules to collect the filtrate

The filtrate passes through each of these segments before reaching the pelvis of the kidney.

The proximal tubule is a highly coiled structure that dips toward the renal pelvis to become the descending limb of the loop of Henle. The ascending loop of Henle returns to the region of the renal corpuscle, where it becomes the distal tubule. The distal convoluted tubule, which begins at the juxtaglomerular complex, is divided into two segments—the **diluting segment** and the **late distal tubule**. The late distal tubule fuses with the collecting tubule. Like the distal tubule, the collecting duct is divided into two segments—the **cortical collecting tubule** and the **inner medullary collecting tubule**.

Throughout its course, the tubule is composed of a single layer of epithelial cells resting on a basement membrane. The structure of the epithelial cells varies with tubular function. The cells of the proximal tubule have a fine, villous structure that increases the surface area for reabsorption. They also are rich in mitochondria, which support active transport processes. The epithelial layer of the thin segment of the loop of Henle has few mitochondria, indicating minimal metabolic activity and reabsorptive function.

**Urine Formation**

Urine formation involves the filtration of blood by the glomerulus to form an **ultrafiltrate of urine** and the tubular reabsorption of electrolytes and nutrients needed to maintain the constancy of the internal environment while eliminating waste materials.

**Glomerular Filtration**

Urine formation begins with the filtration of essentially protein-free plasma through the glomerular capillaries into Bowman space. The movement of fluid through the glomerular capillaries is determined by the same factors (i.e., capillary filtration pressure, colloidal osmotic pressure, and capillary permeability) that affect fluid movement through other capillaries in the body. The glomerular filtrate has a chemical composition similar to plasma, but it contains almost no proteins because large molecules do not readily cross the glomerular wall. Approximately 125 mL of filtrate is formed each minute. This is called the **glomerular filtration rate (GFR)**. This rate can vary from a few milliliters per minute to as high as 200 mL/minute. The average adult has a GFR of 125 mL/minute or 180 L/day.

The location of the glomerulus between two arterioles allows for maintenance of a high-pressure filtration system. The capillary filtration pressure (approximately 60 mm Hg) in the glomerulus is approximately two to three times higher than that of other capillary beds in the body. The filtration pressure and the GFR are regulated by the constriction and relaxation of the afferent and efferent arterioles. Constriction of the efferent arteriole increases resistance to outflow from the glomeruli and increases the glomerular pressure and the GFR.

**Tubular Reabsorption and Secretion**

From Bowman capsule, the glomerular filtrate moves into the tubular segments of the nephron. In its movement through the lumen of the tubular segments, the glomerular filtrate is changed considerably by the tubular transport of water and solutes. Tubular transport can result in reabsorption of substances from the tubular fluid into the peritubular capillaries or secretion of substances into the tubular fluid from the blood in the peritubular capillaries (Fig. 38.6).

The basic mechanisms of transport across the tubular epithelial cell membrane are similar to those of other cell membranes in the body and include active and passive transport mechanisms. Water and urea are passively absorbed along concentration gradients. Sodium, K+, chloride (Cl−), calcium (Ca2+), and phosphate (PO43−) ions, as well as urate, glucose, and amino acids are reabsorbed using primary or secondary active transport mechanisms to move across the tubular membrane. Some substances, such as hydrogen, potassium, and urate ions, are secreted into the tubular fluids. Under normal conditions, only approximately 1 mL of the 125 mL of glomerular filtrate that is formed each minute is excreted in the urine. The other 124 mL is reabsorbed in the tubules. This means that the average output of urine is approximately 60 mL/hour.

Renal tubular cells have two membrane surfaces through which substances must pass as they are reabsorbed from the tubular fluid. The outside membrane that lies adjacent to the interstitial fluid is called the **basolateral membrane**, and the side that is in contact with the tubular lumen and tubular filtrate is called the **luminal membrane**. In most cases, substances move from the tubular filtrate into the tubular cell along a concentration gradient, but they require facilitated transport or carrier systems to move across the basolateral membrane into the interstitial fluid, where they are absorbed into the peritubular capillaries.

The bulk of energy used by the kidney is for active sodium transport mechanisms that facilitate sodium reabsorption and...
cotransport of other electrolytes and substances such as glucose and amino acids. This is called secondary active transport or cotransport (Fig. 38.7). Secondary active transport depends on the energy-dependent Na⁺/K⁺-adenosine triphosphatase (ATPase) pump on the basolateral side of renal tubular cells.² The pump maintains a low intracellular sodium concentration that facilitates the downhill (i.e., from a higher to lower concentration) movement of sodium from the filtrate across the luminal membrane. Cotransport uses a carrier system in which the downhill movement of one substance such as sodium is coupled to the uphill movement (i.e., from a lower to higher concentration) of another substance such as glucose or an amino acid. A few substances, such as the hydrogen (H⁺) ion, are secreted into the tubule using countertransport, in which the movement of one substance, such as sodium, enables the movement of a second substance in the opposite direction.²

Proximal Tubule. Approximately 65% of all reabsorptive and secretory processes that occur in the tubular system take place in the proximal tubule. There is almost complete reabsorption of nutritionally important substances, such as glucose, amino acids, lactate, and water-soluble vitamins (Fig. 38.8). Electrolytes, such as Na⁺, K⁺, Cl⁻, and bicarbonate (HCO₃⁻), are 65% to 80% reabsorbed.² As these solutes move into the tubular cells, their concentration in the tubular lumen decreases, providing a concentration gradient for the osmotic reabsorption of water and urea. The proximal tubule is highly permeable to water, and the osmotic movement of water occurs so rapidly that the concentration difference of solutes on either side of the membrane seldom is more than a few milliosmoles.²

Many substances, such as glucose, are freely filtered in the glomerulus and reabsorbed by energy-dependent cotransport carrier mechanisms. The maximum amount of substance that these transport systems can reabsorb per unit time is called the transport maximum. The transport maximum is related to the number of carrier proteins that are available for transport and usually is sufficient to ensure that all of a filtered substance such as glucose can be reabsorbed rather than being eliminated in the urine. The plasma level at which the substance appears in the urine is called the renal threshold. Under some circumstances, the amount of substance filtered in the glomerulus exceeds the transport maximum. For example, when the blood glucose level is elevated in uncontrolled diabetes mellitus, the amount that is filtered in the glomerulus often exceeds the transport maximum (approximately 320 mg/minute), and glucose spills into the urine.²

In addition to reabsorbing solutes and water, cells in the proximal tubule also secrete organic cations and anions into the urine filtrate (see Figs. 38.6 and 38.8). Many of these organic anions and cations are end products of metabolism (e.g., urate, oxalate) that circulate in the plasma. The proximal tubule also secretes exogenous organic compounds such as
penicillin, aspirin, and morphine. Many of these compounds can be bound to plasma proteins and are not freely filtered in the glomerulus. Therefore, excretion by filtration alone eliminates only a small portion of these potentially toxic substances from the body.2

The Loop of Henle. The loop of Henle plays an important role in controlling the concentration of the urine. It does this by establishing a high concentration of osmotically active particles in the interstitium surrounding the medullary collecting tubules where the antidiuretic hormone (ADH) exerts its effects.

The loop of Henle is divided into three segments—the thin descending segment, the thin ascending segment, and the thick ascending segment. The loop of Henle, taken as a whole, always reabsorbs more sodium and chloride than water. This is in contrast to the proximal tubule, which reabsorbs sodium and water in equal proportions. The thin descending limb is highly permeable to water and moderately permeable to urea, sodium, and other ions. As the urine filtrate moves down the descending limb, water moves out of the filtrate into the surrounding interstitium. Thus, the osmolality of the filtrate reaches its highest point at the elbow of the loop of Henle. In contrast to the descending limb, the ascending limb of the loop of Henle is impermeable to water. In this segment, solutes are reabsorbed, but water cannot follow and remains in the filtrate. As a result, the tubular filtrate becomes more and more dilute, often reaching an osmolality of 100 mOsm/kg of H2O as it enters the distal convoluted tubule, compared with the 285 mOsm/kg of H2O in plasma. This allows for excretion of free water from the body. For this reason, it is often called the diluting segment.2

The thick segment of the loop of Henle begins in the ascending limb where the epithelial cells become thickened. As with the thin ascending limb, this segment is impermeable to water. The thick segment contains a Na+/K+/2Cl− cotransport system4 (Fig. 38.9). This system involves the cotransport of a positively charged Na+ and a positively charged K+ ion accompanied by two negatively charged Cl− ions. The gradient for the operation of this cotransport system is provided by the basolateral Na+/K+-ATPase pump, which maintains a low intracellular sodium concentration. Approximately 20% to 25% of the filtered load of sodium, potassium, and chloride is reabsorbed in the thick loop of Henle. Movement of these ions out of the tubule leads to the development of a transmembrane potential.
potential that favors the passive reabsorption of small divalent cations such as calcium and magnesium. The thick ascending loop of Henle is the site of the powerful “loop” diuretics (e.g., furosemide [Lasix]), which exert their action by inhibiting the Na+/K+/2Cl− cotransporters.

**Distal and Collecting Tubules.** Like the thick ascending loop of Henle, the distal convoluted tubule is relatively impermeable to water, and reabsorption of sodium chloride from this segment further dilutes the tubular fluid. Sodium reabsorption occurs through a Na+/Cl− cotransport mechanism. Approximately 5% of filtered sodium chloride is reabsorbed in this section of the tubule. Unlike the thick ascending loop of Henle, neither Ca++ nor Mg++ is passively absorbed in this segment of the tubule. Instead, Ca++ ions are actively reabsorbed in a process that is largely regulated by parathyroid hormone and possibly by vitamin D. The thiazide diuretics exert their action by inhibiting sodium chloride reabsorption in this segment of the renal tubules.

The late distal tubule and the cortical collecting tubule constitute the site where aldosterone exerts its action on sodium reabsorption and potassium secretion and elimination. Although responsible for only 2% to 5% of sodium chloride reabsorption, this site is largely responsible for determining the final sodium concentration of the urine. The late distal tubule with the cortical collecting tubule is also the major site for regulation of potassium excretion by the kidney. When the body is confronted with a potassium excess, as occurs with a diet high in potassium content, the amount of potassium secreted at this site may exceed the amount filtered in the glomerulus.

The mechanism for sodium reabsorption and potassium secretion in this section of the nephron is distinct from other tubular segments. This tubular segment is composed of two types of cells, the *intercalated cells*, where potassium is reabsorbed and hydrogen is secreted, and the *principal cells*, where aldosterone exerts its action. The secretion of H+ ions into the tubular fluid by the intercalated cells is accompanied by the reabsorption of HCO3⁻ ions. The intercalated cells can also reabsorb K+ ions. The principal cells reabsorb Na+ and facilitate the movement of K+ into the urine filtrate (Fig. 38.10). Under the influence of aldosterone, sodium moves from the urine filtrate into principal cells; from there, it moves into the surrounding interstitial fluid and peritubular capillaries. Potassium moves from the peritubular capillaries into the principal cells and then into the urine filtrate.

**Regulation of Urine Concentration**

The kidney responds to changes in the osmolality of the extracellular fluids by producing either concentrated or dilute urine. The ability of the kidney to respond in this manner depends on the establishment of a high concentration of osmotically active particles (approximately 1200 mOsml/kg of H2O) in the interstitium of the kidney medulla and the action of the ADH in regulating the water permeability of the surrounding medullary collecting tubules (see Understanding: How the Kidney Concentrates Urine).

![Figure 38.10](image-url)  
*Mechanism of sodium reabsorption and potassium secretion by principal cells of the late distal and collecting tubules. Aldosterone exerts its action by increasing the activity of the Na+/K+−ATPase pump that transports sodium outward through the basolateral membrane of the cell and into the blood at the same time it pumps potassium into the cell. Aldosterone also increases the permeability of the luminal membrane for potassium.*

In approximately one fifth of the juxtamedullary nephrons, the loops of Henle and special hairpin-shaped capillaries called the *vasa recta* descend into the medullary portion of the kidney. There they form a countercurrent system that controls water and solute movement so that water is kept out of the area surrounding the tubule and solutes are retained. The term *countercurrent* refers to a flow of fluids in opposite directions in adjacent structures. In this case, there is an exchange of solutes between the adjacent descending and ascending loops of Henle and between the ascending and descending sections of the vasa recta. Because of these exchange processes, a high concentration of osmotically active particles (approximately 1200 mOsm/kg of H2O) collects in the interstitium of the kidney medulla. The presence of these osmotically active particles in the interstitium surrounding the medullary collecting tubules facilitates the ADH-mediated reabsorption of water (Fig. 38.11).

ADH assists in maintenance of the extracellular fluid volume by controlling the permeability of the medullary collecting tubules. Osmoreceptors in the hypothalamus sense an increase in osmolality of extracellular fluids and stimulate the release of ADH from the posterior pituitary gland. In exerting its effect, ADH, also known as vasopressin, binds to receptors on the basolateral side of the tubular cells. Binding of ADH to the vasopressin receptors causes water channels, known as aquaporin-2 channels, to move into the luminal side of the tubular cell membrane, producing a marked increase in water permeability. At the basolateral side of the membrane, water...
The osmolarity of body fluids relies heavily on the ability of the kidney to produce dilute or concentrated urine. Urine concentration depends on three factors: (1) the osmolarity of interstitial fluids in the urine-concentrating part of the kidney, (2) the antidiuretic hormone (ADH), and (3) the action of ADH on the cells in the collecting tubules of the kidney.

**Understanding How the Kidney Concentrates Urine**

In approximately one fifth of the juxtamedullary nephrons, the loops of Henle and special hairpin-shaped capillaries called the vasa recta descend into the medullary portion of the kidney to form a countercurrent system—a set of parallel passages in which the contents flow in opposite directions. The countercurrent design serves to increase the osmolarity in this part of the kidney by promoting the exchange of solutes between the adjacent descending and ascending loops of Henle and between the descending and ascending sections of the vasa recta. Because of these exchange processes, a high concentration of osmotically active particles (approximately 1200 mOsm/kg of H₂O) collects in the interstitium surrounding the collecting tubules where the ADH-mediated reabsorption of water takes place.

ADH, which regulates the ability of the kidneys to concentrate urine, is synthesized by neurons in the hypothalamus and transported down their axons to the posterior pituitary gland and then released into the circulation. One of the main stimuli for synthesis and release of ADH is an increase in serum osmolarity. ADH release is also controlled by cardiovascular reflexes that respond to changes in blood pressure or blood volume.

**Antidiuretic Hormone**

Continued
**Understanding How the Kidney Concentrates Urine (Continued)**

### Action of ADH

ADH, also known as vasopressin, acts at the level of the collecting tubule to increase water absorption. It exerts its action by binding to vasopressin receptors on the basolateral membrane of the tubular cell. Binding of ADH to the vasopressin receptors causes water channels (aquaporin-2 channels) to move into the luminal side of the cell membrane, which is normally impermeable to water. Insertion of the channels allows water from the tubular fluids to move into the tubular cell and then out into the surrounding hyperosmotic interstitial fluid on the basolateral side of the cell, and from there it moves into the peritubular capillaries for return to the circulatory system. Thus, when ADH is present, the water that moved from the blood into the urine filtrate in the glomeruli is returned to the circulatory system, and when ADH is absent, the water is excreted in the urine.

Several humoral substances, including angiotensin II, ADH, and the endothelins, produce vasoconstriction of renal vessels. The endothelins are a group of peptides released from damaged endothelial cells in the kidney and other tissues. Although not thought to be an important regulator of renal blood flow during everyday activities, endothelin 1 (ET-1) may play a role in reduction of blood flow in conditions such as post-ischemic acute renal failure. In this situation, ET-1 can be a most potent vasoconstrictor and worsen the acute renal failure.

### Regulation of Renal Blood Flow

In the adult, the kidneys are perfused with 1000 to 1300 mL of blood per minute, or 20% to 25% of the cardiac output. This large blood flow is mainly needed to ensure a sufficient GFR for the removal of waste products from the blood, rather than for the metabolic needs of the kidney. Feedback mechanisms, both intrinsic (e.g., autoregulation, local hormones) and extrinsic (e.g., sympathetic nervous system, blood-borne hormones), normally keep blood flow and GFR constant despite changes in arterial blood pressure.

### Neural and Humoral Control Mechanisms

The kidney is richly innervated by the sympathetic nervous system. Increased sympathetic activity causes constriction of the afferent and efferent arterioles and thus a decrease in renal blood flow. Intense sympathetic stimulation such as occurs in shock and trauma can produce marked decreases in renal blood flow and GFR, even to the extent of causing blood flow to cease altogether.
Autoregulatory Mechanisms

A process called autoregulation maintains the constancy of renal blood flow. Normally, autoregulation of blood flow is designed to maintain blood flow at a level consistent with the metabolic needs of the tissues. In the kidney, autoregulation of blood flow also must allow for precise regulation of solute and water excretion. For autoregulation to occur, the resistance to blood flow through the kidneys must be varied in direct proportion to the arterial pressure. The exact mechanisms responsible for the intrarenal regulation of blood flow are unclear. One of the proposed mechanisms is a direct effect on vascular smooth muscle that causes the blood vessels to relax when there is an increase in blood pressure and to constrict when there is a decrease in pressure. A second proposed mechanism is the juxtaglomerular complex.

The Juxtaglomerular Complex. The juxtaglomerular complex is thought to represent a feedback control system that links changes in the GFR with renal blood flow. The juxtaglomerular complex is located at the site where the distal tubule extends back to the glomerulus and then passes between the afferent and efferent arterioles (Fig. 38.12A). The distal tubular site that is nearest to the glomerulus is characterized by densely nucleated cells called the macula densa. In the adjacent afferent arteriole, the smooth muscle cells of the media are modified as special secretory cells called juxtaglomerular cells. These cells contain granules of inactive renin, an enzyme that functions in the conversion of angiotensinogen to angiotensin. Renin functions by means of angiotensin II to produce vasoconstriction of the efferent arteriole as a means of preventing large decreases in the GFR. Angiotensin II also increases sodium reabsorption indirectly by stimulating aldosterone secretion from the adrenal gland and directly by increasing sodium reabsorption by the proximal tubule cells.

Because of its location between the afferent and efferent arterioles, the juxtaglomerular complex is thought to play an essential feedback role in linking the level of arterial blood pressure and renal blood flow to the GFR and the composition of the distal tubular fluid (see Fig. 38.12B). It is thought to monitor the systemic arterial blood pressure by sensing the stretch of the afferent arteriole and the concentration of sodium chloride in the tubular filtrate as it passes through the macula densa. This information is then used in determining how much renin should be released to keep the arterial blood pressure within its normal range and maintain a relatively constant GFR. It is thought that a decrease in the GFR slows the flow rate of the urine filtrate in the ascending loop of Henle, thereby increasing sodium and chloride reabsorption. This, in turn, decreases the delivery of sodium chloride to the macula densa. The decrease in delivery of sodium chloride to the macula densa has two effects: It decreases resistance in the afferent arterioles, which raises glomerular filtration pressure, and it increases the release of renin from the juxtaglomerular cells. The renin from these cells functions as an enzyme to convert angiotensinogen to angiotensin I, which is converted to angiotensin II. Finally, angiotensin II acts to constrict the arterioles, thus maintaining a relatively constant GFR.
efferent arteriole as a means of producing a further increase in the glomerular filtration pressure and thereby returning the GFR toward a more normal range.

**Effect of Increased Protein and Glucose Load**

Even though renal blood flow and glomerular filtration are relatively stable under most conditions, two conditions can increase renal blood flow and glomerular filtration. These are an increased amount of protein in the diet and an increase in blood glucose. With ingestion of a high-protein diet, renal blood flow increases 20% to 30% within 1 to 2 hours. Although the exact mechanism for this increase is uncertain, it is thought to be related to the fact that amino acids and sodium are absorbed together in the proximal tubule (secondary active transport). As a result, delivery of sodium to the macula densa is decreased, which elicits an increase in renal blood flow through the juxtaglomerular complex feedback mechanism. The resultant increase in blood flow and GFR allows sodium excretion to be maintained at a near-normal level while increasing the excretion of the waste products of protein metabolism, such as urea. The same mechanism is thought to explain the large increases in renal blood flow and GFR that occur with high blood glucose levels in people with uncontrolled diabetes mellitus.

**Elimination Functions of the Kidney**

The functions of the kidney focus on elimination of water, waste products, excess electrolytes, and unwanted substances from the blood.

**Renal Clearance**

Renal clearance is the volume of plasma that is completely cleared each minute of any substance that finds its way into the urine. It is determined by the ability of the substance to be filtered in the glomeruli and the capacity of the renal tubules to reabsorb or secrete the substance. Every substance has its own clearance rate, the units of which are always volume of plasma per unit time. It can be determined by measuring the amount of a substance that is excreted in the urine (i.e., urine concentration x urine flow rate in milliliters per minute) and dividing by its plasma concentration. Inulin, a large polysaccharide, is freely filtered in the glomeruli and neither reabsorbed nor secreted by the tubular cells. After intravenous injection, the amount that appears in the urine is equal to the
amount that is filtered in the glomeruli (i.e., the clearance rate is equal to the GFR). Because of these properties, insulin can be used as a laboratory measure of the GFR. Some substances, such as urea, are freely filtered in the glomeruli, but the volume that is cleared from the plasma is less than the GFR, indicating that at least some of the substance is being reabsorbed. At normal plasma levels, glucose has a clearance of zero because it is reabsorbed in the tubules and none appears in the urine.

**Regulation of Sodium and Potassium Elimination**

Elimination of sodium and potassium is regulated by the GFR and by humoral agents that control their reabsorption. Aldosterone functions in the regulation of sodium and potassium elimination. Atrial natriuretic peptide (ANP) contributes to the regulation of sodium elimination. Sodium reabsorption in the distal tubule and collecting duct is highly variable and depends on the presence of aldosterone, a hormone secreted by the adrenal gland. In the presence of aldosterone, almost all the sodium in the distal tubular fluid is reabsorbed, and the urine essentially becomes sodium free. In the absence of aldosterone, virtually no sodium is reabsorbed from the distal tubule. The remarkable ability of the distal tubular and collecting duct cells to alter sodium reabsorption in relation to changes in aldosterone allows the kidneys to excrete urine with sodium levels that range from a few tenths of a gram to 40 g/day.

Like sodium, potassium is freely filtered in the glomerulus, but unlike sodium, potassium is reabsorbed from and secreted into the tubular fluid. The secretion of potassium into the tubular fluid occurs in the distal tubule and, like that of sodium, is regulated by aldosterone. Only approximately 70 mEq of potassium is delivered to the distal tubule each day, but the average person consumes this much and more potassium in the diet. Excess potassium that is not filtered in the glomerulus and delivered to the collecting tubule therefore must be secreted (i.e., transported from the blood) into the tubular fluid for elimination from the body. In the absence of aldosterone, as in Addison disease, potassium secretion becomes minimal. In these circumstances, potassium reabsorption exceeds secretion, and blood levels of potassium increase.

ANP, discovered in 1981, is a hormone believed to have an important role in salt and water excretion by the kidney. It is synthesized in muscle cells of the atria of the heart and released when the atria are stretched. The actions of ANP include vasodilation of the afferent and efferent arterioles, which results in an increase in renal blood flow and GFR. ANP inhibits aldosterone secretion by the adrenal gland and sodium reabsorption from the collecting tubules through its action on aldosterone and through direct action on the tubular cells. ANP also inhibits ADH release from the posterior pituitary gland, thereby increasing excretion of water by the kidneys. ANP also has vasodilator properties. Whether these effects are sufficient to produce long-term changes in blood pressure is uncertain.

**Regulation of pH**

The kidneys regulate body pH by conserving base bicarbonate and eliminating hydrogen ions (H+). Neither the blood buffer systems nor the respiratory control mechanisms for carbon dioxide elimination can eliminate hydrogen ions from the body. The kidneys accomplish this. Virtually all the hydrogen ions excreted in the urine are secreted into the tubular fluid by means of tubular secretory mechanisms. The lowest tubular fluid pH that can be achieved is 4.4 to 4.5. The ability of the kidneys to excrete hydrogen ions depends on buffers in the urine that combine with the hydrogen ion. The three major urine buffers are bicarbonate (HCO3−), phosphate (HPO42−), and ammonia (NH3). Bicarbonate ions, which are present in the urine filtrate, combine with hydrogen ions that have been secreted into the tubular fluid; this results in the formation of carbon dioxide and water. The carbon dioxide is then absorbed into the tubular cells and bicarbonate is regenerated. The phosphate ion is a metabolic end product that is filtered into the tubular fluid. It combines with a secreted hydrogen ion and is not reabsorbed. Ammonia is synthesized in tubular cells by deamination of the amino acid glutamine. It diffuses into the tubular fluid and combines with the hydrogen ion. An important aspect of this buffer system is that the deamination process increases whenever the body’s hydrogen ion concentration remains elevated for 1 to 2 days.

**KEY POINTS**

THE FUNCTIONS OF THE KIDNEY

- The kidney regulates the composition and pH of body fluids through the reabsorption and elimination or conservation of sodium, potassium, hydrogen, chloride, and bicarbonate ions.
- It serves to regulate the osmolality of the extracellular fluid through the action of ADH.
- It plays a central role in blood pressure regulation through the renin–angiotensin–aldosterone mechanism and the regulation of salt and water elimination.

**pH-Dependent Elimination of Organic Ions**

The proximal tubule actively secretes large amounts of different organic anions. Foreign anions (e.g., salicylates, penicillin) and endogenously produced anions (e.g., bile acids, uric acid) are actively secreted into the tubular fluid. Most of the anions that are secreted use the same transport system, allowing the kidneys to rid the body of many different drugs and environmental agents. Because the same transport system is shared by different anions, there is competition for transport such that elevated levels of one substance tend to
inhibit the secretion of other anions. The proximal tubules also possess an active transport system for organic cations that is analogous to that for organic ions.

**Uric Acid Elimination**

Uric acid is a product of purine metabolism. Excessively high blood levels (i.e., hyperuricemia) can cause gout, and excessive urine levels can cause kidney stones. Uric acid is freely filtered in the glomerulus and is reabsorbed and secreted into the proximal tubules. Uric acid is one of the anions that use the previously described anion transport system in the proximal tubule. Tubular reabsorption normally exceeds secretion, and the net effect is removal of uric acid from the filtrate. Although the rate of reabsorption exceeds secretion, the secretory process is homeostatically controlled to maintain a constant plasma level. Many people with elevated uric acid levels secrete less uric acid compared to people with normal uric acid levels.

Uric acid uses the same transport systems as other anions, such as aspirin, sulfipyrazone, and probenecid. Small doses of aspirin compete with uric acid for secretion into the tubular fluid and reduce uric acid secretion, and large doses compete with uric acid for reabsorption and increase uric acid excretion in the urine. Because of its effect on uric acid secretion, aspirin is not recommended for treatment of gouty arthritis. Thiazide and loop diuretics (i.e., furosemide and ethacrynic acid) also can cause hyperuricemia and gouty arthritis, presumably through a decrease in extracellular fluid volume and enhanced uric acid reabsorption.

**Urea Elimination**

Urea is an end product of protein metabolism. The normal adult produces 25 to 30 g/day. The quantity rises when a high-protein diet is consumed, when there is excessive tissue breakdown, or in the presence of gastrointestinal bleeding. With gastrointestinal bleeding, the blood proteins are broken down to form ammonia in the intestine. The ammonia is then absorbed into the portal circulation and converted to urea by the liver before being released into the bloodstream. The kidneys, in their role as regulators of blood urea nitrogen (BUN) levels, filter urea in the glomeruli and then reabsorb it in the tubules. This enables maintenance of a normal BUN, which is in the range of 8 to 25 mg/dL (2.9 to 8.9 mmol/L). During periods of dehydration, the blood volume and GFR drop, and BUN levels increase. The renal tubules are permeable to urea, which means that the longer the tubular fluid remains in the kidneys, the greater is the reabsorption of urea into the blood. Only small amounts of urea are reabsorbed into the blood when the GFR is high, but relatively large amounts of urea are returned to the blood when the GFR is reduced.

**Drug Elimination**

Many drugs are eliminated in the urine. These drugs are selectively filtered in the glomerulus and reabsorbed or secreted into the tubular fluid. Only drugs that are not bound to plasma proteins are filtered in the glomerulus and therefore able to be eliminated by the kidneys. Many drugs are weak acids or weak bases and are present in the renal tubular fluid partly as water-soluble ions and partly as nonionized lipid-soluble molecules.

**Endocrine Functions of the Kidney**

In addition to their function in regulating body fluids and electrolytes, the kidneys function as an endocrine organ in that they produce chemical mediators that travel through the blood to distant sites where they exert their actions. The kidneys participate in control of blood pressure in the following ways:

- Via the renin–angiotensin–aldosterone mechanism
- Via regulation of red blood cell production through the synthesis of erythropoietin
- Via calcium metabolism by activating vitamin D

**The Renin–Angiotensin–Aldosterone Mechanism**

The renin–angiotensin–aldosterone mechanism plays an important part in short- and long-term regulation of blood pressure. Renin is an enzyme that is synthesized and stored in the juxtaglomerular cells of the kidney. This enzyme is thought to be released in response to a decrease in renal blood flow or a change in the composition of the distal tubular fluid, or as the result of sympathetic nervous system stimulation. Renin itself has no direct effect on blood pressure. Rather, it acts enzymatically to convert a circulating plasma protein called angiotensinogen to angiotensin I. Angiotensin I, which has few vasoconstrictor properties, leaves the kidneys and enters the circulation; as it is circulated through the lungs, angiotensin-converting enzyme catalyzes the conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor, and it acts directly on the kidneys to decrease salt and water excretion. Both mechanisms have relatively short periods of action. Angiotensin II also stimulates aldosterone secretion by the adrenal gland. Aldosterone acts on the distal tubule to increase sodium reabsorption and exerts a longer-term effect on the maintenance of blood pressure. Renin also functions via angiotensin II to produce constriction of the efferent arteriole as a means of preventing a serious decrease in glomerular filtration pressure.

**Erythropoietin**

Erythropoietin is a polypeptide hormone that regulates the differentiation of red blood cells in the bone marrow. Between 89% and 95% of erythropoietin is formed in the kidneys. The synthesis of erythropoietin is stimulated by tissue hypoxia, which may be brought about by anemia, residence at high altitudes, or impaired oxygenation of tissues due to cardiac or pulmonary disease. Persons with end-stage kidney disease often are anemic because of an inability of the kidneys...
to produce erythropoietin. This anemia usually is managed by the administration of a recombinant erythropoietin (epoetin alfa) produced through DNA technology to stimulate erythropoiesis.9

**Vitamin D**

Activation of vitamin D occurs in the kidneys. Vitamin D increases calcium absorption from the gastrointestinal tract and helps to regulate calcium deposition in bone. It also has a weak stimulatory effect on renal calcium absorption. Although vitamin D is not synthesized and released from an endocrine gland, it often is considered as a hormone because of its pathway of molecular activation and mechanism of action.

Vitamin D exists in two forms—natural vitamin D (cholecalciferol), produced in the skin from ultraviolet irradiation, and synthetic vitamin D (ergocalciferol), derived from irradiation of ergosterol. The active form of vitamin D is 1,25-dihydroxycholecalciferol. Cholecalciferol and ergocalciferol must undergo chemical transformation to become active: first to 25-hydroxycholecalciferol in the liver and then to 1,25-dihydroxycholecalciferol in the kidneys. People with end-stage renal disease are unable to transform vitamin D to its active form and may require pharmacologic preparations of the active vitamin (calcitriol) for maintaining mineralization of their bones.4 New research is in process to develop vitamin D compounds to assist people with chronic renal disease.10

**Action of Diuretics**

Diuretics are drugs that increase urine volume. Many diuretic agents (loop diuretics, thiazide diuretic, and potassium-sparing diuretics) exert their effects by blocking the reabsorption of sodium in the renal tubules. Others exert osmotic effects that prevent water reabsorption in the water-permeable parts of the nephron.8

**Diuretics That Block Sodium Reabsorption**

Most diuretics share the same mechanism of action—blockade of sodium and chloride reabsorption. By blocking the reabsorption of these solutes, diuretics create an osmotic pressure gradient within the nephron that prevents the passive reabsorption of water. Thus, diuretics cause water and sodium to be retained in the nephron, thereby promoting the excretion of both. The increase in urine flow that a diuretic produces is related to the amount of sodium and chloride reabsorption that it blocks. Because the amount of sodium becomes progressively less as the urine filtrate flows from the proximal tubule to the collecting ducts, drugs that act early in the nephron have the opportunity to block the greatest amount of sodium reabsorption. Approximately 65% of sodium that is filtered in the glomeruli of the kidney is reabsorbed in the proximal tubule, 20% is reabsorbed in the thick ascending loop of Henle, 10% in the early distal convoluted tubule, and 2% to 5% is reabsorbed in the late distal and cortical collecting tubules (Fig. 38.13).4

**FIGURE 38.13** • Tubular sites of diuretic action and percentage of sodium reabsorption.
The so-called loop diuretics exert their effect in the thick ascending loop of Henle. Because of their site of action, these drugs are the most effective diuretic agents available. These drugs inhibit the coupled Na+/K+/2Cl− transport system on the luminal side of the ascending loop of Henle (see Fig. 38.10). By inhibiting this transport system, they reduce the reabsorption of sodium chloride, decrease potassium reabsorption, and increase calcium and magnesium elimination. Prolonged use can cause significant loss of magnesium in some people. Because calcium is actively reabsorbed in the distal convoluted tubule, loop diuretics usually do not cause hypocalcemia. The loop diuretics may also increase uric acid retention and impair glucose tolerance.

The thiazide diuretics act by preventing the reabsorption of sodium chloride in the early distal convoluted tubule. Because of their site of action, the thiazide diuretics are less effective than loop diuretics in terms of effecting diuresis. The thiazide diuretics produce increased losses of potassium in the urine, uric acid retention, and some impairment in glucose tolerance. In contrast to the situation in the loop of Henle, where the loop diuretics inhibit calcium reabsorption, the thiazide diuretics actually enhance calcium reabsorption in the distal convoluted tubule.

The aldosterone antagonists, also called potassium-sparing diuretics, reduce sodium reabsorption and decrease potassium secretion in the late distal tubule and cortical collecting tubule site regulated by aldosterone (see Fig. 38.11). Because potassium secretion is linked to sodium reabsorption in this segment of the tubule, these agents are also effective in reducing potassium excretion and may, in some cases, cause severe hyperkalemia. These agents also tend to interfere with secretion of hydrogen ions in the collecting duct, explaining in part the metabolic acidosis sometimes seen with the use of these agents.

There are two types of potassium-sparing diuretics—those that act as direct aldosterone antagonists and those that act independently of aldosterone. The first type (e.g., spironolactone) binds to the mineralocorticoid receptor in the tubule, preventing aldosterone from entering the cell and exerting its effects. The second type (e.g., triamterene, amiloride) does not bind to the receptor, but instead directly interferes with sodium entry through the sodium-selective ion channel. The potassium-sparing diuretics produce only mild diuresis because they inhibit such a small percentage of sodium reabsorption. However, as the name implies, their main use is in combination with other diuretics to inhibit K+ secretion by the principal cells. These diuretics may also be used during states of mineralocorticoid (i.e., aldosterone) excess.

**Osmotic Diuretics**

The osmotic diuretics act in the proximal tubule and ascending loop of Henle, both of which are highly permeable to water. In contrast to the loop, thiazide, and potassium-sparing diuretics that exert their effects by blocking specific tubular Na+ transport mechanisms, the osmotic diuretics, which are filtered but not reabsorbed, cause water to be retained in the urine filtrate and promote water diuresis. One such agent, mannitol, is used mainly to reduce increased intracranial pressure but is occasionally used to promote prompt removal of toxins. Because it is not absorbed, mannitol must be given parenterally to act as a diuretic. If given orally, it causes osmotic diarrhea.

**IN SUMMARY**

The kidneys perform excretory and endocrine functions. In the process of excreting wastes, the kidneys filter the blood and then selectively reabsorb those materials that are needed to maintain a stable internal environment. The kidneys rid the body of metabolic wastes, regulate fluid volume, regulate the concentration of electrolytes, assist in maintaining acid–base balance, aid in regulation of blood pressure through the renin–angiotensin–aldosterone mechanism and control of extracellular fluid volume, regulate red blood cell production through erythropoietin, and aid in calcium metabolism by activating vitamin D.

The nephron is the functional unit of the kidney. It is composed of a glomerulus, which filters the blood, and a tubular component, where electrolytes and other substances needed to maintain the constancy of the internal environment are reabsorbed back into the bloodstream, while unneeded materials are secreted into the tubular filtrate for elimination. Urine concentration occurs in the collecting tubules under the influence of ADH. ADH maintains extracellular volume by returning water to the vascular compartment, producing concentrated urine by removing water from the tubular filtrate.

The GFR is the amount of filtrate that is formed each minute as blood moves through the glomeruli. It is regulated by the arterial blood pressure and renal blood flow in the normally functioning kidney. The juxtaglomerular complex is thought to represent a feedback control system that links changes in the GFR with renal blood flow. Renal clearance is the volume of plasma that is completely cleared each minute of any substance that finds its way into the urine. It is determined by the ability of the substance to be filtered in the glomeruli and the capacity of the renal tubules to reabsorb or secrete the substance.

Diuretics are drugs that increase urine volume. Many diuretic agents (loop diuretics, thiazide diuretics, and potassium-sparing diuretics) exert their effect by blocking the reabsorption of sodium at specific sites in the renal tubules. Others exert osmotic effects that prevent water reabsorption in the water-permeable parts of the nephron. The effectiveness of a diuretic is related to its site of action. Accordingly, diuretics such as the loop diuretics that act in the thick ascending loop of Henle, where approximately 20% of sodium reabsorption takes place, produce the greatest diuresis.
Chapter 38  Structure and Function of the Kidney  1015

TESTS OF RENAL FUNCTION

After completing this section of the chapter, you should be able to meet the following objectives:

• Explain the value of urine-specific gravity in evaluating renal function.
• Explain the concept of the glomerular filtration rate.
• Explain the value of serum creatinine and blood urea nitrogen levels in evaluating renal function.

The function of the kidneys is to filter the blood, selectively reabsorb those substances that are needed to maintain the constancy of body fluid, and excrete metabolic wastes. The composition of urine and blood provides valuable information about the adequacy of renal function. Radiologic tests, endoscopy, and renal biopsy afford means for viewing the gross and microscopic structures of the kidneys and urinary system.

Urine Tests

Urine is a clear, amber-colored fluid that is approximately 95% water and 5% dissolved solids. The kidneys normally produce approximately 1.5 L of urine each day. Normal urine contains metabolic wastes and few or no plasma proteins, blood cells, or glucose molecules. Urine tests can be performed on a single urine specimen or on a 24-hour urine specimen. First-voided morning specimens are useful for qualitative protein and specific gravity testing. A freshly voided specimen is most reliable. Urine specimens that have been left standing may contain lysed red blood cells, disintegrating casts, and rapidly multiplying bacteria.6 Table 38.1 describes urinalysis values for normal urine.

Casts are molds of the distal nephron lumen. A gel-like substance called Tamm-Horsfall mucoprotein, which is formed in the tubular epithelium, is the major protein constituent of urinal casts.4 Casts composed of this gel but devoid of cells are called hyaline casts. These casts develop when the protein concentration of the urine is high (as in nephrotic syndrome), urine osmolality is high, and urine pH is low. The inclusion of granules or cells in the matrix of the protein gel leads to the formation of various other types of casts.4

Proteinuria represents excessive protein excretion in the urine. Because of the glomerular capillary filtration barrier, less than 150 mg/L of protein is excreted in the urine over 24 hours in a healthy person. Urine tests for proteinuria are used to detect abnormal filtering of albumin in the glomeruli or defects in its reabsorption in the renal tubules. A protein reagent dipstick can be used as a rapid screening test for the presence of proteins in the urine. Once the presence of proteinuria has been detected, a 24-hour urine test is often used to quantify the amount of protein that is present.6

Albumin, which is the smallest of the plasma proteins, is filtered more readily than globulins or other plasma proteins. Thus, microalbuminuria tends to occur long before clinical proteinuria becomes evident. A dipstick test for microalbuminuria is available for screening purposes. The microalbuminuria dipstick method, however, only indicates an increase in urinary albumin that is below the detectable range of the standard proteinuria test. It does not specify the amount of albumin that is present in the urine. Therefore, a 24-hour urine collection is the standard method for detecting microalbuminuria (an albumin excretion >30 mg/day is abnormal).6

The specific gravity of urine varies with its concentration of solutes. Urine-specific gravity provides a valuable index of the hydration status and functional ability of the kidneys. Healthy kidneys can produce concentrated urine with a specific gravity of 1.030 to 1.040. During periods of marked hydration, the specific gravity can approach 1.000. With diminished renal function, there is a loss of renal concentrating ability,

and the urine specific gravity may fall to levels of 1.006 to 1.010 (usual range is 1.010 to 1.025 with normal fluid intake).\textsuperscript{6} 

Urine osmolality, which depends on the number of particles of solute in a unit of solution, is a more exact measurement of urine concentration than specific gravity.\textsuperscript{5} More information concerning renal function can be obtained if the serum and urine osmolality tests are done at the same time. The normal ratio between urine and serum osmolality is 3:1. A high urineto-serum ratio is seen in concentrated urine. With poor concentrating ability, the ratio is low.

**Glomerular Filtration Rate**

The GFR provides a gauge of renal function. It can be measured clinically by collecting timed samples of blood and urine. Creatinine, a product of creatine metabolism by the muscle, is filtered by the kidneys but not reabsorbed in the renal tubule. Creatinine levels in the blood and urine can be used to measure GFR. The clearance rate for creatinine is the amount that is completely cleared by the kidneys in 1 minute. The formula is expressed as \( C = \frac{UV}{P} \), in which \( C \) is the clearance rate (mL/minute), \( U \) is the urine concentration (mg/dL), \( V \) is the urine volume excreted (mL/minute or 24 hours), and \( P \) is plasma concentration (mg/dL).\textsuperscript{6}

Normal creatinine clearance is 115 to 125 mL/minute.\textsuperscript{6} This value is corrected for body surface area, which reflects the muscle mass where creatinine metabolism takes place. The test may be done on a 24-hour basis, with blood being drawn when the urine collection is completed. In another method, two 1-hour urine specimens are collected, and a blood sample is drawn in between.

**Blood Tests**

Blood tests can provide valuable information about the kidneys’ ability to remove metabolic wastes from the blood and maintain normal electrolyte and pH composition of the blood. Normal blood values are listed in Table 38.2. Serum levels of potassium, phosphate, BUN, and creatinine increase in renal failure.\textsuperscript{7} Serum pH, calcium, and bicarbonate levels decrease in renal failure.

**Serum Creatinine**

Serum creatinine levels reflect the GFR. Because these measurements are easily obtained and relatively inexpensive, they often are used as a screening measure of renal function. Creatinine is a product of creatine metabolism in muscles; its formation and release are relatively constant and proportional to the amount of muscle mass present. Creatinine is freely filtered in the glomeruli, is not reabsorbed from the tubules into the blood, and is only minimally secreted into the tubules from the blood. Therefore, its blood values depend closely on the GFR.

The normal creatinine value is approximately 0.7 mg/dL of blood for a woman with a small frame, approximately 1.0 mg/dL of blood for a normal adult man, and approximately 1.5 mg/dL of blood (60 to 130 mmol/L) for a muscular man.\textsuperscript{6} There is an age-related decline in creatinine clearance in many older adults because muscle mass and the GFR decline with age. A normal serum creatinine level usually indicates normal renal function. In addition to its use in calculating the GFR, the serum creatinine level is used in estimating the functional capacity of the kidneys (Fig. 38.14). If the value doubles, the GFR (and renal function) probably has fallen to one half of its normal state. A rise in the serum creatinine level to three times its normal value suggests that there is a 75% loss of renal function, and with creatinine values of 10 mg/dL or more, it can be assumed that approximately 90% of renal function has been lost.\textsuperscript{5}

Recently it has been proposed that another serum protein, cystatin-C (a cysteine protease inhibitor), could be useful as a marker of GFR because it has a stable production rate, is freely filtered at the glomerulus, and in several studies has shown a greater sensitivity in detecting a decreased GFR, which could assist in determining a quicker management plan. For example, one study used serum creatinine,
urine albumin to creatinine ratios (ACR), and cystatin-C levels and found the ACR and cystatin-C parameters to be better predictors for diagnosing end-stage renal disease. Another study found that cystatin-C levels are a better predictor of GFR in people postrenal transplant compared to other parameters. Further clinical studies are needed to determine the clinical efficacy of cystatin-C as a marker and to determine whether there is an advantage to its use compared with creatinine.

**Blood Urea Nitrogen**

Urea is formed in the liver as a by-product of protein metabolism and is eliminated entirely by the kidneys. BUN therefore is related to the GFR but, unlike creatinine, also is influenced by protein intake, gastrointestinal bleeding, and hydration status. In gastrointestinal bleeding, the intestinal flora breaks down the blood, and the nitrogenous waste is absorbed into the portal vein and transported to the liver, where it is converted to urea. During dehydration, elevated BUN levels result from increased concentration. Approximately two thirds of renal function must be lost before a significant rise in the BUN level occurs.

The BUN is less specific for renal insufficiency than creatinine, but the **BUN–creatinine ratio** may provide useful diagnostic information. The ratio normally is approximately 10:1. Ratios greater than 15:1 represent prerenal conditions, such as congestive heart failure and upper gastrointestinal tract bleeding, that produce an increase in BUN, but not in creatinine. A ratio of less than 10:1 occurs in people with liver disease and in those who receive a low-protein diet or chronic dialysis, because BUN is more readily dialyzable than creatinine.

**Cystoscopy**

Cystoscopy provides a means for direct visualization of the urethra, bladder, and ureteral orifices. It relies on the use of a cystoscope, an instrument with a lighted lens. The cystoscope is inserted through the urethra into the bladder. Biopsy specimens, lesions, small stones, and foreign bodies can be removed from the bladder. Urethroscopy may be used to remove stones from the ureter and aid in the treatment of ureteral disorders such as ureteral strictures.

**Ultrasonography**

Ultrasonographic studies use the reflection of ultrasonic waves to visualize the deep structures of the body. The procedure is painless, noninvasive, and requires no patient preparation. Ultrasonography is used to visualize the structures of the kidneys and has proved useful in the diagnosis of many urinary tract disorders, including congenital anomalies, renal abscesses, hydronephrosis, and kidney stones. It can differentiate a renal cyst from a renal tumor. The use of ultrasonography also enables accurate placement of needles for renal biopsy and catheters for percutaneous nephrostomy.

**Radiologic and Other Imaging Studies**

Radiologic studies include a simple flat plate of the kidneys, ureters, and bladder that can be used to determine the size, shape, and position of the kidneys and observe any radiopaque stones that may be in the kidney pelvis or ureters. In excretory urography, or **intravenous pyelography**, a radiopaque dye is injected into a peripheral vein. The dye is then filtered by the glomerulus and excreted into the urine, and x-ray films are taken as the dye moves through the kidneys and ureters.

Urography is used to detect space-occupying lesions of the kidneys, pyelonephritis, hydronephrosis, vesicoureteral reflux, and kidney stones. Some people are allergic to the dye used for urography and may have an anaphylactic reaction after its administration. Every person undergoing urographic studies should be questioned about previous reactions to the dye or to similar dyes. If the test is considered essential in such people, premedication with antihistamines and corticosteroids may be used. The dye also reduces renal blood flow. Acute renal failure can occur, particularly in people with vascular disease or preexisting renal insufficiency.

Other diagnostic tests include computed tomographic (CT) scans, magnetic resonance imaging (MRI), radionuclide imaging, and renal angiography. CT scans may be used to outline the kidneys and detect renal masses and tumors. MRI is becoming readily available and is used in imaging the kidneys, retroperitoneum, and urinary bladder. It is particularly useful in evaluating vascular abnormalities in and around the kidneys. Radionuclide imaging involves the injection of a radioactive material that subsequently is detected externally by a scintillation camera, which detects the radioactive emissions. Radionuclide imaging is used to evaluate renal function and structures, as well as the ureters and bladder. It is particularly useful in evaluating the function of kidney transplants. Renal angiography provides x-ray pictures of the blood vessels that supply the kidneys. It involves the injection of a radiopaque dye directly into the renal artery. A catheter usually is introduced through the femoral artery and advanced under fluoroscopic view into the abdominal aorta. The catheter tip then is maneuvered into the renal artery, and the dye is injected. This test is used to evaluate people suspected of having renal artery stenosis, abnormalities of renal blood vessels, or vascular damage to the renal arteries after trauma.

**IN SUMMARY**

Urinalysis and blood tests that measure serum levels of pH, electrolytes, and by-products of metabolism provide valuable information about renal function. Urine specific gravity is used to assess the kidneys’ ability to concentrate urine. Dipstick and 24-hour urine tests for proteinuria and microalbuminuria are used to detect abnormal filtering of albumin in the glomeruli or defects in its reabsorption in the renal tubules. Creatinine is a product of creatine metabolism in muscles that is freely filtered in the glomeruli and...
neither reabsorbed nor secreted in the tubules; therefore, serum creatinine levels are commonly used to estimate the GFR. Urea is formed in the liver as a by-product of protein metabolism and is eliminated entirely by the kidneys. BUN is therefore related to the GFR but, unlike creatinine, also is influenced by protein intake, gastrointestinal bleeding, and hydration status.

Cystoscopic examinations can be used for direct visualization of the urethra, bladder, and ureters. Ultrasonography can be used to determine kidney size, and renal radionuclide imaging can be used to evaluate the kidney structures. Radiologic methods, such as excretory urography, provide a means by which kidney structures such as the renal calyces, pelvis, ureters, and bladder can be outlined. Other diagnostic tests include CT scans, MRI, radionuclide imaging, and renal angiography.

4. A 60-year-old woman with a diagnosis of hypertension is being treated with a thiazide diuretic.
   A. What diuretic effect would you expect the woman to have based on the percentage of sodium reaching the site where the diuretic exerted its action?
   B. What type of effects might be expected in terms of renal losses of potassium and calcium?

Fluids and electrolytes are present in body cells, in the tissue spaces between the cells, and in the blood that fills the vascular compartment. Body fluids transport gases, nutrients, and wastes; help generate the electrical activity needed to power body functions; take part in the transforming of food into energy; and otherwise maintain the overall function of the body. Although fluid volume and composition remain relatively constant in the presence of a wide range of changes in intake and output, conditions such as environmental stresses and disease can impair intake, increase losses, and interfere with mechanisms that regulate fluid volume, composition, and distribution. This chapter discusses the composition and compartmental distribution of body fluids; sodium and water balance; potassium balance; and calcium, phosphorus, and magnesium balance.
Body fluids are distributed between the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. The ICF compartment consists of fluid contained within all of the billions of cells in the body. It is the larger of the two compartments, with approximately two thirds of the body water in healthy adults. The remaining one third of body water is in the ECF compartment, which contains all the fluids outside the cells, including those in the interstitial or tissue spaces and blood vessels (Fig. 39.1).

The ECF, including blood plasma and interstitial fluids, contains large amounts of sodium and chloride and moderate amounts of bicarbonate but only small quantities of potassium, magnesium, calcium, and phosphorus. In contrast to the ECF, the ICF contains almost no calcium; small amounts of sodium, chloride, bicarbonate, and phosphorus; moderate amounts of magnesium; and large amounts of potassium (Table 39.1). It is the ECF levels of electrolytes in the blood or blood plasma that are measured clinically. Although blood levels usually are representative of the total-body levels of an electrolyte, this is not always the case, particularly with potassium, which has only about 2% in the ECF. Potassium is the most abundant intracellular electrolyte.

The cell membrane serves as the primary barrier to the movement of substances between the ECF and ICF compartments. Lipid-soluble substances (e.g., oxygen [O₂] and carbon dioxide [CO₂]), which dissolve in the lipid bilayer of the cell membrane, pass directly through the membrane, whereas many ions (e.g., sodium [Na⁺] and potassium [K⁺]) rely on transport mechanisms such as the Na⁺/K⁺ pump located in the cell membrane for movement across the membrane. Because the Na⁺/K⁺ pump relies on adenosine triphosphate (ATP) and the enzyme ATPase for energy, it is often referred to as the Na⁺/K⁺-ATPase membrane pump. Water crosses the cell membrane by osmosis using special transmembrane protein channels that are called aquaporins.

**Dissociation of Electrolytes**

Body fluids contain water and electrolytes. Electrolytes are substances that dissociate in solution to form charged particles, or ions. For example, a sodium chloride (NaCl) molecule dissociates to form a positively charged Na⁺ and a negatively charged Cl⁻ ion. Particles that do not dissociate into ions such as glucose and urea are called nonelectrolytes. Positively charged ions are called cations because they are attracted to the cathode of a wet electric cell, and negatively charged ions are called anions because they are attracted to the anode. The ions found in body fluids carry one charge (i.e., monovalent ion) or two charges (i.e., divalent ion). Because of their attraction forces, positively charged cations are always accompanied by negatively charged anions. Thus, all body fluids contain equal amounts of anions and cations. However, cations and anions may be exchanged one for another, providing they carry the same charge. For example, a positively charged H⁺ ion may be exchanged for a positively charged K⁺ ion, and a negatively charged HCO₃⁻ ion may be exchanged for a negatively charged Cl⁻ ion.

**Diffusion and Osmosis**

**Diffusion**

Diffusion is the movement of charged or uncharged particles along a concentration gradient. All molecules and ions, including...
water and dissolved molecules, are in constant random motion. It is the motion of these particles, each colliding with one another, that supplies the energy for diffusion. Because there are more molecules in constant motion in a concentrated solution, particles move from an area of higher concentration to one of lower concentration.

**Measurement Units**

The amount of electrolytes and solutes in body fluids is expressed as a concentration or amount of solute in a given volume of fluid, such as milligrams per deciliter (mg/dL), milliequivalents per liter (mEq/L), or millimoles per liter (mmol/L). The milligrams per deciliter measurement unit expresses the weight of the solute in one tenth of a liter (dL) or 100 mL of solution. The concentration of electrolytes, such as calcium, phosphate, and magnesium, is often expressed in mg/dL.

The milliequivalent is used to express the charge equivalency for a given weight of an electrolyte. Electroneutrality requires that the total number of cations in the body equals the total number of anions. When cations and anions combine, they do so according to their ionic charge, not according to their atomic weight. Thus, 1 mEq of sodium has the same number of charges as 1 mEq of chloride, regardless of molecular weight (although sodium is positive and chloride is negative). The number of milliequivalents of an electrolyte in a liter of solution can be derived from the following equation:

\[
\text{mEq} = \frac{\text{mg}}{100 \text{ mL}} \times 10 \times \text{valence} \times \frac{1}{\text{atomic weight}}
\]

The Système Internationale (SI) units express electrolyte content of body fluids in millimoles per liter (mmol/L). A millimole is one thousandth of a mole, or the molecular weight of a substance expressed in milligrams. The number of millimoles of an electrolyte in a liter of solution can be calculated using the following equation:

\[
\text{mmol/L} = \frac{\text{mEq/L} \times \text{valence}}{\text{atomic weight}}
\]

For monovalent electrolytes such as sodium and potassium, the mmol and mEq values are identical. For example, 140 mEq is equal to 140 mmol of sodium.

**Osmosis**

Osmosis is the movement of water across a semipermeable membrane (i.e., one that is permeable to water but impermeable to most solutes). As with particles, water diffuses down its concentration gradient, moving from the side of the membrane with the lesser number of particles and greater concentration of water to the side with the greater number of particles and lesser concentration of water (Fig. 39.2). As water moves across the semipermeable membrane, it generates a pressure called the osmotic pressure. The magnitude of the osmotic pressure represents the hydrostatic pressure (measured in millimeters of mercury [mm Hg]) needed to oppose the movement of water across the membrane.

The osmotic activity that nondiffusible particles exert in pulling water from one side of the semipermeable membrane to the other is measured by a unit called an osmole. The osmole is derived from the gram molecular weight of a substance (i.e., 1 g molecular weight of a nondiffusible and nonionizable substance is equal to 1 osmole). In the clinical setting, osmotic activity usually is expressed in milliosmoses (one thousandth of an osmole) per liter. Each nondiffusible particle, large or small, is equally effective in its ability to pull water through a semipermeable membrane. Thus, it is the number, rather than the size, of the nondiffusible particles that determines the osmotic activity of a solution.

The osmotic activity of a solution may be expressed in terms of either its osmolarity or osmolality. Osmolarity refers to the osmolar concentration in 1 L of solution (mOsm/L) and osmolality to the osmolar concentration in 1 kg of water (mOsm/kg of H2O). Osmolarity is usually used when referring to fluids outside the body and osmolality for describing fluids inside the body. Because 1 L of water weighs 1 kg, the terms osmolarity and osmolality are often used interchangeably.

The predominant osmotically active particles in the ECF are Na+ and its attendant anions (Cl− and HCO3−), which together account for 90% to 95% of the osmotic pressure. Blood urea nitrogen (BUN) and glucose, which also

![FIGURE 39.2 Movement of water across a semipermeable membrane. Water moves from the side that has fewer nondiffusible particles to the side that has more. The osmotic pressure is equal to the hydrostatic pressure needed to oppose water movement across the membrane.](image-url)
are osmotically active, account for less than 5% of the total osmotic pressure in the extracellular compartment.\(^2\) This can change, however, as when blood glucose levels are elevated in people with diabetes mellitus or when BUN levels change rapidly in people with chronic kidney disease. Serum osmolality, which normally ranges between 275 and 295 mOsm/kg, can be calculated using the following equation:\(^4\)

\[
\text{Osmolality (mOsm/kg)} = \frac{2\left[\text{Na}^+ (\text{mEq/L})\right]}{18} + \frac{\text{glucose (mg/dL)*}}{18} + \frac{\text{BUN (mg/dL)*}}{2.8}
\]

*1 mOsm of glucose = 180 mg/L
and 1 mOsm of urea = 28 mg/L

Ordinarily, the calculated and measured osmolality are within 10 mOsm of one another. The difference between the calculated and measured osmolality is called the osmolar gap. An osmolar gap larger than 10 mOsm suggests the presence of an unmeasured, osmotically active substance such as alcohol, acetone, or mannitol.

### Clinical Application

#### Urine Osmolality

Urine osmolality reflects the kidneys’ ability to produce a concentrated or diluted urine based on serum osmolality and the need for water conservation or excretion. The ratio of urine osmolality to serum osmolality in a 24-hour urine sample normally exceeds 1:1, and after a period of overnight water deprivation, it should be greater than 3:1. A dehydrated person (one who has a loss of water) may have a urine–serum ratio that approaches 4:1. In these persons, urine osmolality may exceed 1000 mOsm/kg H\(_2\)O. In those who have difficulty concentrating their urine, e.g., those with DI or chronic renal failure), the urine–serum ratio often is less than or equal to 1:1.

Urine specific gravity compares the weight of urine with that of water, providing an index for solute concentration. Water is considered to be 1.000. A change in specific gravity of 1.010 to 1.020 is an increase of 400 mOsm/kg H\(_2\)O. In the sodium-depleted state, the kidneys usually try to conserve sodium, urine specific gravity is normal, and urine sodium and chloride concentrations are low.

#### Tonicity

A change in water content causes cells to swell or shrink. The term tonicity refers to the tension or effect that the effective osmotic pressure of a solution with impermeable solutes exerts on cell size because of water movement across the cell membrane. An effective osmole is one that exerts an osmotic force and cannot permeate the cell membrane, whereas an ineffective osmole is one that exerts an osmotic force but crosses the cell membrane. Tonicity is determined solely by effective solutes such as glucose that cannot penetrate the cell membrane, thereby producing an osmotic force that pulls water out of the cell. In contrast, urea, which is osmotically active but lipid soluble, tends to distribute equally across the cell membrane. Therefore, when ECF levels of urea are elevated, ICF levels also are elevated. Urea is therefore considered to be an ineffective osmole. It is only when extracellular levels of urea change rapidly, as during hemodialysis treatment, that urea affects tonicity.

Solutions to which body cells are exposed can be classified as isotonic, hypotonic, or hypertonic depending on whether they cause cells to swell or shrink (Fig. 39.3). Cells placed in an isotonic solution, which has the same effective osmolality as the ICF (i.e., 280 mOsm/L), neither shrink nor swell. An example of an isotonic solution is 0.9% NaCl. When cells are placed in a hypotonic solution, which has a lower effective osmolality than the ICF, they swell as water moves into the cell, and when they are placed in a hypertonic solution, which has a greater effective osmolality than the ICF, they shrink as water is pulled out of the cell. However, an iso-osmotic solution is not necessarily isotonic. For example, the intravenous administration of a solution of 5% dextrose in water, which is iso-osmotic, is equivalent to the infusion of a hypotonic solution of distilled water because the glucose is rapidly metabolized to CO\(_2\) and water.

### Compartmental Distribution of Body Fluids

Body water in the average adult male is about 60% of body weight (or about 42 L of water). Because adult females have more adipose tissue, approximately 50% of their body weight is made up of body water.\(^3\) Body water is distributed between the ICF and ECF compartments. In the adult, the fluid in the ICF compartment constitutes approximately 40% of body weight, and fluid in the ECF constitutes approximately 20%.\(^3\) The fluid in the ECF compartment is further divided into two major subdivisions: the plasma compartment, which
constitutes approximately one fourth of the ECF, and the interstitial fluid compartment, which constitutes approximately three fourths of the ECF² (Fig. 39.4).

A third, usually minor, subdivision of the ECF compartment is the transcellular compartment. It includes the cerebrospinal fluid and fluid contained in the various body spaces, such as the peritoneal, pleural, and pericardial cavities; the joint spaces; and the gastrointestinal tract. Normally, only approximately 1% of ECF is in the transcellular space. This amount can increase considerably in conditions such as ascites, in which large amounts of fluid are sequestered in the peritoneal cavity. When the transcellular fluid compartment becomes considerably enlarged, it is referred to as a third space, because this fluid is not readily available for exchange with the rest of the ECF.

**Intracellular Fluid Volume**

The ICF volume is regulated by proteins and organic compounds within the body cells and by water and solutes that move between the ECF and ICF. The membrane in most cells is freely permeable to water. Therefore, water moves between the ECF and ICF as a result of osmosis. In contrast, osmotically active proteins and other organic compounds cannot pass through the membrane. Water entry into the cell is regulated by these osmotically active substances as well as by solutes such as sodium and potassium that pass through the cell membrane. Many of the intracellular proteins are negatively charged and attract positively charged ions such as K⁺, accounting for its higher concentration in the ICF. Na⁺, which has a greater concentration in the ECF than the ICF, tends to enter the cell by diffusion. Na⁺ is osmotically active, and, if left unchecked, its entry would pull water into the cell until it ruptured. The reason this does not occur is because the Na⁺/K⁺-ATPase membrane pump continuously removes three Na⁺ ions from the cell for every two K⁺ ions that are moved back into the cell. Situations that impair the function of the Na⁺/K⁺-ATPase pump, such as hypoxia, cause cells to swell because of an accumulation of Na⁺ ions.

The ICF volume is also affected by the concentration of osmotically active substances in the ECF that cannot cross the cell membrane. In diabetes mellitus, for example, glucose cannot enter the cell, and its increased concentration in the ECF pulls water out of the cell. Some cells, such as those in the central nervous system (CNS), defend against significant shifts in fluid volume through a change in osmotically active intracellular molecules. As an initial compensatory mechanism to preserve cell volume, there is a rapid shift of sodium, potassium, chloride, and water out of brain cells in response to a decrease in ECF osmolality and into brain cells in response to an increase in ECF osmolality. After 48 to 72 hours, a slower adaptive process takes place, during which brain cells mobilize organic osmolytes, composed mainly of amino acids, in an effort to maintain a normal cellular volume.

**Extracellular Fluid Volume**

The ECF is divided between the vascular, interstitial, and transcellular fluid compartments. The vascular compartment contains blood, which is essential to the transport of substances such as electrolytes, gases, nutrients, and waste products throughout the body. The fluid in the interstitial spaces acts as a transport vehicle for gases, nutrients, wastes, and other materials that move between the vascular compartment and body cells. Interstitial fluid also provides a reservoir from which the vascular volume can be maintained during periods of hemorrhage or loss of vascular fluid. A tissue gel, which is a sponge like material composed of large quantities of proteoglycan filaments, fills the tissue spaces and aids in even distribution of interstitial fluid² (see Fig. 39.1). Normally, most of the fluid in the interstitium is in gel form. The tissue gel is supported by collagen fibers that hold the gel in place. The tissue gel, which has a firmer consistency than water, opposes the outflow of water from the capillaries and helps to prevent the accumulation of free water in the interstitial spaces.

**Capillary-Interstitial Fluid Exchange**

The transfer of water between the vascular and interstitial compartments occurs at the capillary level. Four forces control the movement of water between the capillary and interstitial spaces:

1. The capillary filtration pressure, which pushes water out of the capillary into the interstitial spaces
2. The capillary colloidal osmotic pressure, which pulls water back into the capillary
3. The interstitial hydrostatic pressure, which opposes the movement of water out of the capillary
4. The tissue colloidal osmotic pressure, which pulls water out of the capillary into the interstitial spaces²

Normally, the combination of these four forces is such that only a small excess of fluid remains in the interstitial compartment. This excess fluid is removed from the interstitium by the lymphatic system and returned to the systemic circulation.

**Capillary filtration** refers to the movement of water through capillary pores because of a mechanical, rather than
an osmotic, force. The capillary filtration pressure (about 30 to 40 mm Hg at the arterial end, 10 to 15 mm Hg at the venous end, and 25 mm Hg in the middle), sometimes called the capillary hydrostatic pressure, is the pressure pushing water out of the capillary into the interstitial spaces. It reflects the arterial and venous pressures, the precapillary (arterioles) and postcapillary (venules) resistances, and the force of gravity. A rise in arterial or venous pressure increases capillary pressure. The force of gravity increases capillary pressure in the dependent parts of the body. In a person who is standing absolutely still, the weight of blood in the vascular column causes an increase of 1 mm Hg in pressure for every 13.6 mm of distance from the heart. This pressure results from the weight of water and is therefore called hydrostatic pressure. In the adult who is standing absolutely still, the pressure in the veins of the feet can reach 90 mm Hg. This pressure is then transmitted to the capillaries.

The capillary colloidal osmotic pressure (about 28 mm Hg) is the osmotic pressure generated by the plasma proteins that are too large to pass through the pores of the capillary wall. The term colloidal osmotic pressure differentiates this type of osmotic pressure from the osmotic pressure that develops at the cell membrane from the presence of electrolytes and nonelectrolytes. Because plasma proteins do not normally penetrate the capillary pores and because their concentration is greater in the plasma than in the interstitial fluids, it is the capillary colloidal osmotic pressure that pulls fluids back into the capillary.

The interstitial fluid pressure (about −3 mm Hg) and the tissue colloidal osmotic pressure (about 8 mm Hg) contribute to movement of water into and out of the interstitial spaces. The interstitial fluid pressure, which is normally negative, contributes to the outward movement of water into the interstitial spaces. The tissue colloidal osmotic pressure, which reflects the small amount of plasma proteins that normally escape into the interstitial spaces from the capillary, also pulls water out of the capillary into the tissue spaces.

The lymphatic system represents an accessory route whereby fluid from the interstitial spaces can return to the circulation. More important, the lymphatic system provides a means for removing plasma proteins and osmotically active particulate matter from the tissue spaces, neither of which can be reabsorbed into the capillaries.

**Edema**

Edema can be defined as palpable swelling produced by expansion of the interstitial fluid volume. In fact, the interstitial fluid spaces can actually contract to hold an additional 10 to 30 L of fluid. The physiologic mechanisms that contribute to edema formation include factors that increase the capillary filtration pressure; decrease the capillary colloidal osmotic pressure; increase capillary permeability; or produce obstruction to lymph flow. The causes of edema are summarized in Chart 39.1.

**Increased Capillary Filtration Pressure.** As the capillary filtration pressure rises, the movement of vascular fluid into the interstitial spaces increases. Among the factors that increase capillary pressure are (1) increased arterial pressure or decreased resistance to flow through the precapillary sphincters, (2) an increase in venous pressure or increased resistance to outflow at the postcapillary sphincter, and (3) capillary distention due to increased vascular volume.

Edema can be either localized or generalized. The localized edema that occurs with urticaria (i.e., hives) or other allergic or inflammatory conditions results from the release of histamine and other inflammatory mediators that cause dilation of the precapillary sphincters and arterioles that supply the swollen lesions. Thrombophlebitis obstructs venous flow, producing an elevation of venous pressure and edema of the affected part, usually one of the lower extremities.

Generalized body edema (termed anasarca) is frequently the result of increased vascular volume. The swelling of hands and feet that occurs in healthy people during hot weather is an example of edema that is caused by the vasodilation of superficial blood vessels along with sodium and water retention. Generalized edema is common in conditions such as congestive heart failure that produce fluid retention and

---

**Chart 39.1 CAUSES OF EDEMA**

**Increased Capillary Pressure**
- Increased vascular volume
  - Heart failure
  - Kidney disease
  - Premenstrual sodium retention
  - Pregnancy
  - Environmental heat stress
  - Thiazolidinedione (e.g., pioglitazone, rosiglitazone) therapy
- Venous obstruction
  - Liver disease with portal vein obstruction
  - Acute pulmonary edema
  - Venous thrombosis (thrombophlebitis)
- Decreased arteriolar resistance
  - Calcium channel–blocking drug responses

**Decreased Colloidal Osmotic Pressure**
- Increased loss of plasma proteins
  - Protein-losing kidney diseases
- Decreased production of plasma proteins
- Liver disease
- Starvation, malnutrition

**Increased Capillary Permeability**
- Inflammation
  - Allergic reactions (e.g., hives)
  - Malignancy (e.g., ascites, pleural effusion)
- Tissue injury and burns

**Obstruction of Lymphatic Flow**
- Malignant obstruction of lymphatic structures
- Surgical removal of lymph nodes
venous congestion. In right-sided heart failure, blood pools throughout the entire venous system, causing organ congestion and edema of the dependent extremities.

Because of the effects of gravity, edema resulting from increased capillary pressure commonly causes fluid to accumulate in the dependent parts of the body, a condition referred to as dependent edema. For example, edema of the ankles and feet becomes more pronounced during prolonged periods of standing.

**Decreased Capillary Colloidal Osmotic Pressure.** Plasma proteins exert the osmotic force needed to pull fluid back into the capillary from the tissue spaces. The plasma proteins constitute a mixture of proteins, including albumin, globulins, and fibrinogen. Albumin, the smallest of the plasma proteins, has a molecular weight of 69,000; globulins have molecular weights of approximately 140,000; and fibrinogen has a molecular weight of 400,000. Because of its lower molecular weight, 1 g of albumin has approximately twice as many osmotically active molecules as 1 g of globulin and almost six times as many osmotically active molecules as 1 g of fibrinogen. Also, the concentration of albumin (approximately 4.5 g/dL) is greater than that of the globulins (2.5 g/dL) and fibrinogen (0.3 mg/dL).

Edema due to decreased capillary colloidal osmotic pressure usually is the result of inadequate production or abnormal loss of plasma proteins, mainly albumin. The plasma proteins are synthesized in the liver. In people with severe liver failure, the impaired synthesis of albumin results in a decrease in colloidal osmotic pressure. In starvation and malnutrition, edema develops because there is a lack of amino acids for plasma protein synthesis.

The most common site of plasma protein loss is the kidney. In kidney diseases such as glomerulonephritis, the glomerular capillaries become permeable to the plasma proteins, particularly albumin, which is the smallest of the proteins. When this happens, large amounts of albumin are filtered out of the blood and lost in the urine. An excessive loss of plasma proteins also occurs when large areas of skin are injured or destroyed. Edema is a common problem during the early stages of a burn, resulting from capillary injury and loss of plasma proteins.1

Because the plasma proteins are evenly distributed throughout the body and are not affected by the force of gravity, edema due to a decrease in capillary colloidal osmotic pressure tends to affect tissues in nondependent as well as dependent parts of the body. There is swelling of the face as well as the legs and feet.

**Increased Capillary Permeability.** When the capillary pores become enlarged or the integrity of the capillary wall is damaged, capillary permeability is increased. When this occurs, plasma proteins and other osmotically active particles leak into the interstitial spaces, increasing the tissue colloidal osmotic pressure and thereby contributing to the accumulation of interstitial fluid. Among the conditions that increase capillary permeability are burn injury, capillary congestion, inflammation, and immune responses.

**Obstruction of Lymph Flow.** Osmotically active plasma proteins and other large particles that cannot be reabsorbed through the pores in the capillary membrane rely on the lymphatic system for movement back into the circulatory system. Edema due to impaired lymph flow caused by a disruption or malformation of the lymphatic system develops as a result of high protein swelling in an area of the body is referred to as lymphedema. Malignant involvement of lymph structures and removal of lymph nodes at the time of cancer surgery are common causes of lymphedema. Another cause of lymphedema is infection and trauma involving the lymphatic channels and lymph nodes.

**Clinical Manifestations.** The effects of edema are determined largely by its location. Edema of the brain, larynx, or lungs is an acute, life-threatening condition. Although not life threatening, edema may interfere with movement, limiting joint motion. Swelling of the ankles and feet often is insidious in onset and may or may not be associated with disease. At the tissue level, edema increases the distance for diffusion of O₂, nutrients, and wastes. Edematous tissues usually are more susceptible to injury and development of ischemic tissue damage, including pressure ulcers. Edema can also compress blood vessels. The skin of a severely swollen finger can act as a tourniquet, shutting off the blood flow to the finger. Edema can also be disfiguring, causing psychological effects and disturbances in self-concept. It can also create problems with obtaining proper-fitting clothing and shoes.

**Pitting edema** occurs when the accumulation of interstitial fluid exceeds the absorptive capacity of the tissue gel. In this form of edema, the tissue water becomes mobile and can be translocated with pressure exerted by a finger. Nonpitting edema usually reflects a condition in which plasma proteins have accumulated in the tissue spaces and coagulated. It is seen most commonly in areas of localized infection or trauma. The area often is firm and discolored.

**Assessment and Treatment.** Methods for assessing edema include daily weight, visual assessment, measurement of the affected part, and application of finger pressure to assess for pitting edema. Daily weight performed at the same time each day with the same amount of clothing provides a useful index of water gain (1 L of water weighs 1 kg [2.2 lb]) due to edema. Visual inspection and measurement of the circumference of an extremity can also be used to assess the degree of swelling. This is particularly useful when swelling is due to thrombophlebitis. Finger pressure can be used to assess the degree of pitting edema. If an indentation remains after the finger has been removed, pitting edema is identified. It is evaluated on a scale of +1 (minimal) to +4 (severe) (Fig. 39.5).

Distinguishing lymphedema from other forms of edema can be challenging, especially early in its course. Papillomatosis, a characteristic honeycomb appearance of the skin due to dilated lymph vessels that are enveloped in fibrotic tissue, distinguishes lymphedema from other edemas. Computed tomography (CT) or magnetic resonance imaging (MRI) may be used to confirm the diagnosis.
Edema of the lower extremities may respond to simple measures such as elevating the feet. Diuretic therapy commonly is used to treat edema associated with an increase in ECF volume. Serum albumin levels can be measured, and albumin may be administered intravenously to raise the plasma colloidal osmotic pressure when edema is caused by hypoalbuminemia.

Elastic support stockings and sleeves increase interstitial fluid pressure and resistance to outward movement of fluid from the capillary into the tissue spaces. These support devices typically are prescribed for people with conditions such as lymphatic or venous obstruction and are most efficient if applied before the tissue spaces have filled with fluid—in the morning, for example, before the effects of gravity have caused fluid to move into the ankles. Moderate to severe lymphedema is usually treated with light-pressure massage designed to increase lymph flow by encouraging opening and closing of lymph vessel valves; compression garments or pneumatic compression pumps; range-of-motion exercises; and scrupulous skin care to prevent infection.

**Third-Space Accumulation**

Third spacing represents the loss or trapping of ECF into the transcellular space. The serous cavities are part of the transcellular compartment (i.e., third space) located in strategic body areas where there is continual movement of body structures—the pericardial sac, the peritoneal cavity, and the pleural cavity. The exchange of ECF between the capillaries, the interstitial spaces, and the transcellular space of the serous cavity uses the same mechanisms as capillaries elsewhere in the body. The serous cavities are closely linked with lymphatic drainage systems. The milking action of the moving structures, such as the lungs, continually forces fluid and plasma proteins back into the circulation, keeping these cavities empty. Any obstruction to lymph flow causes fluid accumulation in the serous cavities. As with edema fluid, third-space fluids represent an accumulation or trapping of body fluids that contribute to body weight but not to fluid reserve or function. Some causes of third spacing include systemic inflammatory response syndrome or leaky capillary syndrome in pancreatitis; hypoalbuminemia, which occurs with severe liver failure; and third-degree burns.

The prefix hydro- may be used to indicate the presence of excessive fluid, as in hydrothorax, which means excessive fluid in the pleural cavity. The accumulation of fluid in the peritoneal cavity is called ascites. The transudation of fluid into the serous cavities is also referred to as effusion. Effusion can contain blood, plasma proteins, inflammatory cells (i.e., pus), and ECF.

**IN SUMMARY**

Body fluids, which contain water and electrolytes, are distributed between the ICF and ECF compartments of the body. Two thirds of body fluid is contained in the body cells of the ICF compartment, and one third is contained in the vascular compartment, interstitial spaces, and third-space areas of the ECF compartment. The ICF has high concentrations of potassium, calcium, phosphorus, and magnesium and the ECF high concentrations of sodium, chloride, and bicarbonate.

Electrolytes and nonelectrolytes move by diffusion across cell membranes that separate the ICF and ECF compartments. Water crosses the cell membrane by osmosis, using special protein channels called aquaporins. It moves from the side of the membrane that has the lesser number of particles and greater concentration of water to the side that has the greater number of particles and lesser concentration of water. The osmotic tension or effect that a solution exerts on cell volume in terms of causing the cell to swell or shrink is called tonicity.

Edema represents an increase in interstitial fluid volume. The physiologic mechanisms that contribute to the development of edema include factors that (1) increase capillary filtration pressure, (2) decrease capillary colloidal osmotic pressure, (3) increase capillary permeability, and (4) obstruct lymphatic flow. The effect that edema exerts on body function is determined by its location. Edema of the brain, larynx, or lungs is an acute, life-threatening situation, whereas swelling of the ankles and feet can be a normal discomfort that accompanies hot weather. Fluid can also accumulate in the transcellular compartment—the joint spaces, the pericardial sac, the peritoneal cavity, and the pleural cavity. Because this fluid is not easily exchanged with the rest of the ECF, it is often referred to as third-space fluid.
Movement of fluid between the vascular compartment and the interstitial fluid compartment surrounding the body cells occurs at the capillary level. The direction and amount of fluid that flows across the capillary wall are determined by (1) the hydrostatic pressure of the two compartments, (2) the colloidal osmotic pressures of the two compartments, and (3) the removal of excess fluid and osmotically active particles from the interstitial spaces by the lymphatic system.

**Understanding Capillary Fluid Exchange**

**Hydrostatic Pressure**

The hydrostatic pressure is the pushing force exerted by a fluid. Inside the capillaries, the hydrostatic pressure is the same as the capillary filtration pressure, about 30 mm Hg at the arterial end and 10 mm Hg at the venous end. The interstitial fluid pressure is the force of fluid in the interstitial spaces pushing against the outside of the capillary wall. Evidence suggests that the interstitial pressure is slightly negative (~3 mm Hg), contributing to the outward movement of fluid from the capillary.

**Colloidal Osmotic Pressure**

The colloidal osmotic pressure is the pulling force created by the presence of evenly dispersed particles, such as the plasma proteins, that cannot pass through the pores of the capillary membrane. The capillary colloidal osmotic pressure is normally about 28 mm Hg throughout the length of the capillary bed. The interstitial colloidal osmotic pressure (about 8 mm Hg) represents the pulling pressure exerted by the small amounts of plasma proteins that leak through the pores of the capillary wall into the interstitial spaces. The capillary colloidal osmotic pressure, which is greater than both the hydrostatic pressure at the venous end of the capillary and the interstitial colloidal osmotic pressure, is largely responsible for the movement of fluid back into the capillary.

*Continued*
Lymph Drainage

The lymphatic system represents an accessory system by which fluid can be returned to the circulatory system. Normally the forces moving fluid out of the capillary into the interstitium are greater than those returning fluid to the capillary. Any excess fluids and osmotically active plasma proteins that may have leaked into the interstitium are picked up by vessels of the lymphatic system and returned to the circulation. Without the function of the lymphatic system, excessive amounts of fluid would accumulate in the interstitial spaces.

Understanding Capillary Fluid Exchange (Continued)

Body Water Balance

Total body water (TBW) varies with sex and weight. These differences can be explained by differences in body fat, which is essentially water free (i.e., fat is approximately 10% water by composition, compared with 75% for skeletal muscle). In young adult males, TBW approximates 60% of body weight, while TBW is approximately 50% for young adult females. The TBW tends to decrease with old age due to more adipose tissue and less muscle. Obesity produces further decreases in TBW since adipose tissue only contains about 10% water.

Infants normally have more TBW than older children or adults. TBW constitutes approximately 75% of body weight in full-term infants and an even greater proportion in premature infants. In addition to having proportionately more body water than adults, infants have relatively more water in their ECF compartment. Infants have more than half of their TBW in the ECF compartment. The greater ECF water content of an infant can be explained in terms of its higher metabolic rate, larger surface area in relation to body mass, and its inability to concentrate urine because of immature kidney structures. Because ECFs are more readily lost from the body, infants are more vulnerable to fluid deficit than older children and adults. As an infant grows older, TBW decreases, and by the second year of life, the percentages and distribution of body water approach those of an adult.

Gains and Losses

Regardless of age, all healthy people require approximately 100 mL of water per 100 calories metabolized for dissolving

SODIUM AND WATER BALANCE

After completing this section of the chapter, you should be able to meet the following objectives:

- State the functions and physiologic mechanisms controlling body water levels and sodium concentration, including the effective circulating volume, sympathetic nervous system, renin–angiotensin–aldosterone system, and antidiuretic hormone.
- Describe the relationship between antidiuretic hormone and aquaporin-2 channels in reabsorption of water by the kidney.
- Compare the pathology, manifestations, and treatment of diabetes insipidus and the syndrome of inappropriate antidiuretic hormone.

The movement of body fluids between the ICF and ECF compartments occurs at the cell membrane and depends on ECF levels of water and sodium. Almost 93% of body fluids are made up of water, and sodium salts account for approximately 90% to 95% of ECF solutes. Normally, equivalent changes in sodium and water are such that the volume and osmolality of ECF are maintained within a normal range. Because it is the concentration of sodium that controls ECF osmolality, changes in sodium are usually accompanied by proportionate changes in water volume.
and eliminating metabolic wastes. This means that a person who expends 1800 calories for energy requires approximately 1800 mL of water for metabolic purposes. The metabolic rate increases with fever; it rises approximately 12% for every 1°C (7% for every 1°F) increase in body temperature. Fever also increases the respiratory rate, resulting in additional loss of water vapor through the lungs.

The main source of water gain is through oral intake and metabolism of nutrients. Water, including that obtained from liquids and solid foods, is absorbed from the gastrointestinal tract. Tube feedings and parenterally administered fluids are also sources of water gain. Metabolic processes also generate a small amount of water.

Normally, the largest loss of water occurs through the kidneys, with lesser amounts being lost through the skin, lungs, and gastrointestinal tract. Even when oral or parenteral fluids are withheld, the kidneys continue to produce urine as a means of ridding the body of metabolic wastes. The urine output that is required to eliminate these wastes is called the obligatory urine output. The obligatory urine loss is approximately 300 to 500 mL/day. Water losses that occur through the skin and lungs are referred to as insensible water losses. The gains and losses of body water are summarized in Table 39.2.

**SODIUM AND WATER BALANCE**

- It is the amount of water and its effect on sodium concentration in the ECF that serves to regulate the distribution of fluid between the ICF and the ECF compartments.
- Hyponatremia or hypernatremia that is brought about by disproportionate losses or gains in sodium or water exerts its effects on the ICF compartment, causing water to move in or out of body cells. Many of the manifestations of changes in sodium concentration reflect changes in the intracellular volume of cells, particularly those in the nervous system.

**Sodium Balance**

Sodium is the most abundant cation in the body, averaging approximately 60 mEq/kg of body weight. Most of the body’s sodium is in the ECF compartment (135 to 145 mEq/L [135 to 145 mmol/L]), with only a small amount (10 to 14 mEq/L [10 to 14 mmol/L]) located in the ICF compartment. The resting cell membrane is relatively impermeable to sodium; sodium that enters the cell is transported out of the cell against an electrochemical gradient by the Na+/K+-ATPase membrane pump.

Sodium functions mainly in regulating the ECF volume. As the major cation in the ECF compartment, Na+ and its attendant anions (Cl− and HCO3−) account for approximately 90% to 95% of the osmotic activity in the ECF. Because sodium is part of the sodium bicarbonate molecule, it is important in regulating acid–base balance. As a current-carrying ion, Na+ contributes to the function of the nervous system and other excitable tissue.

**Gains and Losses**

Sodium normally enters the body through the gastrointestinal tract and is eliminated by the kidneys or lost from the gastrointestinal tract or skin. Sodium intake normally is derived from dietary sources. Body needs for sodium usually can be met by as little as 500 mg/day. The average salt intake is approximately 6 to 15 g/day, or 12 to 30 times the daily requirement. Dietary intake, which frequently exceeds the amount needed by the body, is often influenced by culture and food preferences rather than need. As package labels indicate, many commercially prepared foods and soft drinks contain considerable amounts of sodium. Other sources of sodium are intravenous saline infusions and medications that contain sodium.

Most sodium losses occur through the kidneys. The kidneys are extremely efficient in regulating sodium output, and when sodium intake is limited or conservation of sodium is needed, the kidneys are able to reabsorb almost all the sodium that has been filtered by the glomerulus. This results in essentially sodium-free urine. Conversely, urinary losses of sodium increase as intake increases.

Usually less than 10% of sodium intake is lost through the gastrointestinal tract and skin. Although the sodium concentration of fluids in the upper part of the gastrointestinal tract approaches that of the ECF, sodium is reabsorbed as the fluids move through the lower part of the bowel, so that the concentration of sodium in the stool is only approximately 40 mEq/L (40 mmol/L). Sodium losses increase with conditions such as vomiting, diarrhea, fistula drainage, and gastrointestinal suction that remove sodium from the gastrointestinal tract. Irrigation of gastrointestinal tubes with distilled water removes sodium from the gastrointestinal tract, as do repeated tap water enemas.

Sodium leaves the skin through the sweat glands. Sweat is a hypotonic solution containing both sodium and chloride. Although sodium losses due to sweating are usually negligible, they can increase greatly during exercise and periods of
Mechanisms of Regulation

The major regulator of sodium and water balance is the maintenance of the **effective circulating volume** also called the **effective arterial blood volume**. This is the vascular bed that perfuses the body. A low effective circulating volume activates feedback mechanisms that produce an increase in renal sodium and water retention, and a high effective circulating volume triggers feedback mechanisms that decrease sodium and water retention.

The effective circulating volume is monitored by a number of sensors that are located in both the vascular system and the kidney. These sensors are the **baroreceptors** because they respond to pressure-induced stretch of the vessel walls. There are baroreceptors located in the low-pressure side of the circulation (walls of the cardiac atria and large pulmonary vessels) that respond primarily to fullness of the circulation. Baroreceptors are also present in the high-pressure arterial side of the circulation (aortic arch and carotid sinus) that respond primarily to changes in the arterial pressure. The activity of both types of receptors regulates water elimination by modulating sympathetic nervous system outflow and antidiuretic hormone (ADH) secretion. The sympathetic nervous system responds to changes in arterial pressure and blood volume by adjusting the glomerular filtration rate and thus the rate at which sodium is filtered from the blood. Sympathetic activity also regulates tubular reabsorption of sodium and renin release. An additional mechanism related to renal sodium excretion is atrial natriuretic peptide (ANP), which is released from cells in the atria of the heart. ANP, which is released in response to atrial stretch and overfilling, increases sodium excretion by the kidney, which in turn pulls out more water.

Pressure-sensitive receptors in the kidney, particularly in the afferent arterioles, respond directly to changes in arterial pressure through stimulation of the sympathetic nervous system and release of renin with activation of the renin–angiotensin–aldosterone system (RAAS). The RAAS exerts its action through angiotensin II and aldosterone. Renin is a small protein enzyme that is released by the kidney in response to changes in arterial pressure, the glomerular filtration rate, and the amount of sodium in the tubular fluid. Most of the renin that is released leaves the kidney and enters the bloodstream, where it interacts enzymatically to convert a circulating plasma protein called angiotensinogen to angiotensin I.

Angiotensin I is rapidly converted to angiotensin II by the angiotensin-converting enzyme (ACE) in the small blood vessels of the lung. Angiotensin II acts directly on the renal tubules to increase sodium reabsorption. It also acts to constrict renal blood vessels, thereby decreasing the glomerular filtration rate and slowing renal blood flow so that less sodium is filtered and more is reabsorbed.

Angiotensin II is also a powerful regulator of aldosterone, a hormone secreted by the adrenal cortex. Aldosterone acts at the level of the cortical collecting tubules of the kidneys to increase sodium reabsorption while increasing potassium elimination. The sodium-retaining action of aldosterone can be inhibited by blocking the actions of aldosterone with potassium-sparing diuretics (e.g., spironolactone, amiloride, and triamterene), by suppressing renin release (e.g., β-adrenergic blocking drugs), by inhibiting the conversion of angiotensin I to angiotensin II (i.e., ACE inhibitors), or by blocking the action of angiotensin II on the angiotensin receptor (i.e., angiotensin II receptor blockers [ARBs]).

Thirst and Antidiuretic Hormone

Two other mechanisms that contribute directly to the regulation of body water and indirectly to the regulation of sodium are thirst and ADH. Thirst is primarily a regulator of water intake and ADH a regulator of water output. Both thirst and ADH are responsive to changes in extracellular osmolality and the resultant effective circulating volume (Fig. 39.7).

Disorders of Thirst

Thirst is the conscious sensation of the need to obtain and drink fluids high in water content. Drinking of water or other fluids often occurs as the result of habit or for reasons other than those related to thirst. Most people drink without being thirsty, and water is consumed before it is needed. As a result, thirst is basically an emergency response. It usually occurs only when the need for water has not been anticipated.

Thirst is controlled by the thirst center in the hypothalamus. There are two stimuli for true thirst based on water need: (1) cellular dehydration caused by an increase in ECF osmolality and (2) a decrease in blood volume, which may or may not be associated with a decrease in serum osmolality. Sensory neurons, called osmoreceptors, which are located in or near the thirst center in the hypothalamus, respond to changes in ECF osmolality by swelling or shrinking (see Fig. 39.6). Thirst normally develops when there is as little as a 1% to 2% change in serum osmolality. The previously described stretch receptors in the vascular system that monitor the effective circulating volume also aid in the regulation of thirst. Thirst is one of the earliest symptoms of hemorrhage and is often present before other signs of blood loss appear.

A third important stimulus for thirst is angiotensin II, levels of which increase in response to low blood volume and low blood pressure. The renin–angiotensin mechanism contributes to nonosmotic thirst. This system is considered a backup system for thirst should other systems fail. Because it is a backup system, it probably does not contribute to the regulation of normal thirst. However, elevated levels of angiotensin II may lead to thirst in conditions, such as chronic kidney disease and congestive heart failure, in which renin levels may be elevated.

Dryness of the mouth, such as the thirst a lecturer experiences during speaking, produces a sensation of thirst that...
Polydipsia. Polydipsia, or excessive thirst, is normal when it accompanies conditions of water deficit. Increased thirst and drinking behavior can be classified into three categories: (1) symptomatic or true thirst, (2) inappropriate or false thirst that occurs despite normal levels of body water and serum osmolality, and (3) compulsive water drinking. Symptomatic thirst develops when there is a loss of body water and resolves after the loss has been replaced. Among the most common causes of symptomatic thirst are water losses associated with diarrhea, vomiting, diabetes mellitus, and diabetes insipidus (DI). Inappropriate or excessive thirst may persist despite adequate hydration. It is a common complaint in people with congestive heart failure, diabetes mellitus, and chronic kidney disease. Although the cause of thirst in these people is unclear, it may result from increased angiotensin levels. Thirst is also a common complaint in people with dry mouth caused by decreased salivary function or treatment with drugs with an anticholinergic action (e.g., antihistamines, atropine) that leads to decreased salivary flow.

Psychogenic polydipsia involves compulsive water drinking and is usually seen in people with psychiatric disorders, most commonly schizophrenia. People with the disorder drink large amounts of water and excrete large amounts of urine. The cause of excessive water drinking in these people is uncertain. The condition may be compounded by antipsychotic medications that increase ADH levels and interfere with water excretion by the kidneys. Cigarette smoking, which is common among people with psychiatric disorders, also stimulates ADH secretion. Excessive water ingestion coupled with impaired water excretion (or rapid ingestion at a rate that exceeds renal excretion) in people with psychogenic polydipsia can lead to water intoxication. Treatment usually consists of water restriction and behavioral measures aimed at decreasing water consumption.

Disorders of Antidiuretic Hormone
The reabsorption of water by the kidneys is regulated by ADH, also known as vasopressin. ADH is synthesized by cells in the supraoptic and paraventricular nuclei of the hypothalamus and then transported along a neural pathway (i.e., hypothalamo-hypophysial tract) to the posterior pituitary gland, where it is stored. When the supraoptic and paraventricular nuclei in the hypothalamus are stimulated by increased serum osmolality or other factors, nerve impulses travel down the hypothalamo-hypophysial tract to the posterior pituitary gland, causing the stored ADH to be released into the circulation (see Fig. 39.6).

ADH exerts its effects through two types of vasopressin (V) receptors—V₁ and V₂. V₁ receptors, which are located in vascular smooth muscle, cause vasoconstriction—hence the name vasopressin. Although ADH can increase blood pressure through V₁ receptors, this response occurs only when ADH levels are very high. The V₂ receptors, which are located on the tubular cells of the cortical collecting duct, control water reabsorption by the kidney. These renal mechanisms for water reabsorption are responsible for maintaining the osmolality of body fluids.

Hypodipsia. Hypodipsia represents a decrease in the ability to sense thirst. It is commonly associated with lesions in the area of the hypothalamus (e.g., head trauma, meningiomas, occult hydrocephalus, subarachnoid hemorrhage). There is also evidence that thirst is decreased and water intake reduced in oldest older adults (age >80 years), despite higher plasma sodium and osmolality levels. The inability to perceive and respond to thirst is compounded in older adults who have had a stroke and may be further influenced by confusion, sensory deficits, and motor disturbances.
Diabetes Insipidus. DI is caused by a deficiency of or a decreased response to ADH. People with DI are unable to concentrate their urine during periods of water restriction, and they excrete large volumes of urine, usually 3 to 20 L/day, depending on the degree of ADH deficiency or renal insensitivity to ADH. This large urine output is accompanied by excessive thirst. As long as the thirst mechanism is normal and fluid is readily available, there is little or no alteration in the fluid levels of people with DI. The danger arises when the condition develops in someone who is unable to communicate the need for water or is unable to secure the needed water. In such cases, inadequate fluid intake rapidly leads to hypertonic dehydration and increased serum osmolality.

There are two types of DI: neurogenic or central DI, which occurs because of a defect in the synthesis or release of ADH, and nephrogenic DI, which occurs because the kidneys do not respond to ADH. In neurogenic DI, loss of 80% to 90% of ADH-secreting neurons is necessary before polyuria becomes evident. Most people with neurogenic DI have an incomplete form of the disorder and retain some ability to concentrate their urine. Temporary neurogenic DI may follow head injury or surgery near the hypothalamohypophysial tract. Nephrogenic DI is characterized by impairment of urine-concentrating ability and free-water conservation. It may be due to a genetic trait that affects the V_2 receptor that binds ADH or the aquaporin-2 protein that forms the water channels in the collecting tubules. Other, acquired causes of nephrogenic DI are drugs such as lithium and electrolyte disorders such as potassium depletion or chronic hypercalcemia. Lithium and the electrolyte disorders are thought to interfere with the postreceptor actions of ADH on the permeability of the collecting ducts.

Diagnosis of DI usually starts by attempting to document the total 24-hour urine output. Also, it must be documented that an osmotic diuresis is not caused by glucose or such disorders as kidney disease. Further evaluation is based on measurement of ADH levels along with plasma and urine osmolality before and after a period of fluid deprivation or hypertonic saline infusion. Persons with neurogenic DI do not increase their ADH levels in response to ADH. People with nephrogenic DI do not respond to pharmacologic preparations of the hormone. When central DI is suspected, diagnostic methods such as MRI studies of the pituitary–hypothalamic area are used to determine the cause of the disorder. MRI studies localize the normal posterior pituitary as a high-intensity area. A large “bright spot” is related to the content of stored ADH. This high-intensity signal is present in most (but not all) normal subjects and is absent in most (but not all) people with DI.

The management of central DI depends on the cause and severity of the disorder. Many people with incomplete neurogenic DI maintain near-normal water balance when permitted to ingest water in response to thirst. Pharmacologic preparations of ADH are available for people who cannot be managed by conservative measures. The preferred drug for treating chronic DI is desmopressin acetate (DDAVP). It is usually given orally, but it is also available in parenteral and

Without ADH, the luminal membranes of the tubular epithelial cells of the collecting ducts are almost impermeable to water. In the presence of ADH, pores or water channels, called aquaporins, are inserted into the membrane of these tubular cells, making them permeable to water. The specific water channel that is controlled by ADH is aquaporin-2.

As with thirst, ADH levels are controlled by ECF volume and osmolality. Osmoreceptors in the hypothalamus are capable of detecting fluctuation in ECF osmolality and can stimulate the production and release of ADH. Likewise, stretch receptors that are sensitive to changes in blood pressure and the effective circulating volume aid in the regulation of ADH release (i.e., nonosmotic ADH secretion). A blood volume decrease of 5% to 10% produces a maximal increase in ADH levels. As with many other homeostatic mechanisms, acute conditions produce greater changes in ADH levels than do chronic conditions.

The abnormal synthesis and release of ADH occurs in a number of stress situations. Severe pain, nausea, trauma, surgery, certain anesthetic agents, and some narcotics (e.g., morphine and meperidine) increase ADH levels. Among the drugs that affect ADH are nicotine, which stimulates its release, and alcohol, which inhibits it (Table 39.3). Two important conditions alter ADH levels: DI and inappropriate secretion of ADH.

ADH, antidiuretic hormone.
nasal forms. The oral antidiabetic agent chlorpropamide may be used to stimulate ADH release in partial neurogenic DI. It usually is reserved for special cases because of its ability to cause hypoglycemia. Both neurogenic and nephrogenic forms of DI respond partially to the thiazide diuretics (e.g., hydrochlorothiazide). These diuretics are thought to act by increasing sodium excretion by the kidneys, leading to ECF volume contraction, a decrease in the glomerular filtration rate (along with filtered load of sodium), and an increase in sodium and water reabsorption. It also has been postulated that the thiazide diuretics increase water permeability in the collecting tubules.

**Syndrome of Inappropriate Antidiuretic Hormone.** The syndrome of inappropriate ADH (SIADH) results from a failure of the negative feedback system that regulates the release and inhibition of ADH. In people with this syndrome, ADH secretion continues even when serum osmolality is decreased, causing marked water retention and dilutional hyponatremia.

SIADH may occur as a transient condition, as in a stress situation, or, more commonly, as a chronic condition, resulting from disorders such as lung or brain tumors. Stimuli such as surgery, pain, stress, and temperature changes are capable of triggering ADH release through action of the CNS. Drugs induce SIADH in different ways. Some drugs are thought to increase hypothalamic production and release of ADH, and others are believed to act directly on the renal tubules to enhance the action of ADH. More chronic forms of SIADH may result from lung tumors, chest lesions, and CNS disorders. Tumors, particularly bronchogenic carcinomas and cancers of the lymphoid tissue, prostate, and pancreas, are known to produce and release ADH independent of normal hypothalamic control mechanisms. Other intrathoracic conditions, such as advanced tuberculosis, severe pneumonia, and positive-pressure breathing, also cause SIADH. The suggested mechanism for SIADH in positive-pressure ventilation is activation of baroreceptors (e.g., aortic baroreceptors, cardiopulmonary receptors) that respond to marked changes in intrathoracic pressure. Disease and injury to the CNS can cause direct pressure on or direct involvement of the hypothalamic–posterior pituitary structures. Examples include brain tumors, hydrocephalus, head injury, meningitis, and encephalitis. Human immunodeficiency virus (HIV) infection is an established cause of SIADH (e.g., related to associated infections, tumors, drugs).

The manifestations of SIADH are those of dilutional hyponatremia. Urine osmolality is high and serum osmolality is low. Urine output decreases despite adequate or increased fluid intake. Hematocrit and the plasma sodium and BUN levels are all decreased because of the expansion of the ECF volume. The diagnosis of SIADH should be considered only if the five cardinal features are fulfilled: (1) hypotonic hyponatremia, (2) natriuresis (>20 mEq/L [20 mmol/L]), (3) urine osmolality in excess of plasma osmolality, (4) absence of edema and volume depletion, and (5) normal renal, thyroid, and adrenal function.

The treatment of SIADH depends on its severity. In mild cases, treatment consists of fluid restriction. If fluid restriction is not sufficient, diuretics such as mannitol and furosemide (Lasix) may be given to promote diuresis and free-water clearance. Lithium and the antibiotic demeclocycline inhibit the action of ADH on the renal collecting ducts and sometimes are used in treating the disorder. In cases of severe water intoxication, a hypertonic (e.g., 3%) NaCl solution may be administered intravenously. The recently developed antagonists to the antidiuretic action of ADH (aquaresics) offer a new therapeutic approach to the treatment of euvolemic hyponatremia. These agents (e.g., conivaptan) are specific ADH V₂ receptor antagonists and result in aquarexis (i.e., the electrolyte-sparing excretion of free water).

**Disorders of Sodium and Water Balance**

Disorders of sodium and water balance can be divided into two main categories:

1. Isotonic contraction or expansion of ECF volume
2. Hypotonic dilution (hyponatremia) or hypertonic concentration (hypernatremia) of extracellular sodium brought about by changes in extracellular water (Fig. 39.7)

Isotonic disorders usually are confined to the ECF compartment, producing a contraction (fluid volume deficit) or expansion (fluid volume excess) of the interstitial and vascular fluids. Disorders of sodium concentration produce a change in the osmolality of the ECF, with movement of water from the ECF compartment into the ICF compartment (hyponatremia) or from the ICF compartment into the ECF compartment (hypernatremia).

**Isotonic Fluid Volume Deficit**

Fluid volume deficit is characterized by a decrease in the ECF, including the circulating blood volume. The term *isotonic fluid volume deficit* is used to differentiate the type of fluid deficit in which there are proportionate losses in sodium and water from water deficit and the hyperosmolar state associated with hypernatremia. Unless other fluid and electrolyte imbalances are present, the concentration of plasma electrolytes remains essentially unchanged. When the effective circulating blood volume is compromised, the condition is often referred to as hypovolemia.

**Etiology.** Isotonic fluid volume deficit results when water and electrolytes are lost in isotonic proportions (Table 39.4). It is almost always caused by a loss of body fluids and is often accompanied by a decrease in fluid intake. It can occur because of a loss of gastrointestinal fluids, polyuria, or sweating due to fever and exercise. Fluid intake may be reduced because of a lack of access to fluids, impaired thirst, unconsciousness, oral trauma, impaired swallowing, or neuromuscular problems that prevent fluid access.
In a single day, 8 to 10 L of ECF is secreted into the gastrointestinal tract. Most of it is reabsorbed in the ileum and proximal colon, and only approximately 150 to 200 mL/day is eliminated in the feces. Vomiting and diarrhea interrupt the reabsorption process and, in some situations, lead to increased secretion of fluid into the intestinal tract. In Asiatic cholera, death can occur within a matter of hours as the cholera organism causes excessive amounts of fluid to be secreted into the bowel. These fluids are then lost as vomitus or excreted as diarrheal fluid. Gastrointestinal suction, fistulas, and drainage tubes can remove large amounts of fluid from the gastrointestinal tract. Excess sodium and water losses also can occur through the kidney. Certain forms of kidney disease are characterized by salt wasting due to impaired sodium reabsorption. Fluid volume deficit also can result from osmotic diuresis or injudicious use of diuretic therapy. Glucose in the urine filtrate prevents reabsorption of water by the renal tubules, causing a loss of sodium and water. In Addison disease, a condition of chronic adrenocortical insufficiency, there is unregulated loss of sodium in the urine with a resultant loss of ECF. This is accompanied by increased potassium retention.

The skin acts as an exchange surface for heat and as a vapor barrier to prevent water from leaving the body. Body surface losses of sodium and water increase when there is excessive sweating or when large areas of skin have been damaged. Hot weather and fever increase sweating. In hot weather, water losses through sweating may be increased by as much as 1 to 3 L/hour, depending on acclimatization. The respiratory rate and sweating usually are increased as body temperature rises. As much as 3 L of water may be lost in a single day as a result of fever. Burns are another cause of excess fluid loss. Evaporative losses can increase 10-fold with severe burns, up to 3 to 5 L/day.

Third-space losses cause sequestering of ECF in the serous cavities, extracellular spaces in injured tissues, or lumen of the gut. Because the fluid remains in the body, fluid volume deficit caused by third spacing does not usually cause weight loss.

Clinical Manifestations. The manifestations of fluid volume deficit reflect a decrease in ECF volume. They include thirst, loss of body weight, signs of water conservation by the kidney, impaired temperature regulation, and signs of reduced interstitial and vascular volume (see Table 39.4).

A loss in fluid volume is accompanied by a decrease in body weight. One liter of water weighs 1 kg (2.2 lb). A mild ECF deficit exists when weight loss equals 2% of body weight. In a person who weighs 68 kg (150 lb), this percentage of weight loss equals 1.4 L of water. To be accurate, weight must be measured at the same time each day with the person wearing the same amount of clothing. Because the ECF is trapped in the body in people with third-space losses, their body weight may not decrease.

Thirst is a common symptom of fluid deficit, although it is not always present in the early stages of isotonic fluid deficit. It develops as the effective circulatory volume decreases to a point sufficient to stimulate the thirst mechanism. Urine output decreases and urine osmolality and specific gravity
increase as ADH levels rise because of a decrease in vascular volume. Although there is an isotonic loss of fluid from the vascular compartment, the other blood components such as red blood cells (RBCs) and BUN become more concentrated.

The fluid content of body tissues decreases as fluid is removed from the interstitial spaces. The eyes assume a sunken appearance and feel softer than normal as the fluid content in the anterior chamber of the eye is decreased. Fluids add resiliency to the skin and underlying tissues that is referred to as skin or tissue turgor. Tissue turgor is assessed by pinching a fold of skin between the thumb and forefinger. The skin should immediately return to its original configuration when the fingers are released.\(^9\) If 3% to 5% of body water is lost in children, there is fairly normal turgor, whereas with 6% to 9% loss of body water, there is poor turgor and a sunken anterior fontanel.\(^9\) Decreased tissue turgor is less predictive of fluid deficit in older persons (>65 years) because of the loss of tissue elasticity. In infants, fluid deficit may be evidenced by depression of the anterior fontanel due to a decrease in cerebrospinal fluid.

Arterial and venous volumes decline during periods of fluid deficit, as does filling of the capillary circulation. As the volume in the arterial system declines, the blood pressure decreases, the heart rate increases, and the pulse becomes weak and thready. Postural hypotension (a drop in blood pressure on standing) is an early sign of fluid deficit. On the venous side of the circulation, the veins become less prominent. When volume depletion becomes severe, signs of hypovolemic shock and vascular collapse appear.

Diagnosis and Treatment. Diagnosis of fluid volume deficit is based on a history of conditions that predispose to sodium and water losses, weight loss, and observations of altered physiologic function indicative of decreased fluid volume. Intake and output measurements afford a means for assessing fluid balance. However, these measurements may not represent actual losses and gains, largely because accurate measurements of intake and output often are difficult to obtain and insensible losses are difficult to estimate.

Measurement of heart rate and blood pressure provides useful information about vascular volume. A simple test to determine venous refill time consists of compressing the distal end of a vein on the dorsal aspect of the hand when it is not in the dependent position. The vein is then emptied by “milking” the blood toward the heart. The vein should refill almost immediately when the occluding finger is removed. In the case of decreased venous volume, as occurs in fluid

deficit, venous refill time increases. Capillary refill time is also increased. Capillary refill can be assessed by applying pressure to a fingernail for 5 seconds and then releasing the pressure and observing the time (normally 1 to 2 seconds) it takes for the color to return to normal.20

Treatment of fluid volume deficit consists of fluid replacement and measures to correct the underlying cause. Usually, isotonic electrolyte solutions are used for fluid replacement. Acute hypovolemia and hypovolemic shock can cause renal damage. Therefore, prompt assessment of the degree of fluid deficit and adequate measures to resolve the deficit and treat the underlying cause are essential.

Isotonic Fluid Volume Excess
Fluid volume excess represents an isotonic expansion of the ECF compartment with increases in both interstitial and vascular volumes. Although increased fluid volume is usually the result of a disease condition, this is not always true. For example, a compensatory isotonic expansion of body fluids can occur in healthy people during hot weather as a mechanism for increasing body heat loss.

Etiology. Isotonic fluid volume excess almost always results from an increase in total body sodium that is accompanied by a proportionate increase in body water. Although it can occur as the result of excessive sodium intake, it is most commonly caused by a decrease in sodium and water elimination by the kidney.

Among the causes of decreased sodium and water elimination are disorders of renal function, heart failure, liver failure, and corticosteroid excess (Table 39.5). Heart failure produces a decrease in the effective circulating volume and renal blood flow and a compensatory increase in sodium and water retention. People with severe congestive heart failure maintain a precarious balance between sodium and water intake and output. Even small increases in sodium intake can precipitate a state of fluid volume excess and a worsening of heart failure. A condition called circulatory overload results from an increase in blood volume; it can occur during infusion of intravenous fluids or transfusion of blood if the amount or rate of administration is excessive. Liver failure (e.g., cirrhosis of the liver) impairs aldosterone metabolism and decreases effective circulating volume and renal perfusion, leading to increased salt and water retention. The corticosteroid hormones increase sodium reabsorption by the kidneys. People taking corticosteroid medications and those with Cushing disease often have problems with sodium retention.

Clinical Manifestations. Isotonic fluid volume excess is manifested by an increase in interstitial and vascular fluids. It is characterized by weight gain over a short period of time. Mild fluid volume excess represents a 2% gain in weight; moderate fluid volume excess, a 5% gain in weight; and severe fluid volume excess, a gain of 8% or more in weight8 (see Table 39.5). The presence of edema is characteristic of isotonic fluid excess. When the excess fluid accumulates gradually, as often happens in debilitating diseases and starvation, edema fluid may mask the loss of tissue mass. There may be a decrease in BUN and hematocrit as a result of dilution due to expansion of the plasma volume. An increase in vascular volume may be evidenced by distended neck veins, slow-emptying peripheral veins, a full and bounding pulse, and an increase in central venous pressure. When excess fluid accumulates in the lungs (i.e., pulmonary edema), there are complaints of shortness of breath and difficult breathing, respiratory crackles, and a productive cough. Ascites and pleural effusion may occur with severe fluid volume excess.

Diagnosis and Treatment. Diagnosis of fluid volume excess is usually based on a history of factors that predispose to sodium and water retention, weight gain, and manifestations such as edema and cardiovascular symptoms indicative of an expanded ECF volume.

The treatment of fluid volume excess focuses on providing a more favorable balance between sodium and water intake and output. A sodium-restricted diet is often prescribed as a means of decreasing extracellular sodium and water levels. Diuretic therapy is commonly used to increase sodium elimination. When there is a need for intravenous fluid administration or transfusion of blood components, the procedure requires careful monitoring to prevent fluid overload.

**Hyponatremia**

The normal plasma concentration of sodium ranges from 135 to 145 mEq/L (135 to 145 mmol/L). Plasma sodium values reflect the sodium concentration expressed in milliequivalents or millimoles per liter, rather than an absolute amount. Because sodium and its attendant anions account for 90% to 95% of the osmolality of ECF, serum osmolality (normal range, 275 to 295 mOsm/kg) usually changes with changes in plasma sodium concentration.

Hyponatremia represents a plasma sodium concentration below 135 mEq/L (135 mmol/L). It is one of the most common electrolyte disorders seen in general hospital patients and is also common in the outpatient population, particularly in older adults. A number of age-related events make the older adult population more vulnerable to hyponatremia, including a decrease in renal function accompanied by limitations in sodium conservation. Although older people maintain body fluid homeostasis under most circumstances, the ability to withstand environmental, drug-related, and disease-associated stresses becomes progressively limited.

**Types and Etiology.** Because of the effects of osmotically active particles such as glucose, hyponatremia can present as a hypotonic or hypertonic state. Hypertonic (translocalational) hyponatremia results from an osmotic shift of water from the ICF to the ECF compartment, such as that occurring in hyperglycemia (the correction for hyperglycemia is a 1.6-mEq/L [1.6 mmol/L] increase in plasma sodium for every 100 mg/dL rise in plasma glucose above the normal 100 mg/dL [5.5 mmol/L]). In this case, the sodium in the ECF becomes diluted as water moves out of cells in response to the osmotic effects of the elevated blood glucose level. Hypotonic (dilutional) hyponatremia, by far the most common type of hyponatremia, is caused by water retention. It can be classified as hypovolemic, euvolemic, or hypervolemic based on accompanying ECF fluid volumes. Because of its effect on both sodium and water elimination, diuretic therapy can cause either hypovolemic or euvolemic hyponatremia.

Hypovolemic hypotonic hyponatremia occurs when water is lost along with sodium, but to a lesser extent. Among the causes of hypovolemic hyponatremia are excessive sweating in hot weather, particularly during heavy exercise, which leads to loss of salt and water. Hyponatremia develops when water, rather than electrolyte-containing liquids, is used to replace fluids lost in sweating. Another potential cause of hypovolemic hyponatremia is the loss of sodium from the gastrointestinal tract caused by frequent gastrointestinal irrigations with distilled water. Isotonic fluid loss, such as that occurring in vomiting or diarrhea, does not usually lower plasma sodium levels unless these losses are replaced with disproportionate amounts of orally ingested or parenterally administered water. Gastrointestinal fluid loss and ingestion of excessively diluted formula are common causes of acute hyponatremia in infants and children. Hypovolemic hyponatremia is also a common complication of adrenal insufficiency and is attributable to a decrease in aldosterone levels. A lack of aldosterone increases renal losses of sodium, and a cortisol deficiency leads to increased release of ADH with water retention.

Euvolemic or normovolemic hypotonic hyponatremia represents retention of water with dilution of sodium while maintaining the ECF volume within a normal range. It is usually the result of SIADH. The risk of normovolemic hyponatremia is increased during the postoperative period. During this time ADH levels are often high, producing an increase in water reabsorption by the kidney. Although these elevated levels usually resolve in about 72 hours, they can persist for as long as 5 days. The hyponatremia becomes exaggerated when electrolyte-free fluids (e.g., 5% glucose in water) are used for fluid replacement.

Hypervolemic hypotonic hyponatremia is seen when hyponatremia is accompanied by edema-associated disorders such as decompensated heart failure, advanced liver disease, and renal disease. Although the total body sodium is increased in heart failure, the effective circulating volume is often sensed as inadequate by the baroreceptors (i.e., relative arterial underfilling), resulting in increased ADH levels (nonosmotic ADH secretion).

Abuse of the drug, methylenedioxymethamphetamine (MDMA), also known as “ecstasy,” can lead to severe neurologic symptoms, including seizures, brain edema, and herniation due to severe hyponatremia.

**Clinical Manifestations.** The manifestations of hypotonic hyponatremia are largely related to sodium dilution (Table 39.6). Serum osmolality is decreased, and cellular swelling occurs owing to the movement of water from the ECF to the ICF compartment. The manifestations of hyponatremia depend on the rapidity of onset and the severity of the sodium dilution. The signs and symptoms may be acute (i.e., onset within 48 hours), as in severe water intoxication, or more insidious in onset and less severe, as in chronic hyponatremia. Because of water movement, hyponatremia produces an increase in intracellular water, which is responsible for many of the clinical manifestations of the disorder. Fingerprint edema is a sign of excess intracellular water. This phenomenon is demonstrated by pressing the finger firmly over the bony surface of the sternum for 15 to 30 seconds. Fingerprint edema exists if an indented fingerprint remains in the sternum where the pressure was applied.
Muscle cramps, weakness, and fatigue reflect the effects of hyponatremia on skeletal muscle function and are often early signs of hyponatremia. These effects commonly are observed in persons with hyponatremia that occurs during heavy exercise in hot weather. Gastrointestinal manifestations such as nausea and vomiting, abdominal cramps, and diarrhea may develop.

The cells of the brain and nervous system are the most seriously affected by increases in intracellular water. Symptoms include apathy, lethargy, and headache, which can progress to disorientation, confusion, gross motor weakness, and depression of deep tendon reflexes. Seizures and coma occur when plasma sodium levels reach extremely low levels. These severe effects, which are caused by brain swelling, may be irreversible. If the condition develops slowly, signs and symptoms do not develop until plasma sodium levels approach 120 mEq/L (120 mmol/L) (i.e., severe hyponatremia). The term water intoxication is often used to describe the neurologic effects of acute hypotonic hyponatremia.

Diagnosis and Treatment. Diagnosis of hyponatremia is based on laboratory reports of a decreased plasma sodium concentration, plasma and urine osmolality, and urine sodium concentration; assessment of the person’s volume status; presence of conditions that predispose to sodium loss or water retention; and signs and symptoms indicative of the disorder.

The treatment of hyponatremia with water excess focuses on the underlying cause. When hyponatremia is caused by water intoxication, limiting water intake or discontinuing medications that contribute to SIADH may be sufficient. The administration of a saline solution orally or intravenously may be needed when hyponatremia is caused by sodium deficiency. Symptomatic hyponatremia (i.e., neurologic manifestations) is often treated with hypertonic saline solution and a loop diuretic, such as furosemide, to increase water elimination. This combination allows for correction of plasma sodium levels while ridding the body of excess water. New, specific ADH V2 receptor antagonists to the antidiuretic action of ADH (aquaretics) offer a new therapeutic approach to the treatment of euvolemic hyponatremia.

There is concern about the rapidity with which plasma sodium levels are corrected, particularly in people with chronic symptomatic hyponatremia. Cells, particularly those in the brain, tend to defend against changes in cell volume caused by changes in ECF osmolality by increasing or decreasing their concentration of organic osmolytes. In the case of prolonged water intoxication, brain cells reduce their concentration of osmolytes as a means of preventing an increase in cell volume. It takes several days for brain cells to restore the osmolytes lost during hyponatremia. Thus, treatment measures that produce rapid changes in serum osmolality may cause a dramatic change in brain cell volume. One of the reported effects of rapid treatment of hyponatremia is an osmotic demyelinating condition called central pontine myelinolysis, which produces serious neurologic sequelae and sometimes causes death. This complication occurs more commonly in premenopausal women and in people with hypoxia.

Hyponatremia

Hyponatremia implies a plasma sodium level above 145 mEq/L (145 mmol/L) and a serum osmolality less than 295 mOsm/kg. Because sodium is functionally an impermeable solute, it contributes to tonicity and induces movement of water across cell membranes. Hyponatremia is characterized by hypertonicity of ECF and almost always causes cellular dehydration.

Etiology. Hyponatremia represents a deficit of water in relation to the body’s sodium stores. It can be caused by net loss of water or sodium gain. Net water loss can occur through the urine, gastrointestinal tract, lungs, or skin. A defect in thirst or inability to obtain or drink water can interfere with water replacement. Rapid ingestion or infusion of sodium with insufficient time or opportunity for water ingestion can produce a disproportionate gain in sodium (Table 39.7). This can occur with critically ill people who present with multiple needs for fluid resuscitation and electrolyte balance. In fact hypernatremia is an independent risk factor linked highly with increased mortality.26

Hypernatremia almost always follows a loss of body fluids that have a lower-than-normal concentration of sodium, so that water is lost in excess of sodium. This can result from increased losses from the respiratory tract during fever or strenuous exercise, from watery diarrhea, or when osmotically active tube feedings are given with inadequate amounts of water. With pure water loss, each body fluid compartment loses an equal percentage of its volume. Because approximately one third of the water is in the ECF compartment, compared with the two thirds in the ICF compartment, more actual water volume is lost from the ICF than the ECF compartment.

Normally, water deficit stimulates thirst and increases water intake. Therefore, hypernatremia is more likely to occur in infants and in people who cannot express their thirst or obtain water to drink. With hypodipsia, or impaired thirst, the need for fluid intake does not activate the thirst response. Hypodipsia is particularly prevalent among older adults. In people with DI, hypernatremia can develop when thirst is impaired or access to water is impeded.

The therapeutic administration of sodium-containing solutions may also cause hypernatremia. Hypertonic saline solution intended for intra-amniotic instillation for therapeutic abortion may inadvertently be injected intravenously, causing hypernatremia. Rarely, salt intake occurs rapidly, as in taking excess salt tablets or during near-drowning in salt water.

Clinical Manifestations. The clinical manifestations of hypernatremia caused by water loss are largely those of ECF loss and cellular dehydration (see Table 39.7). The severity of signs and symptoms is greatest when the increase in plasma sodium is large and occurs rapidly. Body weight is decreased in proportion to the amount of water that has been lost. Because blood plasma is roughly 90% to 93% water, the concentrations of blood cells and other blood components increase as ECF water decreases.

Thirst is an early symptom of water deficit, occurring when water losses are equal to 0.5% of body water. Urine output is decreased and urine osmolality increased because of renal water-conserving mechanisms. Body temperature frequently is elevated, and the skin becomes warm and flushed. The vascular volume decreases, the pulse becomes rapid and thready, and the blood pressure drops. Hypernatremia produces an increase in serum osmolality and results in water being pulled out of body cells. As a result, the skin and mucous membranes become dry, and salivation and lacrimation are decreased. The mouth becomes dry and sticky, and the tongue becomes rough and fissured. Swallowing is difficult. The subcutaneous tissues assume a firm, rubbery texture. Most significantly, water is
pulled out of the cells in the CNS, causing decreased reflexes, agitation, headache, and restlessness. Coma and seizures may develop as hypernatremia progresses.

**Diagnosis and Treatment.** The diagnosis of hypernatremia is based on history, physical examination findings indicative of dehydration, and results of laboratory tests. The treatment of hypernatremia includes measures to treat the underlying cause of the disorder and fluid replacement therapy to treat the accompanying dehydration. Replacement fluids can be given orally or intravenously. The oral route is preferable. Oral glucose–electrolyte replacement solutions are available for the treatment of infants with diarrhea. Until recently, these solutions were used only early in diarrheal illness or as a first step in reestablishing oral intake after parenteral replacement therapy. These solutions are now widely available in grocery stores and pharmacies for use in the treatment of diarrhea and other dehydrating disorders in infants and young children.

One of the serious aspects of fluid volume deficit is dehydration of brain and nerve cells. Serum osmolality should be corrected slowly in cases of chronic hypernatremia. If hypernatremia is corrected too rapidly before the osmolytes have had a chance to dissipate, the plasma may become relatively hypotonic in relation to brain cell osmolality. When this occurs, water moves into the brain cells, causing cerebral edema and potentially severe neurologic impairment.

**IN SUMMARY**

Body fluids are distributed between the ICF and ECF compartments. Regulation of fluid volume, solute concentration, and distribution between the two compartments depends on water and sodium balance. Water provides approximately 90% to 93% of fluid volume, and sodium salts approximately 90% to 95% of extracellular solutes. Both water and sodium are absorbed from the gastrointestinal tract and eliminated by the kidneys. The main regulator of sodium and water is the maintenance of the effective circulating blood volume, which is monitored by stretch receptors in the vascular system, which exert their effects through ADH and the sympathetic nervous system, and those in the kidney, which exert their effects through the sympathetic nervous system and the RAAS. Body water and serum osmolality are also regulated by thirst, which controls water intake, and ADH, which controls urine concentration and renal output.

Isotonic fluid disorders result from contraction or expansion of ECF volume brought about by proportionate losses of sodium and water. **Isotonic fluid volume deficit** is characterized by a decrease in ECF volume. It causes thirst, decreased vascular volume and circulatory function, decreased urine output, and increased urine specific gravity. **Isotonic fluid volume excess** is characterized by
an increase in ECF volume. It is manifested by signs of increased vascular volume and edema. Alterations in extracellular sodium concentration are brought about by a disproportionate gain (hyponatremia) or loss (hyponatremia) of water. As the major cation in the ECF compartment, sodium controls the ECF osmolality and its effect on cell volume. Hyponatremia can present as a hypertonic (translocational) hyponatremia in which water moves out of the cell in response to elevated blood glucose levels or as a hypotonic (dilutional) hyponatremia that is caused by retention of water by the body in excess of sodium. Hypotonic hyponatremia, which can present as a hypovolemic, euvolemic, or hypervolemic state, is characterized by water being pulled into the cell from the ECF compartment, causing cells to swell. It is manifested by muscle cramps and weakness; nausea, vomiting, abdominal cramps, and diarrhea; and CNS signs such as headache, lethargy, depression of deep tendon reflexes, and in severe cases seizure and coma.

Hypernatremia represents a disproportionate loss of body water in relation to sodium. It is characterized by intracellular water being pulled into the ECF compartment, causing cells to shrink. It is manifested by thirst and decreased urine output; dry mouth and decreased tissue turgor; signs of decreased vascular volume (tachycardia, weak and thready pulse); and CNS signs such as decreased reflexes, agitation, headache, and in severe cases seizures and coma.

**Regulation of Potassium Balance**

Potassium is the second most abundant cation in the body and the major cation in the ICF compartment. Approximately 98% of body potassium is contained within body cells, with an intracellular concentration of 140 to 150 mEq/L (140 to 150 mmol/L). The potassium content of the ECF (3.5 to 5 mEq/L [3.5 to 5 mmol/L]) is considerably lower. Because potassium is an intracellular ion, the total body stores of potassium are related to body size and muscle mass. In adults, total body potassium is approximately 50 mEq/kg of body weight.28

**Gains and Losses**

Potassium intake is normally derived from dietary sources. In healthy people, potassium balance usually can be maintained by a daily dietary intake of 50 to 100 mEq. Additional amounts of potassium are needed during periods of trauma and stress. The kidneys are the main source of potassium loss. Approximately 80% to 90% of potassium losses occur in the urine, with the remainder being lost in stools or sweat.

**Mechanisms of Regulation**

Normally, the ECF concentration of potassium is precisely regulated at about 4.2 mEq/L (4.2 mmol/L). The precise control is necessary because many cell functions are sensitive to even small changes in ECF potassium levels. An increase in potassium of as small an amount as 0.3 to 0.4 mEq/L (0.3 to 0.4 mmol/L) can cause serious cardiac dysrhythmias and even death.

Plasma potassium is largely regulated through two mechanisms: (1) renal mechanisms that conserve or eliminate potassium and (2) a transcellular shift between the ICF and ECF compartments.

**Renal Regulation.** The major route for potassium elimination is the kidney. Unlike other electrolytes, the regulation of potassium elimination is controlled by secretion from the blood into the tubular filtrate rather than through reabsorption from the tubular filtrate into the blood. Potassium is filtered in the glomerulus, reabsorbed along with sodium and water in the proximal tubule and with sodium and chloride in the thick ascending loop of Henle, and then secreted into the late distal and cortical collecting tubules for elimination in the urine. The latter mechanism serves to “fine-tune” the concentration of potassium in the ECF.

Aldosterone plays an essential role in regulating potassium elimination by the kidney. The effects of aldosterone on potassium elimination are mediated through an Na⁺/K⁺ exchange mechanism located in the late distal and cortical collecting tubules of the kidney. In the presence of aldosterone, Na⁺ is transported back into the blood and K⁺ is secreted in the tubular filtrate for elimination in the urine. The rate of aldosterone secretion by the adrenal gland is strongly controlled by plasma potassium levels. For example, an increase of less than 1 mEq/L (1 mmol/L) of potassium causes aldosterone levels to triple.2 The effect of plasma potassium on aldosterone secretion is an example of the powerful feedback regulation of potassium elimination. In the absence of aldosterone, as occurs in people with Addison disease, renal elimination of potassium is impaired, causing plasma potassium levels to rise to dangerously high levels. Aldosterone is often referred to as a mineralocorticoid hormone because of its effect on sodium and potassium. The term mineralocorticoid activity is used to describe the aldosterone-like actions of other adrenocortical hormones, such as cortisol.

There is also a K⁺/H⁺ exchange mechanism in the cortical collecting tubules of the kidney. When plasma potassium levels are increased, K⁺ is secreted into the urine and H⁺ is reabsorbed into the blood, producing a decrease in pH and metabolic acidosis. Conversely, when potassium levels are

**POTASSIUM BALANCE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the distribution of potassium in the body and explain how extracellular potassium levels are regulated in relation to body gains and losses.
- Relate the functions of potassium to the manifestations of hypokalemia and hyperkalemia.

**Regulation of Potassium Balance**

Potassium is the second most abundant cation in the body and the major cation in the ICF compartment. Approximately 98% of body potassium is contained within body cells, with an intracellular concentration of 140 to 150 mEq/L (140 to 150 mmol/L). The potassium content of the ECF (3.5 to 5 mEq/L [3.5 to 5 mmol/L]) is considerably lower. Because potassium is an intracellular ion, the total body stores of potassium are related to body size and muscle mass. In adults, total body potassium is approximately 50 mEq/kg of body weight.28

**Gains and Losses**

Potassium intake is normally derived from dietary sources. In healthy people, potassium balance usually can be maintained by a daily dietary intake of 50 to 100 mEq. Additional amounts of potassium are needed during periods of trauma and stress. The kidneys are the main source of potassium loss. Approximately 80% to 90% of potassium losses occur in the urine, with the remainder being lost in stools or sweat.

**Mechanisms of Regulation**

Normally, the ECF concentration of potassium is precisely regulated at about 4.2 mEq/L (4.2 mmol/L). The precise control is necessary because many cell functions are sensitive to even small changes in ECF potassium levels. An increase in potassium of as small an amount as 0.3 to 0.4 mEq/L (0.3 to 0.4 mmol/L) can cause serious cardiac dysrhythmias and even death.

Plasma potassium is largely regulated through two mechanisms: (1) renal mechanisms that conserve or eliminate potassium and (2) a transcellular shift between the ICF and ECF compartments.

**Renal Regulation.** The major route for potassium elimination is the kidney. Unlike other electrolytes, the regulation of potassium elimination is controlled by secretion from the blood into the tubular filtrate rather than through reabsorption from the tubular filtrate into the blood. Potassium is filtered in the glomerulus, reabsorbed along with sodium and water in the proximal tubule and with sodium and chloride in the thick ascending loop of Henle, and then secreted into the late distal and cortical collecting tubules for elimination in the urine. The latter mechanism serves to “fine-tune” the concentration of potassium in the ECF.

Aldosterone plays an essential role in regulating potassium elimination by the kidney. The effects of aldosterone on potassium elimination are mediated through an Na⁺/K⁺ exchange mechanism located in the late distal and cortical collecting tubules of the kidney. In the presence of aldosterone, Na⁺ is transported back into the blood and K⁺ is secreted in the tubular filtrate for elimination in the urine. The rate of aldosterone secretion by the adrenal gland is strongly controlled by plasma potassium levels. For example, an increase of less than 1 mEq/L (1 mmol/L) of potassium causes aldosterone levels to triple.2 The effect of plasma potassium on aldosterone secretion is an example of the powerful feedback regulation of potassium elimination. In the absence of aldosterone, as occurs in people with Addison disease, renal elimination of potassium is impaired, causing plasma potassium levels to rise to dangerously high levels. Aldosterone is often referred to as a mineralocorticoid hormone because of its effect on sodium and potassium. The term mineralocorticoid activity is used to describe the aldosterone-like actions of other adrenocortical hormones, such as cortisol.

There is also a K⁺/H⁺ exchange mechanism in the cortical collecting tubules of the kidney. When plasma potassium levels are increased, K⁺ is secreted into the urine and H⁺ is reabsorbed into the blood, producing a decrease in pH and metabolic acidosis. Conversely, when potassium levels are
low, K⁺ is reabsorbed and H⁺ is secreted in the urine, leading to metabolic alkalosis.

**Extracellular–Intracellular Shifts.** To avoid an increase in extracellular potassium levels, excess potassium is temporarily shifted into RBCs and other cells such as those of muscle, liver, and bone. This movement is controlled by the function of the Na⁺/K⁺-ATPase membrane pump and the permeability of the ion channels in the cell membrane.

Among the factors that alter the intracellular–extracellular distribution of potassium are serum osmolality, acid–base disorders, insulin, and β-adrenergic stimulation. Acute increases in serum osmolality cause water to leave the cell. The loss of cell water produces an increase in intracellular potassium, causing it to move out of the cell into the ECF.

The H⁺ and K⁺ ions, which are positively charged, can be exchanged between the ICF and ECF in a cation shift (Fig. 39.8). In metabolic acidosis, for example, H⁺ moves into body cells for buffering, causing K⁺ to leave and move into the ECF. Insulin and the catecholamines (e.g., epinephrine) increase cellular uptake of K⁺ by increasing the activity of the Na⁺/K⁺-ATPase membrane pump. Insulin produces an increase in cellular uptake of potassium after a meal. The catecholamines, particularly epinephrine, facilitate the movement of potassium into muscle tissue during periods of physiologic stress. β-Adrenergic agonist drugs, such as pseudoephedrine and albuterol, have a similar effect on potassium distribution.

Exercise also produces compartmental shifts in potassium. Repeated muscle contraction releases potassium into the ECF. Although the increase usually is small with modest exercise, it can be considerable during exhaustive exercise. Even the repeated clenching and unclenching of the fist during a blood draw can cause potassium to move out of cells and artificially elevate plasma potassium levels.

**Disorders of Potassium Balance**

As the major intracellular cation, potassium is critical to many body functions. It is involved in a wide range of body functions, including the maintenance of the osmotic integrity of cells, acid–base balance, and the kidney’s ability to concentrate urine. Potassium is necessary for growth and it contributes to the intricate chemical reactions that transform carbohydrates into energy, change glucose into glycogen, and convert amino acids to proteins. Potassium also plays a critical role in conducting nerve impulses and the excitability of skeletal, cardiac, and smooth muscle tissue. It does this by regulating the following:

- The resting membrane potential
- The opening of the sodium channels that control the flow of current during the action potential
- The rate of membrane repolarization

Changes in nerve and muscle excitability are particularly important in the heart, where alterations in plasma potassium can produce serious cardiac arrhythmias and conduction defects. Changes in plasma potassium also affect skeletal muscles and the smooth muscle in blood vessels and the gastrointestinal tract.

The resting membrane potential is determined by the ratio of ICF to ECF potassium concentration (Fig. 39.9). A decrease in plasma potassium causes the resting membrane potential to become more negative, moving it further from the threshold for excitation. Thus, it takes a greater stimulus to reach threshold and open the sodium channels that are responsible for the action potential. An increase in plasma potassium has the opposite effect; it causes the resting membrane potential to become more positive, moving it closer to threshold. With severe hyperkalemia, there may be prolonged depolarization that can decrease excitability. The rate of repolarization varies with
plasma potassium levels. It is more rapid in hyperkalemia and delayed in hypokalemia. Both the inactivation of the sodium channels and the rate of membrane repolarization are important clinically because they predispose to cardiac arrhythmias or conduction defects. Hyperkalemia is one of the most life-threatening electrolyte disturbances especially with children.29

**Hypokalemia**

Hypokalemia refers to a decrease in plasma potassium levels below 3.5 mEq/L (3.5 mmol/L). Because of transcellular shifts, temporary changes in plasma potassium may occur as the result of movement between the ICF and ECF compartments.

**Etiology.** The causes of potassium deficit can be grouped into three categories: (1) inadequate intake; (2) excessive gastrointestinal, renal, and skin losses; and (3) redistribution between the ICF and ECF compartments (Table 39.8).30

**Inadequate Intake** Inadequate intake is a frequent cause of hypokalemia. A potassium intake of at least 40 to 50 mEq/day is needed daily. Insufficient dietary intake may result

</table>
from the inability to obtain or ingest food or from a diet that is low in potassium-containing foods. Potassium intake is often inadequate in persons onfad diets and those who have eating disorders. Older adults are particularly likely to have potassium deficits. Many have poor eating habits as a consequence of living alone; they may have limited income, which makes buying foods high in potassium difficult; they may have difficulty chewing many foods that have high potassium content because of dental problems; or they may have problems with swallowing.

Excessive Losses. The kidneys are the main source of potassium loss. Approximately 80% to 90% of potassium losses occur in the urine, with the remaining losses occurring in the stool and sweat. The kidneys do not have the homeostatic mechanisms needed to conserve potassium during periods of insufficient intake. After trauma and in stress situations, urinary losses of potassium are generally increased and can cause a serious hypokalemia.30 This means that a potassium deficit can develop rather quickly if intake is inadequate. Renal losses also can be increased by medications such as thiazides, metabolic alkalosis, magnesium depletion, and increased levels of aldosterone. Some antibiotics, particularly amphotericin B and gentamicin, are impermeable anions that require the presence of positively charged cations for elimination in the urine; this causes potassium wasting.

Diuretic therapy, with the exception of potassium-sparing diuretics, is the most common cause of hypokalemia. Both thiazide and loop diuretics increase the loss of potassium in the urine. The degree of hypokalemia is directly related to diuretic dose and the urine. Increased potassium losses occur in situations such as trauma and surgery that produce a stress-related increase in these hormones. Primary aldosteronism, caused by either a tumor or hyperplasia of the cells of the adrenal cortex that secrete aldosterone, produces severe potassium losses and a decrease in plasma potassium levels.31 Cortisol binds to aldosterone receptors and exerts aldosterone-like effects on potassium conservation.

Renal losses of potassium are accentuated by aldosterone and cortisol. Increased potassium losses occur in situations such as trauma and surgery that produce a stress-related increase in these hormones. Primary aldosteronism, caused by either a tumor or hyperplasia of the cells of the adrenal cortex that secrete aldosterone, produces severe potassium losses and a decrease in plasma potassium levels.31 Cortisol binds to aldosterone receptors and exerts aldosterone-like effects on potassium conservation.

Other rare, genetic disorders that can also result in hypokalemia are the Bartter, Gitelman, and Liddle syndromes. Bartter syndrome, which involves the Na⁺/K⁺/2Cl⁻ cotransporter in the thick loop of Henle, is manifested by metabolic alkalosis, hypercalcia and hypocalciuria or excess loss of calcium in the urine, and normal blood pressure.32 Because the loop diuretics act at the same site in the kidney, these features are identical to those seen with chronic loop diuretic ingestion. The manifestations of Gitelman syndrome, which involves the Na⁺/Cl⁻ transporter in the distal tubule, are similar to those of Bartter syndrome, but with hypocalciuria and hypomagnesemia due to renal magnesium wasting.34 Because this is the site where the thiazide diuretics exert their action, these manifestations are identical to those seen with chronic thiazide diuretic ingestion. Liddle syndrome has manifestations similar to Bartter syndrome, but with high blood pressure due to excessive sodium reabsorption.35

Although potassium losses from the skin and the gastrointestinal tract usually are minimal, these losses can become excessive under certain conditions. For example, burns increase surface losses of potassium. Losses due to sweating increase in persons who are acclimated to a hot climate, partly because increased secretion of aldosterone during heat acclimatization increases the loss of potassium in urine and sweat. Gastrointestinal losses also can become excessive; this occurs with vomiting and diarrhea and when gastrointestinal suction is being used. The potassium content of liquid stools, for example, is approximately 40 to 60 mEq/L (40 to 60 mmol/L).

Transcellular Shifts. Because of the high ratio of intracellular to extracellular potassium, conditions that produce a redistribution of potassium from the ECF to the ICF compartment can cause a marked decrease in plasma potassium levels (see Fig. 39.8). Insulin increases the movement of glucose and potassium into cells; therefore, potassium deficit often develops during treatment of diabetic ketoacidosis. A wide variety of β₂-adrenergic agonist drugs (e.g., decongestants and bronchodilators) shift potassium into cells and cause transient hypokalemia.

Clinical Manifestations. The manifestations of hypokalemia include alterations in renal, gastrointestinal, cardiovascular, and neuromuscular function (see Table 39.8). These manifestations reflect both the intracellular functions of potassium as well as the body’s attempt to regulate ECF potassium levels within the very narrow range needed to maintain the normal electrical activity of excitable tissues such as nerve and muscle cells. The signs and symptoms of potassium deficit seldom develop until plasma potassium levels have fallen to levels below 3 mEq/L (3 mmol/L). They are typically gradual in onset, and therefore the disorder may go undetected for some time.

The renal processes that conserve potassium during hypokalemia interfere with the kidney’s ability to concentrate urine. Urine output and plasma osmolality are increased, urine specific gravity is decreased, and complaints of polyuria, nocturia, and thirst are common (an example of nephrogenic DI). Metabolic alkalosis and renal chloride wasting are signs of severe hypokalemia.36

There are numerous signs and symptoms associated with gastrointestinal function, including anorexia, nausea, and vomiting. Atony of the gastrointestinal smooth muscle can cause constipation, abdominal distention, and, in severe hypokalemia, paralytic ileus. When gastrointestinal symptoms occur gradually and are not severe, they often impair potassium intake and exaggerate the condition.

The most serious effects of hypokalemia are those affecting cardiovascular function. Postural hypotension is common. Most people with plasma potassium levels below 3 mEq/L (3 mmol/L) demonstrate electrocardiographic (ECG) changes
Complaints of weakness, fatigue, and muscle cramps, particularly during exercise, are common in moderate hypokalemia (plasma potassium 3 to 2.5 mEq/L [3 to 2.5 mmol/L]). Muscle paralysis with life-threatening respiratory insufficiency can occur with severe hypokalemia (plasma potassium <2.5 mEq/L [2.5 mmol/L]). Leg muscles, particularly the quadriceps, are most prominently affected. Some people complain of muscle tenderness and paresthesias rather than weakness. In chronic potassium deficiency, muscle atrophy may contribute to muscle weakness.

In a rare genetic condition called hypokalemic familial periodic paralysis, episodes of hypokalemia cause attacks of severe muscle weakness and flaccid paralysis that last 6 to 48 hours if untreated. The paralysis may be precipitated by situations that cause severe hypokalemia by producing an intracellular shift in potassium, such as ingestion of a high-carbohydrate meal or administration of insulin, epinephrine, or glucocorticoid drugs. The paralysis often can be reversed by potassium replacement therapy.

**Treatment.** When possible, hypokalemia caused by potassium deficit is treated by increasing the intake of foods high in potassium content—meats, dried fruits, fruit juices (particularly orange juice), and bananas. Oral potassium supplements are prescribed for persons whose intake of potassium is insufficient in relation to losses. This is particularly true of people who are receiving diuretic therapy and those who are taking digitalis.

Potassium may be given intravenously when the oral route is not tolerated or when rapid replacement is needed. It is necessary to consistently measure serum magnesium levels because if a person has hypokalemia they often also have magnesium deficiency. The rapid infusion of a concentrated potassium solution can cause death from cardiac arrest. Health personnel who assume responsibility for administering intravenous solutions that contain potassium should be fully aware of all the precautions pertaining to their dilution and flow rate.

**Hyperkalemia**

Hyperkalemia refers to an increase in plasma levels of potassium in excess of 5 mEq/L (5 mmol/L). It seldom occurs in healthy people because the body is extremely effective in preventing excess potassium accumulation in the ECF.

**Etiology.** The three major causes of potassium excess are (1) decreased renal elimination, (2) excessively rapid administration, and (3) movement of potassium from the ICF to ECF compartment (Table 39.9). A pseudohyperkalemia can occur secondary to release of potassium from intracellular stores after a blood sample has been collected, hemolysis of RBCs from excessive agitation of a blood sample, traumatic venipuncture, or prolonged application of a tourniquet during venipuncture.

The most common cause of hyperkalemia is decreased renal function. Chronic hyperkalemia is almost always associated with renal failure. Usually, the glomerular filtration rate must decline to less than 10 mL/minute before hyperkalemia develops. Some renal disorders, such as sickle cell
renal function is adequate and the aldosterone Na+/K+ exchange system is functioning. An exception to this rule is the intravenous route of administration. In some cases, severe and fatal incidents of hyperkalemia have occurred when intravenous potassium solutions were infused too rapidly. Because the kidneys control potassium elimination, intravenous solutions that contain potassium should never be started until urine output has been assessed and renal function has been deemed to be adequate.

The movement of potassium out of body cells into the ECF also can lead to elevated plasma potassium levels. Tissue injury causes release of intracellular potassium into the ECF compartment. For example, burns and crushing injuries cause cell death and release of potassium into the ECF. The same injuries often diminish renal function, which contributes to the development of hyperkalemia. Transient hyperkalemia may be induced during extreme exercise or seizures, when muscle cells are permeable to potassium. In a rare autosomal dominant disorder called hyperkalemic periodic paralysis, hyperkalemia may cause transient periods of muscle weakness and paralysis after exercise, cold exposure, or other situations that cause potassium to move out of the cells. These hyperkalemic-induced periods of paralysis tend to be short in duration.40

Clinical Manifestations. The signs and symptoms of potassium excess are closely related to a decrease in neuromuscular excitability (see Table 39.9). The neuromuscular manifestations of potassium excess usually are absent until the plasma concentration exceeds 6 mEq/L (6 mmol/L). The first symptom associated with hyperkalemia typically is paresthesia. There may be complaints of generalized muscle weakness or dyspnea secondary to respiratory muscle weakness.

The most serious effect of hyperkalemia is on the heart. As potassium levels increase, disturbances in cardiac conduction occur. The earliest changes are peaked, narrow T waves and widening of the QRS complex. If plasma levels continue to rise, the PR interval becomes prolonged, followed by disappearance of P waves (see Fig. 39.10). The heart rate may be slow. Ventricular fibrillation and cardiac arrest are terminal events. Detrimental effects of hyperkalemia on the heart are most pronounced when the plasma potassium level rises rapidly. It is important to realize that multiple transfusions of RBCs can cause hyperkalemia and, if the transfusions are given rapidly, this is potentially life threatening.41

Diagnosis and Treatment. Diagnosis of hyperkalemia is based on complete history, physical examination to detect muscle weakness and signs of volume depletion, plasma potassium levels, and ECG findings. The history should include questions about dietary intake, use of potassium-sparing diuretics, history of kidney disease, and recurrent episodes of muscle weakness.
The treatment of potassium excess varies with the degree of increase in plasma potassium and whether there are ECG and neuromuscular manifestations. Calcium antagonizes the potassium-induced decrease in membrane excitability, restoring excitability toward normal. The protective effect of calcium administration is usually short-lived (15 to 30 minutes), and it must be accompanied by other therapies to decrease the ECF potassium concentration. The administration of sodium bicarbonate, β-adrenergic agonists (e.g., nebulized albuterol), or insulin distributes potassium into the ICF compartment and rapidly decreases the ECF concentration. Intravenous infusions of insulin and glucose are often used for this purpose.

Less emergent measures focus on decreasing or curtailing intake or absorption, increasing renal excretion, and increasing cellular uptake. Decreased intake can be achieved by restricting dietary sources of potassium. The major ingredient in most salt substitutes is potassium chloride, and such substitutes should not be given to people with renal problems. Increasing potassium output often is more difficult. People with renal failure may require hemodialysis or peritoneal dialysis to reduce plasma potassium levels. Sodium polystyrene sulfonate, a cation exchange resin, also may be used to remove K+ ions from plasma potassium levels. Sodium polystyrene sulfonate, a cation exchange resin, also may be used to remove K+ ions from plasma potassium levels.

The Na+ ions in the resin are exchanged for K+ ions, and the potassium-containing resin is eliminated in the stool. Potassium is the major ICF cation. It contributes to the maintenance of intracellular osmolality; plays a critical role in conducting nerve impulses and in the excitability of skeletal, cardiac, and smooth muscle; and influences acid–base balance. Potassium is ingested in the diet and eliminated through the kidney. Because potassium is poorly conserved by the kidney, an adequate daily intake is needed. A transcellular shift can produce a redistribution of potassium between the ECF and ICF compartments, causing blood levels to increase or decrease.

Hypokalemia represents a decrease in plasma potassium to levels below 3.5 mEq/L (3.5 mmol/L). It can result from inadequate intake, excessive losses, or redistribution between the ICF and ECF compartments. The manifestations of potassium deficit include alterations in renal, skeletal muscle, gastrointestinal, and cardiovascular function, reflecting the crucial role of potassium in cell metabolism and neuromuscular function.

Hyperkalemia represents an increase in plasma potassium to levels plasma greater than 5 mEq/L (5 mmol/L). It seldom occurs in healthy people because the body is extremely effective in preventing excess potassium accumulation in the ECF. The major causes of potassium excess are decreased elimination of potassium by the kidney, excessively rapid intravenous administration of potassium, and a transcellular shift of potassium out of the cell to the ECF compartment. The most serious effect of hyperkalemia is cardiac arrest.

**IN SUMMARY**

Potassium is the major ICF cation. It contributes to the maintenance of intracellular osmolality; plays a critical role in conducting nerve impulses and in the excitability of skeletal, cardiac, and smooth muscle; and influences acid–base balance. Potassium is ingested in the diet and eliminated through the kidney. Because potassium is poorly conserved by the kidney, an adequate daily intake is needed. A transcellular shift can produce a redistribution of potassium between the ECF and ICF compartments, causing blood levels to increase or decrease.

**Mechanisms Regulating Calcium, Phosphorus, and Magnesium Balance**

Calcium, phosphorus, and magnesium are the major cations in the body. They are ingested in the diet, absorbed from the intestine, filtered in the glomerulus of the kidney, reabsorbed in the renal tubules, and eliminated in the urine. Approximately 99% of calcium, 85% of phosphorus, and 50% to 60% of magnesium are found in bone. Most of the remaining calcium (approximately 1%), phosphorus (approximately 14%), and magnesium (approximately 40% to 50%) are located inside cells. Only a small amount of these three ions is present in ECF. This small, but vital, amount of ECF calcium, phosphorus, and magnesium is directly or indirectly regulated by vitamin D and parathyroid hormone (PTH). Calcitonin, a hormone produced by C cells in the thyroid, is thought to act on the kidney and bone to remove calcium from the extracellular circulation.

**Vitamin D**

Although classified as a vitamin, vitamin D functions as a hormone. It acts to sustain normal plasma levels of calcium and phosphorus by increasing their absorption from the intestine, and it also is necessary for normal bone formation. Vitamin D is synthesized by ultraviolet irradiation of 7-dehydrocholesterol, which is present in the skin or obtained from foods in the diet, many of which are fortified with vitamin D. The synthesized or ingested forms of vitamin D are essentially prohormones that lack biologic activity and must undergo metabolic transformation to achieve potency. Once vitamin D enters the circulation from the skin or intestine, it is concentrated in the liver. There it is hydroxylated to form 25-hydroxyvitamin D [25-(OH)D₃], also called calcidiol. It is then transported to the kidney, where it is transformed into active 1,25-(OH)₂D₃, also called calcitriol. It is the major action of the activated form of vitamin D, also called calcitriol, to increase the absorption of calcium from the intestine. Calcitriol also sensitizes bone to the resorptive actions of PTH. There is evidence that vitamin D controls parathyroid gland growth and suppresses...
the synthesis and secretion of PTH. The formation of 1,25-(OH)_2D_3 in the kidneys is regulated in feedback fashion by plasma calcium and phosphate levels. Low calcium levels lead to an increase in PTH, which then increases vitamin D activation. A lowering of plasma phosphate also augments vitamin D activation. Additional control of renal activation of vitamin D is exerted by a negative feedback loop that monitors 1,25-(OH)_2D_3 levels.

**Parathyroid Hormone**

PTH, a major regulator of plasma calcium and phosphorus, is secreted by the parathyroid glands. There are four parathyroid glands located on the dorsal surface of the thyroid gland. The dominant regulator of PTH is the plasma calcium concentration. A unique calcium receptor on the parathyroid cell membrane (extracellular calcium-sensing receptor) responds rapidly to changes in plasma calcium levels. When the plasma calcium level is high, PTH is inhibited and the calcium is deposited in the bones. When the level is low, PTH secretion is increased and calcium is mobilized from the bones. The response to a decrease in plasma calcium is prompt, occurring within seconds. Phosphorus does not exert a direct effect on PTH secretion. Instead, it acts indirectly by forming a complex with calcium, thereby decreasing the plasma calcium concentration.

The secretion, synthesis, and action of PTH are also influenced by magnesium. Magnesium serves as a cofactor in the generation of cellular energy and is important in the function of second messenger systems. Magnesium’s effects on the synthesis and release of PTH are thought to be mediated through these mechanisms. Because of its function in regulating PTH release, severe and prolonged hypomagnesemia can markedly inhibit PTH levels.

The main function of PTH is to maintain the calcium concentration of the ECF. It performs this function by promoting the release of calcium from bone, increasing the activation of vitamin D as a means of enhancing intestinal absorption of calcium, and stimulating calcium conservation by the kidney while increasing phosphate excretion (Fig. 39.11). PTH acts on bone to accelerate the mobilization and transfer of calcium to the ECF. The skeletal response to PTH is a two-step process. There is an immediate response in which calcium that is present in bone fluid is released into the ECF and a second, more slowly developing response in which completely mineralized bone is resorbed, resulting in the release of both calcium and phosphorus. The actions of PTH in terms of bone resorption require normal levels of both vitamin D and magnesium. The activation of vitamin D by the kidney is enhanced by the presence of PTH; it is through the activation of vitamin D that PTH increases intestinal absorption of calcium and phosphorus as well as acting on the kidney to increase tubular reabsorption of calcium and magnesium while increasing phosphorus elimination. The accompanying increase in phosphorus elimination ensures that the phosphorus released from bone does not produce hyperphosphatemia and increases the risk of soft tissue deposition of calcium phosphate crystals.

**Hypoparathyroidism.** Hypoparathyroidism reflects deficient PTH secretion, resulting in hypocalcemia. PTH deficiency may be caused by a congenital absence of all of the parathyroid glands, as in DiGeorge syndrome. An acquired deficiency of PTH may occur after neck surgery, particularly if the surgery involves removal of a parathyroid adenoma, thyroidectomy, or bilateral neck resection for cancer. A transient form of PTH deficiency, occurring within 1 to 2 days and lasting up to 5 days, may occur after thyroid surgery owing to parathyroid gland suppression. Hypoparathyroidism also may have an autoimmune origin. Antiparathyroid antibodies have been detected in some persons with hypoparathyroidism, particularly those with multiple autoimmune disorders such as type 1 diabetes, Graves disease, Hashimoto disease, and vitiligo (autoimmune destruction of melanocytes resulting in the development of totally white areas of skin). Other causes of hypoparathyroidism include heavy metal damage such as that occurring in Wilson disease, metastatic tumors, and surgery. Functional impairment of parathyroid function occurs with magnesium deficiency. Correction of the hypomagnesemia results in rapid disappearance of the condition.

Manifestations of acute hypoparathyroidism, which result from a decrease in plasma calcium, include tetany with muscle cramps, carpopedal spasm, and convulsions. Paresthesias, such as tingling of the circumoral area and the hands and feet, are almost always present. Low calcium levels may cause prolongation of the QT interval, resistance to digitalis, hypotension, and refractory heart failure. Symptoms of chronic PTH deficiency include lethargy, anxiety state, and personality changes. There may be blurring of vision because of cataracts, which develop over a number of years. Extrapyramidal signs,
such as those seen with Parkinson disease, may occur because of calcification of the basal ganglia. Successful treatment of the hypocalcemia may improve the disorder and is sometimes associated with a decrease in basal ganglia calcification on radiography. Teeth may be defective if the disorder occurs during childhood.

Diagnosis of hypoparathyroidism is based on low plasma calcium levels, high plasma phosphate levels, and low plasma PTH levels. Plasma magnesium levels usually are measured to rule out hypomagnesemia as a cause of the disorder. Acute hyperparathyroid tetany is treated with intravenous calcium gluconate followed by oral administration of calcium salts and vitamin D. Magnesium supplementation is used when the disorder is caused by magnesium deficiency. Persons with chronic hypoparathyroidism are treated with oral calcium and vitamin D. Plasma calcium levels are monitored at regular intervals (at least every 3 months) as a means of maintaining plasma calcium within a slightly low but asymptomatic range. Maintaining plasma calcium within this range helps to prevent hypercalciumia and kidney damage.

Pseudohypoparathyroidism is a rare familial disorder characterized by target tissue resistance to PTH. It is characterized by hypocalcemia, increased parathyroid function, and a variety of congenital defects in the growth and development of the skeleton, including short stature and short metacarpal and metatarsal bones. There are variants in the disorder, with some persons having pseudohypoparathyroidism with the congenital defects and others having the congenital defects with normal calcium and phosphate levels. The manifestations of the disorder are due primarily to chronic hypocalcemia. Treatment is similar to that for hypoparathyroidism.

**Hyperparathyroidism.** Hyperparathyroidism is caused by hypersecretion of PTH. Hyperparathyroidism can manifest as a primary disorder caused by hyperplasia (15%), an adenoma (85%), and rarely carcinoma of the parathyroid glands, or as a secondary disorder seen in people with chronic renal failure or chronic malabsorption of calcium. Parathyroid adenomas and hyperplasia can occur in several distinct familial diseases (including multiple endocrine neoplasia [MEN] types 1 and 2a).

Primary hyperparathyroidism is seen more commonly after 50 years of age and is more common in women than men. Primary hyperparathyroidism causes hypercalcemia and an increase in calcium in the urine filtrate, resulting in hypercalcuiuria and the potential for development of kidney stones. Chronic bone resorption may produce diffuse demineralization, pathologic fractures, and cystic bone lesions. A dual-energy x-ray absorptiometry (DEXA) bone scan may be used to assess bone mineral density (BMD). Signs and symptoms of the disorder are related to skeletal abnormalities, exposure of the kidney to high calcium levels, and elevated plasma calcium levels. At present, most people with primary hyperparathyroidism manifest an asymptomatic disorder that is discovered in the course of routine biochemical testing.

Diagnostic procedures, which include plasma calcium levels and intact PTH levels, are used to differentiate between the two most common causes of hypercalcemia: primary hyperparathyroidism and hypercalcemia of malignancy (HCM). Assays of intact PTH use two antibodies that bind to different sites on PTH and are designed to measure the intact, biologically active hormone, specifically. In primary hyperparathyroidism the intact PTH levels are elevated in 75% to 90% of affected persons or are inappropriately “normal” in the face of hypercalcemia, when they should be suppressed. In HCM, the intact PTH levels are suppressed. Imaging studies of the parathyroid area may be used to identify a parathyroid adenoma. However, the role of imaging studies before and during surgery is the topic of much debate. Parathyroid surgery is usually the treatment of choice.

Secondary hyperparathyroidism involves hyperplasia of the parathyroid glands and occurs primarily in persons with renal failure. In early renal failure, an increase in PTH results from decreased plasma calcium and activated vitamin D levels. As the disease progresses, there is a decrease in vitamin D and calcium receptors, making the parathyroid glands more resistant to feedback regulation by plasma calcium and vitamin D level. At this point, elevated plasma phosphate levels induce hyperplasia of the parathyroid glands independent of calcium and activated vitamin D. The bone disease seen in people with secondary hyperparathyroidism caused by renal failure is known as *chronic kidney disease–mineral bone disorder (CKD–MBD).* This disorder has three major pathophysiologic manifestations including abnormal metabolism of calcium, phosphate, vitamin D, or PTH; calcification of soft tissue or vessels; and abnormalities in bone turnover. CKD–MBD was formerly called renal osteodystrophy. Evidence suggests that with CKD–MBD, the increased phosphorus levels cause atherosclerosis by increasing the thickness of the carotid intima–media.

Treatment of hyperparathyroidism includes resolving the hypercalcemia with increased fluid intake. People with mild disease are advised to keep active and drink adequate fluids. They also are advised to avoid calcium-containing antacids, vitamin D, and thiazide diuretics, which increase reabsorption of calcium by the kidney. Parathyroidectomy may be indicated in people with symptomatic hyperparathyroidism, kidney stones, or bone disease. Avoiding hyperphosphatemia may lessen the problems of CKD–MBD caused by secondary hyperparathyroidism in renal failure. Calcium acetate or a calcium-free agent (sevelamer HCl [Renagel]) can be given with meals to bind phosphate. Calcitriol, the activated form of vitamin D, may be used to control parathyroid hyperplasia and suppress the synthesis and secretion of PTH. However, because of its potent effect on intestinal absorption and bone mobilization, calcitriol can cause hypercalcemia. Newer analogs of activated vitamin D are being developed that retain the ability to suppress parathyroid function while having minimal effects on calcium or phosphorus reabsorption.
Disorders of Calcium Balance

Calcium enters the body through the gastrointestinal tract, is absorbed from the intestine under the influence of vitamin D, stored in bone, and excreted by the kidney. Approximately 99% of body calcium is found in bone, where it provides strength and stability for the skeletal system and serves as an exchangeable source to maintain extracellular calcium levels. Most of the remaining calcium (approximately 1%) is located inside cells, and only approximately 0.1% to 0.2% (approximately 8.5 to 10.5 mg/dL [2.1 to 2.6 mmol/L]) of the remaining calcium is present in the ECF.

The ECF calcium exists in three forms: (1) protein bound, (2) complexed, and (3) ionized (Fig. 39.11). Approximately 40% of ECF calcium is bound to plasma proteins, mostly albumin, and cannot diffuse or pass through the capillary wall to leave the vascular compartment. Another 10% is complexed (i.e., chelated) with substances such as citrate, phosphate, and sulfate. This form is not ionized. The remaining 50% of ECF calcium is present in the ionized form. It is the ionized form of calcium that is free to leave the vascular compartment and participate in cellular functions. The total plasma calcium level fluctuates with changes in plasma albumin and pH. Ionized calcium serves a number of functions. It participates in many enzyme reactions; exerts an important effect on membrane potentials and neuronal excitability; is necessary for contraction in skeletal, cardiac, and smooth muscle; participates in the release of hormones, neurotransmitters, and other chemical messengers; influences cardiac contractility and automaticity through the slow calcium channels; and is essential for blood clotting. The use of calcium channel–blocking drugs in circulatory disorders demonstrates the importance of Ca\(^{2+}\) ions in the normal functioning of the heart and blood vessels. Calcium is required for all but the first two steps of the intrinsic pathway for blood coagulation. Because of its ability to bind calcium, citrate often is used to prevent clotting in blood that is to be used for transfusions. Studies indicate that admission ionized calcium (iCa) levels in people who are critically ill due to trauma are predictors for the need for multiple blood transfusions and also the low iCa levels predict mortality.50,51

Gains and Losses

The major dietary sources of calcium are milk and milk products. Only 30% to 50% of dietary calcium is absorbed from the duodenum and upper jejunum; the remainder is eliminated in the stool. There is a calcium influx of approximately 150 mg/day into the intestine from the blood. Net absorption of calcium is equal to the amount that is absorbed from the intestine less the amount that moves into the intestine. Calcium balance can become negative when dietary intake (and calcium absorption) is less than intestinal secretion.

Calcium is stored in bone and excreted by the kidney. Approximately 60% to 65% of filtered calcium is passively reabsorbed in the proximal tubule, driven by the reabsorption of NaCl; 15% to 20% is reabsorbed in the thick ascending loop of Henle, driven by the Na\(^+/K^+\)/2Cl\(^-\) cotransport system; and 5% to 10% is reabsorbed in the distal convoluted tubule. The distal convoluted tubule is an important regulatory site for controlling the amount of calcium that enters the urine. PTH and possibly vitamin D stimulate calcium reabsorption in this segment of the nephron. Thiazide diuretics, which exert their effects in the distal convoluted tubule, enhance calcium reabsorption. Other factors that may influence calcium reabsorption in the distal convoluted tubule are phosphate levels and glucose and insulin levels.

Hypocalcemia

Hypocalcemia represents a plasma calcium level of less than 8.5 mg/dL (2.1 mmol/L). Hypocalcemia occurs in many forms of critical illness and has affected as much 70% of people in intensive care units.52

Etiology. The causes of hypocalcemia can be divided into four categories: (1) impaired ability to mobilize calcium from bone stores, (2) abnormal losses of calcium from the kidney, (3) increased protein binding or chelation such that greater proportions of calcium are in the nonionized form, and (4) soft tissue sequestration (Table 39.10). A pseudohypocalcemia is caused by hypoalbuminemia. In this case, a malnourished person may indicate a low serum total calcium level, but have no symptoms.

Plasma calcium exists in a dynamic equilibrium with calcium in bone. The ability to mobilize calcium from bone depends on adequate levels of PTH. Decreased levels of PTH may result from primary or secondary forms of hypoparathyroidism. Suppression of PTH release may also occur when vitamin D levels are elevated. The activated form of vitamin D (calcitriol) can be used to suppress the secondary hyperparathyroidism that occurs in persons with chronic kidney disease. Magnesium deficiency inhibits PTH release and impairs the action of PTH on bone resorption. This form of hypocalcemia is difficult to treat with calcium supplementation alone and requires correction of the magnesium deficiency.

There is an inverse relation between calcium and phosphate excretion by the kidneys. Phosphate elimination is impaired in chronic kidney disease, causing plasma calcium levels to decrease. Hypocalcemia and hyperphosphatemia...
occur when the glomerular filtration rate falls below 59 mL/minute (normal values, which are related to age, sex, and body size, are approximately 120 mL/minute in young women and 130 mL/minute in young men).

Only the ionized form of calcium is able to leave the capillary and participate in body functions. A change in pH alters the proportion of calcium that is in the bound and ionized forms. An acid pH decreases binding of calcium to protein, causing a proportionate increase in ionized calcium, whereas total plasma calcium remains unchanged. An alkaline pH has the opposite effect. As an example, hyperventilation sufficient to cause respiratory alkalosis can produce tetany because of increased protein binding of calcium. Free fatty acids also increase binding of calcium to albumin, causing a reduction in ionized calcium. Elevations in free fatty acids sufficient to alter calcium binding may occur during stressful situations that cause elevations of epinephrine, glucagon, growth hormone, and adrenocorticotropic hormone levels. Heparin, β-adrenergic drugs (i.e., epinephrine, isoproterenol, and nor-ephinephrine), and alcohol can also produce elevations in free fatty acid levels sufficient to increase calcium binding.

Citrate, which complexes with calcium, is often used as an anticoagulant in blood transfusions. Theoretically, excess citrate in donor blood could combine with the calcium in a recipient’s blood, producing a sharp drop in ionized calcium. This normally does not occur because the liver removes the citrate within a matter of minutes. When blood transfusions are administered at a slow rate, there is little danger of hypocalcemia caused by citrate binding.

Hypocalcemia is a common finding in people with acute pancreatitis. Inflammation of the pancreas causes release of proteolytic and lipolytic enzymes. It is thought that the Ca²⁺ combines with free fatty acids released by lipolysis in the pancreas, forming soaps and removing calcium from the circulation.

Calcium deficit due to dietary deficiency exerts its effects on bone stores rather than extracellular calcium levels. A dietary deficiency of vitamin D is still seen today despite many foods being fortified with vitamin D. Vitamin D deficiency is more likely to occur in malabsorption states, such as biliary obstruction, pancreatic insufficiency, and celiac disease, in which the ability to absorb fat and fat-soluble vitamins is impaired. Failure to activate vitamin D is another cause of hypocalcemia. Anticonvulsant medications, particularly phenytoin, can impair initial activation of vitamin D in the liver. The final step in activation of vitamin D is impaired in people with chronic kidney disease. Fortunately, the activated form of vitamin D, calcitriol, has been synthesized and is available for use in the treatment of calcium deficit in persons with chronic kidney disease.

**Clinical Manifestations.** Hypocalcemia can manifest as an acute or chronic condition. The manifestations of acute hypocalcemia reflect the increased neuromuscular excitability

and cardiovascular effects of a decrease in ionized calcium (see Table 39.10). Ionized calcium stabilizes neuromuscular excitability, thereby making nerve cells less sensitive to stimuli. Nerves exposed to low ionized calcium levels show decreased thresholds for excitation, repetitive responses to a single stimulus, and, in extreme cases, continuous activity. The severity of the manifestations depends on the underlying cause, rapidity of onset, accompanying electrolyte disorders, and extracellular pH. Increased neuromuscular excitability can manifest as paresthesias (i.e., tingling around the mouth and in the hands and feet) and tetany (i.e., spasms of the muscles of the face, hands, and feet).53 Severe hypocalcemia can lead to laryngeal spasm, seizures, and even death.

Cardiovascular effects of acute hypocalcemia include hypotension, cardiac insufficiency, cardiac dysrhythmias (particularly heart block and ventricular fibrillation), and failure to respond to drugs such as digitalis, norepinephrine, and dopamine that act through calcium-mediated mechanisms.

The Chvostek and Trousseau tests can be used to assess for an increase in neuromuscular excitability and tetany.53 The Chvostek sign is elicited by tapping the face just below the temple at the point where the facial nerve emerges. Tapping the face over the facial nerve causes spasm of the lip, nose, or face when the test result is positive. An inflated blood pressure cuff is used to test for the Trousseau sign. The cuff is inflated 10 mm Hg above systolic blood pressure for 3 minutes. Contraction of the fingers and hands (i.e., carpopedal spasm) indicates the presence of tetany.

Chronic hypocalcemia is often accompanied by skeletal manifestations and skin changes. There may be bone pain, fragility, deformities, and fractures. The skin may be dry and scaling, the nails brittle, and hair dry. Development of cataracts is common.

**Treatment.** Acute hypocalcemia is an emergency, requiring prompt treatment. An intravenous infusion containing calcium (e.g., calcium gluconate, calcium chloride) is used when tetany or acute symptoms are present or anticipated because of a decrease in the plasma calcium level.54 Chronic hypocalcemia is treated with oral intake of calcium. One glass of milk contains approximately 300 mg of calcium. Oral calcium supplements of carbonate, gluconate, or lactate salts may be used. Long-term treatment may require the use of vitamin D preparations, especially in persons with hypoparathyroidism and chronic kidney disease. The active form of vitamin D is administered when the liver or kidney mechanisms needed for hormone activation are impaired. Synthetic PTH (1-34) can be administered by subcutaneous injection as replacement therapy in hypoparathyroidism.

**Hypercalcemia**

Hypercalcemia represents a total plasma calcium concentration greater than 10.5 mg/dL (2.6 mmol/L). Falsely elevated levels of calcium can result from prolonged drawing of blood with an excessively tight tourniquet. Increased plasma proteins (e.g., hyperalbuminemia, hyperglobulinemia) may elevate the total plasma calcium but not affect the ionized calcium concentration.

**Etiology.** A plasma calcium excess (i.e., hypercalcemia) results when calcium movement into the circulation overwhelms the calcium regulatory hormones or the ability of the kidney to remove excess calcium ions (Table 39.11). The two most common causes of hypercalcemia are increased bone resorption due to neoplasms and hyperparathyroidism.55 These two etiologies account for the majority of all people with hypercalcemia. Hypercalcemia is a common complication of malignancy, occurring in approximately 10% to 20% of people with advanced disease and is called HCM.56 A number of malignant tumors, including carcinoma of the lungs, have been associated with hypercalcemia. Some tumors destroy the bone, whereas others produce humoral agents that stimulate osteoclastic activity, increase bone resorption, or inhibit bone formation. The majority of people with HCM produce PTH-related protein (PTHrP), which is designated the major humoral factor responsible for HCM.56 PTH and PTHrP have marked homology, or structural similarity, at their amino terminal ends. This homology results in both PTH and PTHrP binding to the same receptor (PTH/PTH-rP receptor). PTHrP is detected in people with many types of solid organs and also with adult T cell leukemia/lymphoma.56

Less frequent causes of hypercalcemia are prolonged immobilization, increased intestinal absorption of calcium, excessive doses of vitamin D, or the effects of drugs such as lithium and thiazide diuretics. Children with hypercalcemia will need to expedite urinary excretion of calcium, which is the main treatment goal.57 Prolonged immobilization and lack of weight bearing cause demineralization of bone and release of calcium into the bloodstream. Intestinal absorption of calcium can be increased by excessive doses of vitamin D or as a result of a condition called the milk-alkali syndrome. The milk-alkali syndrome is caused by excessive ingestion of calcium (often in the form of milk) and absorbable antacids. Because of the availability of nonabsorbable antacids, the condition is seen less frequently than in the past, but it may occur in women who are overzealous in taking calcium preparations for osteoporosis prevention. Discontinuance of the antacid repairs the alkalosis and increases calcium elimination.

A variety of drugs elevate calcium levels. The use of lithium to treat bipolar disorders has caused hypercalcemia and hyperparathyroidism. The thiazide diuretics increase calcium resorption in the distal convoluted tubule of the kidney. Although the thiazide diuretics seldom cause hypercalcemia, they can unmask hypercalcemia from other causes such as underlying bone disorders and conditions that increase bone resorption.

**Clinical Manifestations.** The signs and symptoms associated with calcium excess reflect (1) changes in neural excitability, (2) alterations in smooth and cardiac muscle function, and (3) exposure of the kidneys to high concentrations of calcium (see Table 39.11). Neural excitability is decreased in patients with hypercalcemia. There may be a dulling of consciousness,
stupor, weakness, and muscle flaccidity. Behavioral changes may range from subtle alterations in personality to acute psychoses. The heart responds to elevated levels of calcium with increased contractility and ventricular arrhythmias. Digitalis accentuates these responses. Gastrointestinal symptoms reflect a decrease in smooth muscle activity and include constipation, anorexia, nausea, and vomiting. High calcium concentrations in the urine impair the ability of the kidneys to concentrate urine by interfering with the action of ADH (an example of nephrogenic DI). This causes salt and water diuresis and an increased sensation of thirst. Hypercalcuria also predisposes to the development of renal calculi. Pancreatitis is another potential complication of hypercalcemia and is probably related to stones in the pancreatic ducts.

Hypercalcemic crisis describes an acute increase in the plasma calcium level. Malignant disease and hyperparathyroidism are the major causes of hypercalcemic crisis. In hypercalcemic crisis, cardiac dysrhythmias, oliguria, excessive thirst, volume depletion, fever, altered levels of consciousness, and a disturbed mental state accompany other signs of calcium excess. Symptomatic hypercalcemia is associated with a high mortality rate; death often is caused by cardiac arrest.

### Treatment
Treatment of calcium excess usually is directed toward rehydration and use of measures to increase urinary excretion of calcium. Fluid replacement is needed in situations of volume depletion. The excretion of sodium is accompanied by calcium excretion. Diuretics and NaCl can be administered to increase urinary elimination of calcium after the ECF volume has been restored. Loop diuretics commonly are used rather than thiazide diuretics, which increase calcium reabsorption. Initial lowering of calcium levels is followed by measures to inhibit bone resorption. Drugs that are used to inhibit calcium mobilization include bisphosphonates, calcitonin, corticosteroids, mithramycin, and gallium nitrate. The bisphosphonates (e.g., pamidronate, zoledronate), which act mainly by inhibiting osteoclastic activity, provide a significant reduction in calcium levels with relatively few side effects. Calcitonin inhibits osteoclastic activity, thereby decreasing resorption. The corticosteroids and mithramycin inhibit bone resorption and are used to treat hypercalcemia associated with cancer. The long-term use of mithramycin, an antineoplastic drug, is limited because of its potential for nephrotoxicity and hepatotoxicity. Gallium nitrate is highly effective in the treatment of severe hypercalcemia associated with malignancy. It is a chemical compound that inhibits bone resorption.

</table>
although the precise mechanism of action is unclear. Dialysis can be used in hypercalcemic patients with renal failure and in patients with heart failure in whom fluid overload is a concern.

**Disorders of Phosphorus Balance**

Phosphorus is mainly an intracellular anion. Approximately 85% of phosphorus is contained in bone, and most of the remainder (14%) is located in cells. Only approximately 1% is in the ECF compartment, and of that, only a minute proportion is in the plasma. In the adult, the normal plasma phosphorus level ranges from 2.5 to 4.5 mg/dL (0.8 to 1.45 mmol/L). These values are slightly higher in infants (3.7 to 8.5 mg/dL, 0.12 to 0.27 mmol/L) and children (4 to 5.4 mg/dL, 1.3 to 1.7 mmol/L), probably because of increased growth hormone and decreased gonadal hormones.

Disorders of Renal Function and Fluids and Electrolytes

Renal elimination of phosphate is then regulated to maintain normal plasma phosphate levels. The principal regulatory mechanism is phosphate reabsorption by the proximal tubular epithelial cells through the action of a sodium–phosphate cotransporter (NPT2). PTH can play a significant role in regulating phosphate reabsorption by inhibiting the synthesis and expression of the NPT2 transporter. Thus, whenever PTH is increased, tubular reabsorption of phosphate is decreased, and more phosphate is lost in the urine. NPT2 is also inhibited by the hormones called phosphatonin. There are two most significant phosphatonins including fibroblast growth factor 23 (FGF 23) and secreted frizzled-related protein 4 (sFRP4). When these hormones are overproduced, as in tumor-induced osteomalacia, marked hypophosphatemia occurs due to decreased intestinal phosphate absorption. In addition, increased phosphatonin causes excessive calcitriol (active vitamin D) degradation, resulting in osteomalacia or rickets.

**Hypophosphatemia**

Hypophosphatemia is commonly defined by a plasma phosphorus level of less than 2.5 mg/dL (0.8 mmol/L) in adults; it is considered severe at concentrations of less than 1 mg/dL (0.32 mmol/L). Hypophosphatemia may occur despite normal body phosphate stores as a result of movement from the ECF into the ICF compartment. Serious depletion of phosphorus may exist with low, normal, or high plasma concentrations.

**Etiology.** The most common causes of hypophosphatemia are depletion of phosphorus because of insufficient intestinal absorption, transcompartmental shifts, and increased renal losses (Table 39.12). Often, more than one of these mechanisms is active. Unless food intake is severely restricted, dietary intake and intestinal absorption of phosphorus are usually adequate. Intestinal absorption may be inhibited by administration of glucocorticoids, high dietary levels of magnesium, and hypothyroidism. Prolonged ingestion of antacids may also interfere with intestinal absorption. Antacids that contain aluminum hydroxide, aluminum carbonate, and calcium carbonate bind with phosphate, causing increased phosphate losses in the stool. Because of their ability to bind phosphate, calcium-based antacids are sometimes used therapeutically to decrease plasma phosphate levels in people with chronic kidney disease.

Alcoholism is a common cause of hypophosphatemia. The mechanisms underlying hypophosphatemia in the person addicted to alcohol may be related to malnutrition, increased renal excretion rates, or hypomagnesemia. Malnutrition and diabetic ketoacidosis increase phosphate excretion and phosphorus loss from the body. Refeeding of malnourished patients increases the incorporation of phosphorus into nucleic acids and phosphorylated compounds in the cell. The same thing happens when diabetic ketoacidosis is reversed with insulin therapy. Urinary losses of phosphate may be caused by drugs, such as theophylline, corticosteroids, and loop diuretics, which increase renal excretion.

Hypophosphatemia also can occur during prolonged courses of glucose administration or hyperalimentation.
Glucose administration causes insulin release, with transport of glucose and phosphorus into the cell. The catabolic events that occur with diabetic ketoacidosis also deplete phosphorus stores. Usually the hypophosphatemia does not become apparent, however, until insulin and fluid replacement have reversed the dehydration and glucose has started to move back into the cell. Administration of hyperalimentation solutions without adequate phosphorus can cause a rapid influx of phosphorus into the body’s muscle mass, particularly if treatment is initiated after a period of tissue catabolism. Because only a small amount of total body phosphorus is in the ECF compartment, even a small redistribution between the ECF and ICF compartments can cause hypophosphatemia, even though total phosphorus levels have not changed.

Respiratory alkalosis due to prolonged hyperventilation can produce hypophosphatemia through decreased levels of ionized calcium from increased protein binding, increased PTH release, and increased phosphate excretion.

**Clinical Manifestations.** The manifestations of phosphorus deficiency result from a decrease in cellular energy stores due to deficiency in ATP and impaired O2 transport due to a decrease in RBC 2,3-DPG. Hypophosphatemia results in altered neural function, disturbed musculoskeletal function, and hematologic disorders (see Table 39.12).

RBC metabolism is impaired by phosphorus deficiency; the cells become rigid, undergo increased hemolysis, and have diminished ATP and 2,3-DPG levels. The chemotactic and phagocytic functions of white blood cells and the hemostatic functions of the platelets are also impaired. Acute severe hypophosphatemia (0.1 to 0.2 mg/dL) can lead to acute hemolytic anemia with increased erythrocyte fragility, increased susceptibility to infection, and platelet dysfunction with petechial hemorrhages. Anorexia and dysphagia can occur. Neural manifestations (intention tremors, paresthesias, hyporeflexia, stupor, coma, and seizures) are uncommon but serious manifestations. Respiratory insufficiency resulting from impaired function of the respiratory muscles can develop in people with severe hypophosphatemia.

Chronic phosphorus depletion interferes with mineralization of newly formed bone matrix. In growing children, this process causes abnormal endochondral growth and clinical manifestations of rickets. In adults, the condition leads to joint stiffness, bone pain, and skeletal deformities consistent with osteomalacia.

**Treatment.** The treatment of hypophosphatemia is usually directed toward prophylaxis. This may be accomplished with dietary sources high in phosphorus (one glass of milk contains approximately 250 mg of phosphorus) or with oral or intravenous replacement solutions. Phosphorus supplements usually are contraindicated in hyperparathyroidism, chronic kidney disease, and hypercalcemia because of the increased risk of extracellular calcifications.

**Hyperphosphatemia**

Hyperphosphatemia represents a plasma phosphorus concentration in excess of 4.5 mg/dL (1.45 mmol/L) in adults. Growing children normally have plasma phosphate levels higher than those of adults.

**Etiology.** Hyperphosphatemia results from failure of the kidneys to excrete excess phosphate, rapid redistribution of...
intracellular phosphate to the ECF compartment, and excessive intake of phosphorus. The most common cause of hyperphosphatemia is impaired renal function (Table 39.13).

Hyperphosphatemia is a common electrolyte disorder in people with chronic kidney disease. The increase in phosphate levels in people with chronic kidney disease occurs despite compensatory increases in PTH. Evidence illustrates an increase in cardiovascular calcification and mortality with people with CKD and high phosphorous levels. Release of intracellular phosphorus can result from conditions such as massive tissue injury, rhabdomyolysis, heat stroke, potassium deficiency, and seizures. Chemotherapy can raise plasma phosphate levels because of the rapid destruction of tumor cells (tumor lysis syndrome).

The administration of excess phosphate-containing antacids, laxatives, or enemas can be another cause of hyperphosphatemia, especially when there is a decrease in vascular volume and a reduced glomerular filtration rate. Phosphate-containing laxatives and enemas predispose to hypovolemia and a decreased glomerular filtration rate by inducing diarrhea, thereby increasing the risk of hypophosphatemia.

**Clinical Manifestations.** Hyperphosphatemia is accompanied by a decrease in plasma calcium. Many of the signs and symptoms of a phosphate excess are related to a calcium deficit (see Table 39.13). Inadequately treated hyperphosphatemia in chronic disease can lead to secondary hyperparathyroidism, renal osteodystrophies or mineral bone disorders, and extrasosseous calcifications in soft tissues.

**Treatment.** The treatment of hyperphosphatemia is directed at the cause of the disorder. Dietary restriction of foods that are high in phosphorus may be used. Calcium-based phosphate binders are useful in chronic hyperphosphatemia. Sevelamer, a calcium- and aluminum-free phosphate binder, is as effective as a calcium-based binder, but lacks its adverse manifestations such as elevation of the calcium × phosphate product, hypercalcemia, and vascular and cardiac calcifications. Hemodialysis is used to reduce phosphate levels in people with chronic kidney disease.

**KEY POINTS**

**PHOSPHORUS BALANCE**

- Approximately 85% of the phosphorus is contained in bone. Most of the remaining phosphorus is incorporated into organic compounds such as nucleic acids, high-energy compounds (e.g., ATP), and coenzymes that are critically important for cell function.
- Serum phosphorus levels are regulated by the kidneys, which eliminate or conserve phosphate as serum levels change. Serum levels of calcium and phosphate are reciprocally regulated to prevent the damaging deposition of calcium phosphate crystals in the soft tissues of the body. Many of the manifestations of hyperphosphatemia reflect a decrease in serum calcium levels.

**Disorders of Magnesium Balance**

Magnesium is the fourth most abundant cation in the body and the second most abundant intracellular cation after potassium. Of the total magnesium content, approximately 50% to 60% is stored in bone, 39% to 49% is contained in the body cells, and the remaining 1% is dispersed in the ECF. Approximately 20% to 30% of ECF magnesium is protein bound, and only a small fraction of ICF magnesium (15% to 30%) is exchangeable with the ECF. The normal plasma concentration of magnesium is 1.8 to 3.0 mg/dL (0.75 to 1.25 mmol/L).
Only recently has the importance of magnesium to the overall function of the body been recognized. Magnesium acts as a cofactor in many intracellular enzyme reactions, including the transfer of high-energy phosphate groups in the generation of ATP from adenosine diphosphate (ADP). It is essential to all reactions that require ATP, for every step related to replication and transcription of DNA, and for the translation of messenger RNA. It is required for cellular energy metabolism, functioning of the Na+/K+-ATPase membrane pump, membrane stabilization, nerve conduction, ion transport, and potassium and calcium channel activity.63 Potassium channels, including the acetylcholine-sensitive potassium channel, depend on adequate intracellular magnesium levels. Magnesium blocks the outward movement of potassium in cardiac cells. When magnesium levels are low, the channel permits outward flow of potassium, resulting in low levels of intracellular potassium. Many calcium channels are also magnesium dependent. Higher ICF magnesium concentrations inhibit calcium transport into the cell and its release from the sarcoplasmic reticulum. Therefore, magnesium tends to act as a smooth muscle relaxant by altering calcium levels that are responsible for muscle contraction. Magnesium does have an anticonvulsant effect. The suggested mechanism of action is cerebral vasodilation or prevention of ischemic neuronal damage by blockade of N-methyl-D-aspartate (NMDA) receptors in the brain. Magnesium is the first-line drug in the treatment of eclampsia in pregnant women.64 In addition, magnesium is commonly used as a neuroprotective agent for infants. In fact, evidence suggests that approximately 1000 cases per year of cerebral palsy in the United States could be prevented if magnesium was consistently used during labor.65

**Gains and Losses**

Magnesium is ingested in the diet, absorbed from the intestine, and excreted by the kidneys. Intestinal absorption is not closely regulated, and approximately 25% to 65% of dietary magnesium is absorbed. Magnesium is contained in all green vegetables, grains, nuts, meats, and seafood. Magnesium is also present in much of the groundwater in North America.

The kidney is the principal organ of magnesium regulation. The kidneys filter about 70% to 80% of the plasma magnesium and excrete about 6%, although this amount can be influenced by other conditions and medications.57 Magnesium is a unique electrolyte in that only approximately 12% to 20% of the filtered amount is reabsorbed in the proximal tubule.66,67 The greatest quantity, approximately 70%, is passively reabsorbed in the thick ascending loop of Henle. The major driving force for magnesium absorption in the thick ascending loop of Henle is the positive voltage gradient created in the tubular lumen by the Na+/K+/2Cl− cotransport system. Inhibition of this transport system by loop diuretics lowers magnesium reabsorption. Active reabsorption of magnesium takes place in the distal convoluted tubule and accounts for about 10% of the filtered load. Magnesium reabsorption is stimulated by PTH and is decreased in the presence of increased plasma levels of magnesium and calcium.

**Hypomagnesemia**

Magnesium deficiency refers to depletion of total body stores, whereas hypomagnesemia describes a plasma magnesium concentration below 1.8 mg/dL (0.75 mmol/L).68 It is seen in conditions that limit intake or increase intestinal or renal losses, and it is a common finding in emergency departments and intensive care units.

**Etiology.** Magnesium deficiency can result from insufficient intake, excessive losses, or movement between the ECF and ICF compartments (Table 39.14). It can result from conditions that directly limit intake, such as malnutrition, starvation, or prolonged maintenance of magnesium-free parenteral nutrition. Other conditions, such as diarrhea, malabsorption syndromes, prolonged nasogastric suction, or laxative abuse,
decrease intestinal absorption. Another common cause of magnesium deficiency is chronic alcoholism. Many factors contribute to hypomagnesemia in alcoholism, including low intake and gastrointestinal losses from diarrhea. The effects of hypomagnesemia are exaggerated by other electrolyte disorders, such as hypokalemia, hypocalcemia, and metabolic acidosis.

Although the kidneys are able to defend against hypermagnesemia, they are less able to conserve magnesium and prevent hypomagnesemia. Urine losses are increased in diabetic ketoacidosis, hyperparathyroidism, and hyperaldosteronism. Some drugs increase renal losses of magnesium, including both loop and thiazide diuretics and nephrotoxic drugs such as aminoglycoside antibiotics, cyclosporine, cisplatin, and amphotericin B. Several rare, genetic disorders can also result in hypomagnesemia (i.e., Gitelman and Bartter syndromes).

Relative hypomagnesemia may also develop in conditions that promote movement of magnesium between the ECF and ICF compartments, including rapid administration of glucose, insulin-containing parenteral solutions, and alkalosis. Although transient, these conditions can cause serious alterations in body function.

Clinical Manifestations. Magnesium deficiency usually occurs in conjunction with hypocalcemia and hypokalemia, producing a number of related neurologic and cardiovascular manifestations (see Table 39.14). Hypocalcemia is typical of severe hypomagnesemia. Most persons with hypomagnesemia-related hypocalcemia have decreased PTH levels, probably as a result of impaired magnesium-dependent mechanisms that control PTH release and synthesis. There is also evidence that hypomagnesemia decreases both the PTH-dependent and PTH-independent release of calcium from bone. In hypomagnesemia, magnesium ions (Mg^{2+}) are released from bone in exchange for increased uptake of calcium from the ECF.

Hypomagnesemia leads to a reduction in intracellular potassium and impairs the ability of the kidney to conserve potassium. When hypomagnesemia is present, hypokalemia is unresponsive to potassium replacement therapy.

Magnesium is vital to carbohydrate metabolism and the generation of both aerobic and anaerobic metabolisms. Many of the manifestations of magnesium deficit are due to related electrolyte disorders such as hypokalemia and hypocalcemia. Hypokalemia may be evidenced by personality changes and neuromuscular irritability along with tremors, athetoid or choreiform movements, and positive Chvostek or Trousseau signs. Cardiovascular manifestations include tachycardia, hypertension, and ventricular dysrhythmias. There may be ECG changes such as widening of the QRS complex, appearance of peaked T waves, prolongation of the PR interval, T-wave inversion, and appearance of U waves. Ventricular arrhythmias, particularly in the presence of digitalis, may be difficult to treat unless magnesium levels are normalized.

Persistent magnesium deficiency has been implicated as a risk factor for osteoporosis and osteomalacia, particularly in people with chronic alcoholism, diabetes mellitus, and malabsorption syndrome.

Treatment. Hypomagnesemia is treated with magnesium replacement. The route of administration depends on the severity of the condition. Symptomatic, moderate to severe magnesium deficiency is treated by parenteral administration. Treatment must be continued for several days to replace stored and plasma levels. In conditions of chronic intestinal or renal loss, maintenance support with oral magnesium may be required. Magnesium often is used therapeutically to treat cardiac arrhythmia, myocardial infarct, angina, bronchial asthma, and pregnancy complicated by preeclampsia or eclampsia. Caution to prevent hypermagnesemia is essential; it is important to carefully monitor people with any degree of renal failure to prevent magnesium excess.

**Hypermagnesemia**

Hypermagnesemia represents an increase in total body magnesium and a plasma magnesium concentration in excess of 3.0 mg/dL (1.25 mmol/L). Because of the ability of the normal kidney to excrete magnesium, hypermagnesemia is rare.

**Etiology.** When hypermagnesemia does occur, it usually is related to renal insufficiency and the injudicious use of magnesium-containing medications such as antacids, mineral supplements, or laxatives (Table 39.15). Older adults are particularly at risk because they have age-related reductions in renal function and tend to consume more magnesium-containing medications, including antacids and laxatives. Magnesium sulfate is used to treat toxemia of pregnancy and premature labor; in these cases, careful monitoring for signs of hypermagnesemia is essential.

**Clinical Manifestations.** Hypermagnesemia affects neuromuscular and cardiovascular function (see Table 39.15). Because magnesium tends to suppress PTH secretion, hypocalcemia may accompany hypermagnesemia. The signs and symptoms usually occur only when plasma magnesium levels exceed 4.8 mg/dL (2 mmol/L).
Hypermagnesemia diminishes neuromuscular function, causing hyporeflexia, muscle weakness, and confusion. Magnesium decreases acetylcholine release at the myoneural junction and may cause neuromuscular blockade and respiratory paralysis. Cardiovascular effects are related to the calcium channel-blocking effects of magnesium. Blood pressure is decreased, and the ECG shows shortening of the QT interval, T-wave abnormalities, and prolongation of the QRS and PR intervals. Severe hypermagnesemia (>12 mg/dL) is associated with muscle and respiratory paralysis, complete heart block, and cardiac arrest.

**Treatment.** The treatment of hypermagnesemia includes cessation of magnesium administration. Calcium is a direct antagonist of magnesium, and intravenous administration of calcium may be used. Peritoneal dialysis or hemodialysis may be required.

**IN SUMMARY**

Calcium, phosphorus, and magnesium are major divalent ions in the body. Calcium is a major divalent cation. Approximately 99% of body calcium is found in bone; less than 1% is found in the ECF compartment. The calcium in bone is in dynamic equilibrium with ECF calcium. Of the three forms of ECF calcium (i.e., protein bound, complexed, and ionized), only the ionized form can cross the cell membrane and contribute to cellular function. Ionized calcium has a number of functions. It contributes to neuromuscular function, plays a vital role in the blood clotting process, and participates in a number of enzyme reactions. Alterations in ionized calcium levels produce neural effects; neural excitability is increased in hypocalcemia and decreased in hypercalcemia.

Phosphorus is largely an ICF anion. It is incorporated into the nucleic acids and ATP. The most common causes of altered levels of ECF phosphate are alterations in intestinal absorption, transcompartmental shifts, and disorders of renal elimination. Phosphorus deficit causes signs and symptoms of neural dysfunction, disturbed musculoskeletal function, and hematologic disorders. Most of these manifestations result from a decrease in cellular energy stores due to a deficiency in ATP and O₂ transport by 2,3-DPG in the RBC. Phosphorus excess occurs with renal failure and PTH deficit. It is associated with decreased plasma calcium levels.

Magnesium is the second most abundant ICF cation. It acts as a cofactor in many intracellular enzyme reactions and is required for cellular energy metabolism, functioning of the Na⁺/K⁺-ATPase membrane pump, nerve conduction, ion transport, and potassium and calcium channel activity. Magnesium blocks the outward movement of potassium in cardiac cells; when magnesium levels are low, the channel permits outward flow of potassium, resulting in low levels of intracellular potassium. It acts on calcium channels to inhibit the movement of calcium into cells. Magnesium deficiency can result from insufficient intake, excessive losses, or movement between the ECF and ICF compartments. Hypomagnesemia impairs PTH release and the actions of PTH; it leads to a reduction in ICF potassium and impairs the ability of the kidney to conserve potassium. Hypermagnesemia usually is related to renal insufficiency and the indiscriminate use of magnesium-containing medications such as antacids, mineral supplements, or laxatives. It can cause neuromuscular dysfunction with hyporeflexia, muscle weakness, and confusion. Magnesium decreases acetylcholine release at the myoneural junction and may cause neuromuscular blockade and respiratory paralysis.

REVIEW EXERCISES

1. A 40-year-old man with advanced acquired immuno-deficiency syndrome (AIDS) presents with an acute chest infection. Investigations confirm a diagnosis of Pneumocystis jiroveci (formerly P. carinii) pneumonia. Although he is being treated appropriately, his plasma sodium level is 118 mEq/L (118 mmol/L). Results of adrenal function tests are normal.
   A. What is the likely cause of his electrolyte disturbance?
   B. What are the five cardinal features of this condition?
2. A 70-year-old woman who is taking furosemide (a loop diuretic) for congestive heart failure complains of weakness, fatigue, and cramping of the muscles in her legs. Her plasma potassium is 2 mEq (2 mmol/L), and her plasma sodium is 140 mEq/L (140 mmol/L). She also complains that she notices a “strange heartbeat” at times.
   A. What is the likely cause of this woman’s symptoms?
   B. An ECG shows depressed ST segment and low T-wave changes. Explain the physiologic mechanism underlying these changes.
   C. What would be the treatment for this woman?
3. A 50-year-old woman presents with symptomatic hypercalcemia. She has a recent history of breast cancer treatment.
   A. How do you evaluate this person with increased plasma calcium levels?
   B. What is the significance of the recent history of malignancy?
   C. What further tests may be indicated?

The need for precise regulation of hydrogen ion (H+) balance is similar in many ways to that of other ions in the body. Membrane excitability, enzyme systems, and chemical reactions all depend on the H+ concentration being regulated within a narrow physiologic range to function in an optimal way. Many conditions, pathologic or otherwise, can alter H+ concentration and acid–base balance. This chapter has been organized into two sections: Mechanisms of Acid–Base Balance and Disorders of Acid–Base Balance.

Normally, the concentration of body acids and bases is regulated so that the pH of extracellular body fluids is maintained within a very narrow range of 7.35 to 7.45. This balance is maintained through mechanisms that generate, buffer, and eliminate acids and bases. This section of the chapter focuses on acid–base chemistry, the production and regulation of metabolic acids and bicarbonate, calculation of pH, and laboratory tests of acid–base balance.

Acid–Base Chemistry

An acid is a molecule that can release an H+, and a base is an ion or molecule that can accept or combine with an H+. For example, hydrochloric acid (HCl) dissociates in water to form hydrogen (H+) and chloride (Cl−) ions. A base, such as...
the bicarbonate ion (HCO₃⁻), is a base because it can combine with H⁺ to form carboxylic acid (H₂CO₃). Most of the body’s acids and bases are weak acids and bases, the most important being H₂CO₃, which is a weak acid derived from carbon dioxide (CO₂), and bicarbonate (HCO₃⁻), which is a weak base.

Acids and bases exist as buffer pairs or systems—a mixture of a weak acid and its conjugate base or a weak base and its conjugate acid. When an acid (HA) is added to water, it dissociates reversibly to form H⁺ and its conjugate anion (A⁻). An example of this is HA × H⁺ + A⁻. The degree to which an acid dissociates and acts as an H⁺ donor determines whether it is a strong or weak acid. Strong acids, such as sulfuric acid, dissociate completely. Weak acids, such as acetic acid, dissociate only to a limited extent. The same is true of a base and its ability to dissociate and accept an H⁺.

The concentration of H⁺ in body fluids is low compared with other ions.¹ For example, the sodium ion (Na⁺) is present at a concentration approximately 3.5 million times that of H⁺. Because it is cumbersome to work with such a small number, the H⁺ concentration is commonly expressed in terms of the pH. Specifically, pH represents the negative logarithm (log₁₀) of the H⁺ concentration expressed in milliequivalents per liter (mEq/L).¹ Thus, a pH value of 7.0 implies an H⁺ concentration of 10⁻⁷ (0.0000001 mEq/L). Because the pH is inversely related to the H⁺ concentration, a low pH indicates a high concentration of H⁺, and a high pH indicates a low concentration.

The dissociation constant (K) is used to describe the degree to which an acid or base in a buffer system dissociates.¹² The symbol pK refers to the negative log₁₀ of the dissociation constant for an acid and represents the pH at which an acid is 50% dissociated.³ Use of a negative log₁₀ for the dissociation constant allows pH to be expressed as a positive value. Each acid in an aqueous solution has a characteristic pK that varies slightly with temperature and pH. At normal body temperature, the pK for the bicarbonate buffer system of the extracellular fluid (ECF) compartment is 6.1.¹³

**KEY POINTS**

**MECHANISMS OF ACID–BASE BALANCE**

- The pH is regulated by extracellular (carboxylic acid [H₂CO₃] bicarbonate [HCO₃⁻]) and intracellular (proteins) systems that buffer changes in pH that would otherwise occur because of the metabolic production of volatile (CO₂) and nonvolatile (i.e., sulfuric and phosphoric) acids.

**Metabolic Acid and Bicarbonate Production**

Acids are continuously generated as by-products of metabolic processes (Fig. 40.1). Physiologically, these acids fall into two groups: the volatile acid H₂CO₃ and all other nonvolatile or fixed acids. The difference between the two types of acids arises because H₂CO₃ is in equilibrium with CO₂ (H₂CO₃ ↔ CO₂ + H₂O), which is volatile and leaves the body by way of the lungs. Therefore, the lungs and their capacity to exhale CO₂ determine H₂CO₃ concentration. The lungs do not eliminate fixed or nonvolatile acids (e.g., sulfuric, hydrochloric, phosphoric). Instead, they are buffered by body proteins or extracellular buffers, such as HCO₃⁻, and then eliminated by the kidney.

**Carbon Dioxide and Bicarbonate Production**

Body metabolism results in the production of approximately 15,000 mmol of CO₂ each day.³ Carbon dioxide is transported in the circulation in three forms:

1. As a dissolved gas
2. As bicarbonate
3. As carbaminohemoglobin (see “Understanding: Carbon Dioxide Transport”)

![FIGURE 40.1](image-url)
Understanding Carbon Dioxide Transport

Body metabolism results in a continuous production of carbon dioxide (CO$_2$). As CO$_2$ is formed during the metabolic process, it diffuses out of body cells into the tissue spaces and then into the circulation. It is transported in the circulation in three forms: (1) dissolved in the plasma, (2) as bicarbonate, and (3) attached to hemoglobin.

**Plasma**

A small portion (about 10%) of the CO$_2$ that is produced by body cells is transported in the dissolved state to the lungs and then exhaled. The amount of dissolved CO$_2$ that can be carried in plasma is determined by the partial pressure of the gas (PCO$_2$) and its solubility coefficient (0.03 mL/100 mL plasma for each 1 mm Hg PCO$_2$). Thus, each 100 mL of arterial blood with a PCO$_2$ of 40 mm Hg would contain 1.2 mL of dissolved CO$_2$. It is the carbonic acid (H$_2$CO$_3$) formed from hydration of dissolved CO$_2$ that contributes to the pH of the blood.

**Bicarbonate**

Carbon dioxide in excess of that which can be carried in the plasma moves into the red blood cells, where the enzyme carbonic anhydrase (CA) catalyzes its conversion to carbonic acid (H$_2$CO$_3$). The H$_2$CO$_3$, in turn, dissociates into hydrogen (H$^+$) and bicarbonate (HCO$_3^-$) ions. The H$^+$ combines with hemoglobin and the HCO$_3^-$ diffuses into plasma, where it participates in acid–base regulation. The movement of HCO$_3^-$ into the plasma is made possible by a special transport system on the red blood cell membrane in which HCO$_3^-$ ions are exchanged for chloride ions (Cl$^-$).

**Hemoglobin**

The remaining CO$_2$ in the red blood cells combines with hemoglobin to form carbaminohemoglobin (HbCO$_2$). The combination of CO$_2$ with hemoglobin is a reversible reaction characterized by a loose bond, so that CO$_2$ can be easily released in the alveolar capillaries and exhaled from the lung.
Collectively, dissolved CO₂ and HCO₃⁻ account for approximately 77% of the CO₂ that is transported in the ECF; the remaining CO₂ travels as carbaminohemoglobin (CO₂ bound to amino acids in hemoglobin). Although CO₂ is a gas and not an acid, a small percentage of the gas combines with water to form H₂CO₃. The reaction that generates H₂CO₃ from CO₂ and water is catalyzed by an enzyme called carbonic anhydrase, which is present in large quantities in red blood cells, renal tubular cells, and other tissues in the body. The rate of the reaction between CO₂ and water is increased approximately 5000 times by the presence of carbonic anhydrase. Were it not for this enzyme, the reaction would occur too slowly to be of any significance in maintaining acid–base balance.

Because it is almost impossible to measure H₂CO₃, CO₂ measurements are commonly used when calculating pH. The H₂CO₃ content of the blood can be calculated by multiplying the partial pressure of CO₂ (PCO₂) by its solubility coefficient, which is 0.03. This means that the concentration of H₂CO₃ in the arterial blood, which normally has a PCO₂ of approximately 40 mm Hg, is 1.20 mEq/L (40 × 0.03 = 1.20), and that for venous blood, which normally has a PCO₂ of approximately 45 mm Hg, is 1.35 mEq/L.

**Production of Fixed or Nonvolatile Acids and Bases**

The metabolism of dietary proteins and other nutrients results in the generation of fixed or nonvolatile acids and bases. Oxidation of the sulfur-containing amino acids (e.g., methionine, cysteine) results in the production of sulfuric acid. Oxidation of arginine and lysine produces hydrochloric acid, and complete oxidation of phosphorus-containing nucleic acids yields phosphoric acid. Incomplete oxidation of glucose results in the formation of lactic acid and incomplete oxidation of fats, the production of ketoacids. The major source of base is the metabolism of amino acids such as aspartate and glutamate and the metabolism of certain organic anions (e.g., citrate, lactate, acetate). Acid production normally exceeds base production during the breakdown of consumed foods. A normal diet results in 50 to 100 mEq of H⁺ each day as nonvolatile sulfuric acid. Consumption of a vegetarian diet, which contains large amounts of organic anions, results in the net production of base.

**Calculation of pH**

The plasma pH can be calculated using an equation called the Henderson-Hasselbalch equation. This equation uses the pK of the bicarbonate buffer system, which is 6.1, and log₁₀ of the HCO₃⁻ to dissolved CO₂ (H₂CO₃) ratio:

\[
pH = 6.1 + \log_{10}(\text{HCO}_3^-/\text{PCO}_2 \times 0.03)
\]

The pH designation was created to express the low value of H⁺ more easily. It should be noted that it is the ratio rather than the absolute values for bicarbonate and dissolved CO₂ that determines pH (e.g., when the ratio is 20:1, the pH = 7.4). Plasma pH decreases when the ratio is less than 20:1, and it increases when the ratio is greater than 20:1 (Fig. 40.2).

Because it is the ratio rather than the absolute values of HCO₃⁻ or CO₂ that determines pH, the pH can remain within a relatively normal range as long as changes in HCO₃⁻ are accompanied by similar changes in CO₂, or vice versa. For example, the pH will remain at 7.4 when plasma HCO₃⁻ has increased from 24 to 48 mEq/L as long as CO₂ levels have also doubled. Likewise, the pH will remain at 7.4 when plasma HCO₃⁻ has decreased from 24 to 12 mEq/L as long as CO₂ levels have also been reduced by one half. Plasma pH only indicates the balance or ratio and not where problems originate.

**Regulation of pH**

The pH of body fluids (or change in H⁺ concentration) is regulated by three major mechanisms:

1. Chemical buffer systems of the body fluids, which immediately combine with excess acids or bases to prevent large changes in pH
2. The lungs, which control the elimination of CO₂
3. The kidneys, which eliminate H⁺ and both reabsorb and generate new HCO₃⁻

**Chemical Buffer Systems**

The moment-by-moment regulation of pH depends on chemical buffer systems of the intracellular (ICF) and extracellular fluids (ECF). As previously discussed, a buffer system consists of a weak base and its conjugate acid pair. In the process of preventing large changes in pH, the system trades a strong acid for a weak acid or a strong base for a weak base.

The three major buffer systems that protect the pH of body fluids are

1. The bicarbonate buffer system
2. Proteins
3. The transcellular H⁺/K⁺ exchange system

These buffer systems act immediately to combine with excess acids or bases and prevent large changes in pH from occurring during the time it takes for the respiratory and renal mechanisms to become effective. Even though these buffer systems act immediately, they have a limited effect on pH and cannot correct large or long-term changes.

Bone represents an additional source of acid–base buffering. Excess H⁺ ions can be exchanged for Na⁺ and K⁺ on the bone surface, and dissolution of bone minerals with release of compounds such as sodium bicarbonate (NaHCO₃) and calcium carbonate (CaCO₃) into the ECF can be used for buffering excess acids. It has been estimated that as much as 40% of buffering of an acute acid load takes place in bone. The role of bone buffers is even greater in the presence of chronic acidosis. The consequences of bone buffering include demineralization of bone and predisposition to development of kidney stones because of increased urinary excretion of calcium. People with chronic kidney disease are at particular risk for reduction in bone calcium due to acid retention.
Bicarbonate Buffer System. The HCO$_3^-$ buffer system, which is the most powerful ECF buffer, uses H$_2$CO$_3$ as its weak acid and a bicarbonate salt such as sodium bicarbonate (NaHCO$_3$) as its weak base.$^{1,2}$ It substitutes the weak H$_2$CO$_3$ for a strong acid such as hydrochloric acid (HCl + NaHCO$_3$ → H$_2$CO$_3$ + NaCl) or the weak bicarbonate base for a strong base such as sodium hydroxide (NaOH + H$_2$CO$_3$ → NaHCO$_3$ + H$_2$O). The bicarbonate buffer system is a particularly efficient system because its components can be readily added or removed from the body.$^{1-3}$ Metabolism provides an ample supply of CO$_2$, which can replace any H$_2$CO$_3$ that is lost when excess base is added, and CO$_2$ can be readily eliminated when excess acid is added. Likewise, the kidney can conserve or form new HCO$_3^-$ when excess acid is added, and it can excrete HCO$_3^-$ when excess base is added.

Protein Buffer Systems. Proteins are the largest buffer system in the body.$^{1,2}$ Proteins are amphoteric, meaning that they can function either as acids or bases. They contain many ionizable groups that can release or bind H$^+$. The protein buffers are largely located in cells, and H$^+$ ions and CO$_2$ diffuse across cell membranes for buffering by intracellular proteins.
Albumin and plasma globulins are the major protein buffers in the vascular compartment.

**Hydrogen–Potassium Exchange.** The transcompartmental exchange of H+ and potassium ions (K+) provides another important system for regulation of acid–base balance. Both ions are positively charged, and both ions move freely between the ICF and ECF compartments. When excess H+ is present in the ECF, it moves into the ICF in exchange for K+, and when excess K+ is present in the ECF, it moves into the ICF in exchange for H+. Thus, alterations in potassium levels can affect acid–base balance, and changes in acid–base balance can influence potassium levels. Potassium shifts tend to be more pronounced in metabolic acidosis than in respiratory acidosis. Also, metabolic acidosis caused by an accumulation of nonorganic acids (e.g., hydrochloric acid that occurs in diarrhea, phosphoric acid that occurs in chronic kidney disease) produces a greater increase in extracellular K+ levels than does acidosis caused by an accumulation of organic acids (e.g., lactic acid, ketoacids).

**Respiratory Control Mechanisms**

The second line of defense against acid–base disturbances is the control of extracellular CO2 by the lungs. Increased ventilation decreases PCO2, whereas decreased ventilation will increase CO2 and pH and alter the ventilatory rate. Chemoreceptors in the brain stem and medullary respiratory centers in the carotid and aortic bodies, and in the hypothalamus, release chemoactive substances that affect respiration. As CO2 concentration decreases in the cerebral fluids and a slower decrease in CSF HCO3− occurs in reverse. The CO2 and H2O combine to form a new H2CO3 molecule in a carbonic anhydrase-mediated reaction. The H2CO3, in turn, is dissociated into HCO3− and H+. The H+ is secreted into the tubular fluid in exchange for Na+. The Na+ and K+ then reabsorb into the blood along with Na+ and K+, respectively. The ATP used in this process is provided by the reaction of CO2 and H2O that are formed readily cross the luminal membrane and enter the tubular cell. Inside the cell, the reactions of CO2 and H2O are catalyzed by a brush border carbonic anhydrase. The CO2 and H2O that are formed are then reabsorbed in the tubules.1 Loss of even small amounts of HCO3− impairs the body’s ability to buffer its daily load of metabolic acids. Because the amount of H+ that can be filtered in the glomeruli is relatively small compared with HCO3−, its elimination relies on secretion of H+ from the blood into the urine filtrate in the tubules.

Most (85%–90%) of the H+ secretion and reabsorption of HCO3− takes place in the proximal tubule. The process begins with a coupled Na+/H+ transport system in which H+ is secreted into the tubular fluid and Na+ is reabsorbed into the tubular cell (Fig. 40.3). The secreted H+ combines with filtered HCO3− to form H2CO3. The H2CO3 then decomposes into CO2 and H2O, catalyzed by a brush border carbonic anhydrase. The CO2 and H2O that are formed are then reabsorbed in the tubules. Normally, only a few of the secreted H+ ions remain in the tubular fluid because the secretion of H+ is roughly equivalent to the number of HCO3− ions filtered in the glomerulus.

**Renal Control Mechanisms**

The kidneys play three major roles in regulating acid–base balance.2,4 The first is through the excretion of H+ from fixed acids that result from protein and lipid metabolism. The second is accomplished through the reabsorption of the HCO3− that is filtered in the glomerulus, so this important buffer is not lost in the urine. The third is the production of new HCO3− that is released back into the blood. The renal mechanisms for regulating acid–base balance cannot adjust the pH within minutes, as respiratory mechanisms can, but they begin to adjust the pH in hours and continue to function for days until the pH has returned to normal or near-normal range.

**Hydrogen Ion Elimination and Bicarbonate Conservation.** The kidneys regulate pH by excreting excess H+, reabsorbing HCO3−, and producing new HCO3−. Bicarbonate is freely filtered in the glomerulus (approximately 4300 mEq/day) and reabsorbed in the tubules. Loss of even small amounts of HCO3− impairs the body’s ability to buffer its daily load of metabolic acids. Because the amount of H+ that can be filtered in the glomeruli is relatively small compared with HCO3−, its elimination relies on secretion of H+ from the blood into the urine filtrate in the tubules.

Most (85%-90%) of the H+ secretion and reabsorption of HCO3− takes place in the proximal tubule. The process begins with a coupled Na+/H+ transport system in which H+ is secreted into the tubular fluid and Na+ is reabsorbed into the tubular cell (Fig. 40.3). The secreted H+ combines with filtered HCO3− to form H2CO3. The H2CO3 then decomposes into CO2 and H2O, catalyzed by a brush border carbonic anhydrase. The CO2 and H2O that are formed are then reabsorbed in the tubules. Normally, only a few of the secreted H+ ions remain in the tubular fluid because the secretion of H+ is roughly equivalent to the number of HCO3− ions filtered in the glomerulus.

**Figure 40.3** Hydrogen ion (H+) secretion and bicarbonate ion (HCO3−) reabsorption in a renal tubular cell. Carbon dioxide (CO2) diffuses from the blood or urine filtrate into the tubular cell, where it combines with water in a carbonic anhydrase (CA)-catalyzed reaction that yields carbonic acid (H2CO3). The H2CO3 dissociates to form H+ and HCO3−. The H+ is secreted into the tubular fluid in exchange for Na+. The Na+ and HCO3− enter the ECF (ATP, adenosine triphosphate.)
Tubular Buffer Systems. Because an extremely acidic urine filtrate would be damaging to structures in the urinary tract, the minimum urine pH is about 4.5.1,2 Once the urine pH reaches this level of acidity, H⁺ secretion ceases. This limits the amount of unbuffered H⁺ that can be eliminated by the kidney. When the amount of free H⁺ secreted into the tubular fluid threatens to cause the pH of the urine to become too acidic, it must be carried in another form. This is accomplished by combining H⁺ ions with intratubular buffers before they are excreted in the urine. There are two important intratubular buffer systems: the phosphate and ammonia buffer systems.1,9 The HCO₃⁻ that is generated by these two buffer systems is new bicarbonate, demonstrating one of the ways that the kidney is able to replenish the ECF stores of HCO₃⁻.

The phosphate buffer system uses HPO₄²⁻ and H₂PO₄⁻ that are present in the tubular filtrate. Both forms of phosphate become concentrated in the tubular fluid because of their relatively poor absorption and because of reabsorption of water from the tubular fluid. Another factor that makes phosphate so effective as a urinary buffer is the fact that urine pH is close to the pK of the phosphate buffer system. The process of H⁺ secretion in the tubules is the same as that used for reabsorption of HCO₃⁻. As long as there is excess HCO₃⁻ in the tubular fluid, most of the secreted H⁺ combines with HCO₃⁻. However, once all the HCO₃⁻ has been reabsorbed and is no longer available to combine with H⁺, any excess H⁺ combines with HPO₄²⁻ to form H₂PO₄⁻ (Fig. 40.4). After H⁺ combines with HPO₄²⁻, it can be excreted as NaH₂PO₄, carrying the excess H⁺ with it.

Another important but more complex buffer system is the ammonia buffer system. The excretion of H⁺ and generation of HCO₃⁻ by the ammonia buffer system occurs in three major steps:

1. The synthesis of ammonium (NH₄⁺) from the amino acid glutamine in the proximal tubule
2. The reabsorption and recycling of NH₄⁺ within the medullary portion of the kidney
3. The buffering of H⁺ ions by NH₃ in the collecting tubules1,3

The metabolism of glutamate in the proximal tubule results in the formation of two NH₄⁺ and two HCO₃⁻ ions1,3 (Fig. 40.5). The two NH₄⁺ ions are secreted into the tubular fluid by a countertransport mechanism in exchange for Na⁺. The two HCO₃⁻ ions move out of the tubular cell along with the reabsorbed Na⁺ to enter the peritubular capillary system. Thus, for each molecule of glutamine metabolized in the proximal tubule, two NH₄⁺ ions are secreted into the tubular

![FIGURE 40.4](image-url) • The renal phosphate buffer system. The monohydrogen phosphate ion (HPO₄²⁻) enters the renal tubular fluid in the glomerulus. An H⁺ combines with the HPO₄²⁻ to form H₂PO₄⁻ and is then excreted into the urine in combination with Na⁺. The HCO₃⁻ moves into the ECF along with the Na⁺ that was exchanged during secretion of the H⁺. (ATP, adenosine triphosphate; CA, carbonic anhydrase.)

![FIGURE 40.5](image-url) • Acidification along the nephron. The pH of tubular urine decreases along the proximal convoluted tubule, rises along the descending limb of the Henle loop, falls along the ascending limb, and reaches its lowest values in the collecting ducts. Ammonia (NH₃ + NH₄) is chiefly produced in proximal tubule cells and is secreted into the tubular urine. NH₄ is reabsorbed in the thick ascending limb and accumulates in the kidney medulla. NH₃ diffuses into acidic collecting duct urine, where it is trapped as NH₄. (From Rhoades R. A., Bell D. R. (Eds.) (2009). Medical physiology: Principles for clinical medicine (3rd ed., p. 450). Philadelphia, PA: Lippincott Williams & Wilkins.)
filtrate, and two HCO₃⁻ ions are reabsorbed into the blood. The HCO₃⁻ generated by this process constitutes new HCO₃⁻.

A significant portion of the NH₄⁺ secreted by the proximal tubular cells is reabsorbed in the thick ascending loop of Henle, where the NH₄⁺ substitutes for K⁺ on the Na⁺/K⁺/2Cl⁻ cotransporter.

The NH₄⁺ that is reabsorbed by the thick ascending loop of Henle accumulates in the medullary interstitium of the kidney, where it exists in equilibrium with NH₃ (see Fig. 40.5). Although both NH₄⁺ and NH₃ are present in the medullary interstitial fluid, only NH₄⁺ is lipid soluble and can diffuse across the collecting duct cells into the tubular fluid. Once in the tubular fluid, NH₃ combines with secreted H⁺ to form NH₄⁺. NH₄⁺ is not lipid soluble, and thus is trapped in the tubular fluid and excreted in urine. Note that the source of the H⁺ secreted by the cells of the collecting tubules is CO₂ and H₂O. Thus, for each H⁺ that is produced in the cells and secreted, an additional new HCO₃⁻ is generated and added to the blood.

One of the most important features of the ammonia buffer system is that it is subject to physiologic control. Under normal conditions, the amount of H⁺ eliminated by the ammonia buffer system is about 50% of the acid excreted and 50% of new HCO₃⁻ regenerated. However, with chronic acidosis, it can become the dominant mechanism for H⁺ excretion and new HCO₃⁻ generation. The urine anion gap, which is an indirect method for assessing urine NH₄⁺ levels, can be used to assess kidney function in terms of H⁺ elimination.

Potassium–Hydrogen Exchange. Plasma K⁺ levels influence renal elimination of H⁺ and vice versa. Hypokalemia is a potent stimulus for H⁺ secretion and HCO₃⁻ reabsorption. When plasma K⁺ levels fall, there is movement of K⁺ from the ICF to the ECF compartment and a reciprocal movement of H⁺ from the ECF to the ICF compartment. A similar process occurs in the distal tubules of the kidney, where the H⁺/K⁺-adenosine triphosphatase (ATPase) exchange pump actively reabsors K⁺ as well as secretes H⁺. An elevation in plasma K⁺ levels has the opposite effect. Plasma K⁺ levels are similarly altered by acid–base balance. Thus, acidosis tends to increase H⁺ elimination and decrease K⁺ elimination, with a resultant increase in plasma potassium levels, whereas alkalosis tends to decrease H⁺ elimination and increase K⁺ elimination, with a resultant decrease in plasma K⁺ levels.

Aldosterone also influences H⁺ elimination by the kidney. It acts in the collecting duct to stimulate H⁺ secretion indirectly, while increasing Na⁺ reabsorption and K⁺ secretion. Thus, hyperaldosteronism tends to lead to a decrease in plasma K⁺ levels and an increase in pH because of increased H⁺ secretion, whereas hypoaldosteronism has the opposite effect.

Chloride–Bicarbonate Exchange. Another mechanism that the kidneys use in regulating HCO₃⁻ is the chloride–bicarbonate anion exchange that occurs in association with Na⁺ reabsorption. Normally, Cl⁻ is absorbed along with Na⁺ throughout the tubules. In situations of volume depletion due to vomiting and chloride depletion, the kidneys are forced to substitute HCO₃⁻ for the Cl⁻ anion, thereby increasing its absorption of HCO₃⁻. Hypochloremic alkalosis refers to an increase in pH induced by excess HCO₃⁻ reabsorption due to a decrease in Cl⁻ levels, and hyperchloremic acidosis refers to a decrease in pH because of decreased HCO₃⁻ reabsorption due to an increase in Cl⁻ levels.

Laboratory Tests

Laboratory tests that are used in assessing acid–base balance include arterial blood gases and pH, CO₂ content and HCO₃⁻ levels, base excess or deficit, and blood and urine anion gaps. Although useful in determining whether acidosis or alkalosis is present, measurements of the blood pH provide little information about the cause of an acid–base disorder.

Carbon Dioxide and Bicarbonate Levels

The PCO₂ of the arterial blood gas measurement provides a means of assessing the respiratory component of acid–base balance. Arterial blood gases are used because venous blood gases are highly variable, depending on metabolic demands of the various tissues that empty into the vein from which the sample is being drawn. The H₂CO₃ levels can be determined from arterial blood gas measurements using the PCO₂ and the solubility coefficient for CO₂ (normal arterial PCO₂ is 35 to 45 mm Hg). Arterial blood gases also provide a measure of blood oxygen (PO₂) levels. This measure can be important in assessing respiratory function.

The CO₂ content refers to the total CO₂ in the blood, including dissolved CO₂, that is contained in HCO₃⁻, and that attached to hemoglobin (carbaminohemoglobin [CO₂Hb]). The normal range of values for venous HCO₃⁻ concentration is 24 to 31 mEq/L (24 to 31 mmol/L), and arterial is 22 to 26 mEq/L.

Base Excess or Deficit

The total base excess or deficit, also referred to as the whole blood buffer base, measures the level of all the buffer systems of the blood—hemoglobin, protein, phosphate, and HCO₃⁻. The base excess or deficit describes the amount of a fixed acid or base that must be added to a blood sample to achieve a pH of 7.4 (normal ± 2 mEq/L). For clinical purposes, base excess or deficit can be viewed as a measurement of bicarbonate excess or deficit and indicates a nonrespiratory change in acid–base balance. A base excess indicates metabolic alkalosis, and a base deficit indicates metabolic acidosis.

Anion Gap

The anion gap (AG), a diagnostic concept, describes the difference between the plasma concentration of the major measured cation (Na⁺) and the sum of the measured anions (Cl⁻ and HCO₃⁻). This difference represents the concentration of unmeasured anions, such as phosphates, sulfates, organic acids, and proteins (Fig. 40.6). Normally, the AG measured by flame atomic emission spectrometry (FAES) ranges between 8 and 16 mEq/L (a value range of 12 to 20 mEq/L is normal when potassium is included in the calculation). Because albumin is an anion, it is often measured and used in determining the AG in people with decreased albumin levels. For every 1 g/dL decline in plasma albumin concentration, a
The anion gap of urine is useful as a diagnostic tool. The anion gap in acidosis due to excess metabolic acids and excess plasma chloride levels. Unmeasured anions such as phosphates, sulfates, and organic acids increase the anion gap because they replace bicarbonate. This assumes there is no change in sodium content.

The anion gap (AG) is an estimate of ammonium (NH₄⁺) excretion. Because ammonium is a cation, the value of the anion gap becomes more negative as the ammonium level increases. In normal persons secreting 20 to 40 mmol of ammonium per liter, the urine anion gap is close to zero representing electroneutrality. In metabolic acidosis, the amount of unmeasured NH₄⁺ should increase if renal excretion of H⁺ is intact; as a result, the urine anion gap should become more negative.

The anion gap (AG) is an estimate of ammonium (NH₄⁺) excretion. This assumes there is no change in sodium content.

The anion gap (AG) is an estimate of ammonium (NH₄⁺) excretion. This assumes there is no change in sodium content.

Correction factor should be added to the gap that is calculated from the formula: AG = Na⁺ – (Cl⁻ + HCO₃⁻). The AG is used typically in diagnosing causes of metabolic acidosis. An increased level is found in conditions such as lactic acidosis and ketoacidosis that result from elevated levels of metabolic acids. A low AG is found in conditions that produce a fall in unmeasured anions (primarily albumin) or rise in unmeasured cations. The latter can occur in hyperkalemia, hypercalcemia, hypermagnesemia, lithium intoxication, or multiple myeloma, in which an abnormal immunoglobulin is produced.

The anion gap of urine is useful as a diagnostic tool. Urine electrolyte determinations do not include bicarbonate. Instead, the urine anion gap uses the difference between the measurable cations (Na⁺ and K⁺) and anions (Cl⁻) to provide an estimate of ammonium (NH₄⁺) excretion. Because ammonium is a cation, the value of the anion gap becomes more negative as the ammonium level increases. In normal persons secreting 20 to 40 mmol of ammonium per liter, the urine anion gap is close to zero representing electroneutrality. In metabolic acidosis, the amount of unmeasured NH₄⁺ should increase if renal excretion of H⁺ is intact; as a result, the urine anion gap should become more negative.

The terms acidosis and alkalosis describe the clinical conditions that arise as a result of changes in dissolved CO₂ and HCO₃⁻ concentrations. An alkali represents a combination of one or more alkali metals such as sodium or potassium with a highly basic ion such as a hydroxyl ion (OH⁻). Sodium bicarbonate is the main alkali in the ECF. Although the definitions differ somewhat, the terms alkali and base are often used interchangeably. Hence, the term alkalosis has come to mean the opposite of acidosis. Typically, imbalances in acid–base result in acidosis. Alkalosis is usually compensatory.

Normal body function depends on the precise regulation of acid–base balance. The pH of the ECF is normally maintained within the narrow physiologic range of 7.35 to 7.45. Metabolic processes produce volatile and fixed or nonvolatile metabolic acids that must be buffered and eliminated from the body. The volatile acid, H₂CO₃, is in equilibrium with dissolved CO₂, which is eliminated through the lungs. The nonvolatile metabolic acids, which are derived mainly from protein metabolism and incomplete carbohydrate and fat metabolism, are excreted by the kidneys. It is the ratio of the HCO₃⁻ concentration to dissolved CO₂ (H₂CO₃ concentration) that determines the pH of the ECFs. When this ratio is 20:1, the pH is 7.4.

The ability of the body to maintain pH within the normal physiologic range depends on respiratory and renal mechanisms and on chemical buffers in the ICF and ECF, the most important of which is the HCO₃⁻ buffer system. The respiratory regulation of pH is rapid but does not return the pH completely to normal. The kidneys aid in regulation of pH by eliminating H⁺ ions, conserving HCO₃⁻ ions, and producing new HCO₃⁻ ions. In the process of eliminating H⁺, it uses the phosphate and ammonia buffer systems. Body pH is also affected by the distribution of exchangeable cations (K⁺ and H⁺) and anions (Cl⁻ and HCO₃⁻).

Laboratory tests used in assessing acid–base balance include arterial blood gas measurements, CO₂ content and HCO₃⁻ levels, base excess or deficit, and the anion gap. The base excess or deficit describes the amount of a fixed acid or base that must be added to a blood sample to achieve a pH of 7.4. The anion gap describes the difference between the plasma concentration of the major measured cation (Na⁺) and the sum of the anions (Cl⁻ and HCO₃⁻). This difference represents the concentration of unmeasured anions, such as phosphates, sulfates, and organic acids, which are present. The urine anion gap uses the difference between the measurable cations (Na⁺ and K⁺) and anions (Cl⁻) to provide an estimate of ammonium (NH₄⁺) excretion and the ability of the kidney to rid the body of excess H⁺.

DISORDERS OF ACID–BASE BALANCE

After completing this section of the chapter, you should be able to meet the following objectives:

- Define metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis.
- Describe the common causes of metabolic and respiratory acidosis and metabolic and respiratory alkalosis.
- Contrast and compare the clinical manifestations and treatments of metabolic and respiratory acidosis and of metabolic and respiratory alkalosis.

The terms acidosis and alkalosis describe the clinical conditions that arise as a result of changes in dissolved CO₂ and HCO₃⁻ concentrations. An alkali represents a combination of one or more alkali metals such as sodium or potassium with a highly basic ion such as a hydroxyl ion (OH⁻). Sodium bicarbonate is the main alkali in the ECF. Although the definitions differ somewhat, the terms alkali and base are often used interchangeably. Hence, the term alkalosis has come to mean the opposite of acidosis. Typically, imbalances in acid–base result in acidosis. Alkalosis is usually compensatory.
Metabolic Versus Respiratory Acid–Base Disorders

There are two types of acid–base disorders: metabolic and respiratory (Table 40.1). Metabolic disorders produce an alteration in the plasma $\text{HCO}_3^-$ concentration and result from the addition to or loss from the ECF of nonvolatile acid or alkali. A reduction in pH due to a decrease in $\text{HCO}_3^-$ is called metabolic acidosis, and an elevation in pH due to increased $\text{HCO}_3^-$ levels is called metabolic alkalosis. Respiratory disorders involve an alteration in the $\text{PCO}_2$, reflecting an increase or decrease in alveolar ventilation. Respiratory acidosis is characterized by a decrease in pH, reflecting a decrease in ventilation, and an increase in $\text{PCO}_2$. Respiratory alkalosis involves an increase in pH, resulting from an increase in alveolar ventilation and a decrease in $\text{PCO}_2$.

Compensatory Mechanisms

Acidosis and alkalosis typically involve a primary or initiating event and a compensatory or adaptive state that results from homeostatic mechanisms that attempt to correct or prevent large changes in pH. For example, a person may have a primary metabolic acidosis as a result of overproduction of ketoads and respiratory alkalosis because of a compensatory increase in ventilation (see Table 40.1).

Compensatory mechanisms provide a means to control pH when correction is impossible or cannot be achieved immediately. Often, compensatory mechanisms are interim measures that permit survival while the body attempts to correct the primary disorder. Compensation requires the use of mechanisms that are different from those that caused the primary disorder. For example, the lungs cannot compensate for respiratory acidosis that is caused by lung disease, nor can the kidneys compensate for metabolic acidosis that occurs because of chronic kidney disease. The body can, however, use renal mechanisms to compensate for respiratory-induced changes in pH, and it can use respiratory mechanisms to compensate for metabolically induced changes in acid–base balance. Because compensatory mechanisms become more effective with time, there are often differences between the level of pH change that is present in acute and chronic acid–base disorders. There is a distinction between acute and chronic respiratory acid–base disorders but not for metabolic acid–base disorders. This difference is due to the fact that renal compensation for a respiratory disorder may take days, but the respiratory compensation for a metabolic disorder is within minutes to hours.

### Table 40.1 Summary of Single Acid–Base Disturbances and Their Compensatory Responses

<table>

$0.2 \text{ mEq/L} \uparrow \text{HCO}_3^- \rightarrow$  
$0.4 \text{ mEq/L} \uparrow \text{HCO}_3^- \rightarrow$  
$0.7 \text{ mm Hg} \uparrow \text{PCO}_2$ |
| Respiratory alkalosis     | ↑pH and ↓$\text{PCO}_2$  
$\text{PCO}_2 < 35 \text{ mm Hg}$ | None | |

Note: Predicted compensatory responses are in *italics.*

*If blood values are the same as predicted compensatory values, a single acid–base disorder is present; if values are different, a mixed acid–base disorder is present.*

†Acute renal compensation refers to duration of minutes to several hours; chronic renal compensation refers to a duration of several days.
a low plasma HCO$_3^-$ concentration due to metabolic acidosis and a high PCO$_2$ due to chronic lung disease. Values for the predicted renal or respiratory compensatory responses can be used in the diagnosis of these mixed acid–base disorders (see Table 40.1). If the values for the compensatory response fall outside the predicted plasma values, it can then be concluded that more than one disorder (i.e., a mixed disorder) is present. Because the respiratory response to changes in HCO$_3^-$ occurs almost immediately, there is only one predicted compensatory response for primary metabolic acid–base disorders. This is in contrast to the primary respiratory disorders, which have two ranges of predicted values, one for the acute and one for the chronic response. Renal compensation takes several days to become fully effective. The acute compensatory response represents the HCO$_3^-$ levels before renal compensation has occurred, and the chronic response after it has occurred. Thus, the values for the plasma pH tend to be more normal in the chronic phase.

### Metabolic Acidosis

Metabolic acidosis involves a decreased plasma HCO$_3^-$ concentration along with a decrease in pH. In metabolic acidosis, the body compensates for the decrease in pH by increasing the respiratory rate in an effort to decrease PCO$_2$ and H$_2$CO$_3$ levels. The PCO$_2$ can be expected to fall by 1 to 1.5 mm Hg for each 1-mEq/L fall in HCO$_3^-$ (3-17).

### Etiology

Metabolic acidosis can be caused by one or more of the following four mechanisms:

1. Increased production of fixed metabolic acids or ingestion of fixed acids such as salicylic acid
2. Inability of the kidneys to excrete the fixed acids produced from normal metabolism
3. Excessive loss of bicarbonate through the kidneys or gastrointestinal tract
4. Increased plasma Cl$^-$ concentration

The anion gap is often useful in determining the cause of the metabolic acidosis (Chart 40.1). The presence of excess metabolic acids produces an increase in the anion gap as sodium salt of the offending acid (e.g., sodium lactate) replaces sodium bicarbonate. Diarrhea is the most frequent cause of a normal AG metabolic acidosis. When the acidosis results from an increase in plasma Cl$^-$ levels (e.g., hyperchloremic acidosis), the anion gap also remains within normal levels. The pneumatic “MUDPILES” can be used to remember the most common etiologies of a high AG acidosis (Methanol, Uremia, Diabetic ketoacidosis, Paraldehyde, Isoniazid, Lactic acid, Ethanol [ethylene glycol], and Salicylates [starvation]). The causes of metabolic acidosis are summarized in Table 40.2.

### Lactic Acidosis

Acute lactic acidosis is the most common type of metabolic acidosis in people who are hospitalized and develops when there is excess production or diminished removal of lactic acid from the blood. Lactic acid is produced by the anaerobic metabolism of glucose. Most cases
of lactic acidosis are caused by inadequate oxygen delivery, as in shock or cardiac arrest.\(^7\)\(^9\) Such conditions not only increase lactic acid production, but they tend to impair lactic acid clearance because of poor liver and kidney perfusion. Mortality rates are high for people with lactic acidosis due to shock and tissue hypoxia.\(^20\) Severe sepsis is also commonly associated with lactic acidosis.\(^21\) Lactic acidosis can occur during periods of intense exercise in which the metabolic needs of the exercising muscles outpace their aerobic capacity for production of ATP, causing them to revert to anaerobic metabolism and the production of lactic acid.\(^19\)

Lactic acidosis is associated with disorders in which tissue hypoxia does not appear to be present. It has been reported in people with leukemia, lymphomas, and other cancers; those with poorly controlled diabetes; and in people with severe liver failure.\(^7\) Mechanisms causing lactic acidosis in these conditions are poorly understood. Some conditions such as neoplasms may produce local increases in tissue metabolism and lactate production, or they may interfere with blood flow to noncancerous cells.

A variety of drugs can produce life-threatening lactic acidosis by inhibiting mitochondrial function. These drugs include the biguanide antidiabetic drugs (metformin)\(^19\)\(^22\) and the antiretroviral nucleoside reverse transcriptase inhibitors (NRTIs) (e.g., zidovudine [AZT]) that are used to treat acquired immunodeficiency syndrome (AIDS).\(^19\)

A relatively rare form of lactic acidosis, called d-lactic acidosis, can occur in people with intestinal disorders that involve the generation and absorption of d-lactic acid (l-lactic acid is the usual cause of lactic acidosis).\(^23\) It most commonly occurs in people with jejunoileal bypass surgery for the treatment of obesity or who have short bowel syndrome, in which there is impaired absorption of carbohydrate in the small intestine.\(^23\) In these cases, the unabsorbed carbohydrate is delivered to the colon, where it is converted to d-lactic acid by an overgrowth of gram-positive anaerobes. People with d-lactic acidosis experience episodic periods of metabolic acidosis often brought on by eating a meal high in carbohydrates. Neurological manifestations include confusion, cerebellar ataxia, slowed speech, and loss of memory. They may complain of feeling (or appear)
alcohol consumption and can be fatal clinically.4,24 It usually can develop in people who engage in excess

**Ketoacidosis.** Ketoacids (i.e., acetocetate and β-hydroxybutyric acid), produced in the liver from fatty acids, are the source of fuel for many body tissues. An overproduction of ketoacids occurs when carbohydrate stores are inadequate or when the body cannot use available carbohydrates as a fuel. Under these conditions, fatty acids are mobilized from adipose tissue and delivered to the liver, where they are converted to ketones. Ketoacidosis develops when ketone production by the liver exceeds tissue use.4

The most common cause of ketoacidosis is uncontrolled diabetes mellitus, in which an insulin deficiency leads to the release of fatty acids from adipose cells with subsequent production of excess ketoacids.2,3 Ketoacidosis may also develop as the result of fasting or food deprivation, during which the lack of carbohydrates produces a self-limited state of ketoacidosis.4,12

Ketones are formed during the oxidation of alcohol, a process that occurs in the liver. A condition called *alcoholic ketoacidosis* can develop in people who engage in excess alcohol consumption and can be fatal clinically.4,24 It usually follows prolonged alcohol ingestion, particularly if accompanied by decreased food intake and vomiting: conditions that result in using fatty acids as an energy source. Ketone formation may be further enhanced by the hypoglycemia that results from alcohol-induced inhibition of glucose synthesis (i.e., gluconeogenesis) by the liver and impaired ketone elimination by the kidneys because of dehydration. An ECF volume deficit caused by vomiting and decreased fluid intake often contributes to the acidosis. Numerous other factors, such as elevations in cortisol, growth hormone, glucagon, and catecholamines, mediate free fatty acid release and thereby contribute to the development of alcoholic ketoacidosis.

**Salicylate Toxicity.** Salicylates are another potential source of metabolic acids. Acetylsalicylic acid (Aspirin) is readily absorbed in the stomach and small bowel and then rapidly converted to salicylic acid in the body.4,24 Although aspirin is the most common cause of salicylate toxicity, other salicylate preparations such as methyl salicylate, sodium salicylate, and salicylic acid may produce similar effects. Salicylate overdose produces serious toxic effects, including death. The weight-based, acute ingestion of 150 mg/kg or 6.5 g of aspirin requires referral to an emergency department to prevent a fatality.25

A variety of acid–base disturbances occur with salicylate toxicity. The salicylates cross the blood–brain barrier and directly stimulate the respiratory center, causing hyperventilation and respiratory alkalosis. The kidneys compensate by secreting increased amounts of HCO_3^- , K^+, and Na^+ , thereby contributing to the development of metabolic acidosis. Salicylates also interfere with carbohydrate metabolism, which results in increased production of metabolic acids.

One of the treatments for salicylate toxicity is *alkalinization* of the plasma. Salicylic acid, which is a weak acid, exists in equilibrium with the alkaline salicylate anion. It is the salicylic acid that is toxic because of its ability to cross cell membranes and enter brain cells. The salicylate anion crosses membranes poorly and is less toxic. With alkalinization of the ECFs, the ratio of salicylic acid to salicylate is greatly reduced. This allows salicylic acid to move out of cells into the ECF along a concentration gradient. The renal elimination of salicylates follows a similar pattern when the urine is alkalinized.

**Methanol and Ethylene Glycol Toxicity.** Ingestion of methanol and ethylene glycol results in the production of metabolic acids and causes metabolic acidosis. Both produce an osmolar gap because of their small size and osmotic properties. Methanol (wood alcohol) is a component of shellac, varnish, deicing solutions, and other commercial products. A person addicted to alcohol sometimes consumes it as a substitution for ethanol.4 Methanol can be absorbed through the skin or gastrointestinal tract or inhaled through the lungs. A dose as small as 10 mL can be toxic.18 In addition to metabolic acidosis, methanol produces severe optic nerve and central nervous system toxicity. Organ system damage occurs after a 24-hour period in which methanol is converted to formaldehyde and formic acid.

Ethylene glycol is a solvent found in products ranging from antifreeze and deicing solutions to carpet and fabric cleaners. It tastes sweet and is intoxicating, factors that contribute to its abuse potential. The leading cause of death from a chemical agent in the United States.12 Ethylene glycol is the chemical agent in the United States.12 It is rapidly absorbed from the intestine, making treatment with gastric lavage and syrup of ipecac ineffective. Acidosis occurs as ethylene glycol is converted to oxalic and lactic acid. Manifestations of ethylene glycol toxicity occur in three stages:

1. Neurologic symptoms ranging from drunkenness to coma, which appear during the first 12 hours
2. Cardiorespiratory disorders such as tachycardia and pulmonary edema
3. Flank pain and acute renal failure caused by plugging of the tubules with oxalate crystals (from excess oxalic acid production)22

The enzyme alcohol dehydrogenase metabolizes methanol and ethylene glycol into their toxic metabolites. This is the same enzyme that is used in the metabolism of ethanol. Because alcohol dehydrogenase has a greater affinity for ethanol than its affinity for methanol or ethylene glycol, intravenous or oral ethanol is used as an antidote for methanol and ethylene glycol poisoning. Extracellular volume expansion and hemodialysis are also used. Fomepizole (Antizol) is approved by the U.S. Food and Drug Administration as an antidote for methanol and ethylene glycol poisoning.26 In a manner similar to ethanol, it is thought to act as an inhibitor of alcohol dehydrogenase, thereby preventing the formation of the toxic ethylene glycol metabolites.

**Decreased Renal Function.** Chronic kidney disease is the most common cause of chronic metabolic acidosis. The kidneys normally conserve HCO_3^- and secrete H^+ ions into the urine as a means of regulating acid–base balance. In chronic
kidney disease, there is loss of both glomerular and tubular function, with retention of nitrogenous wastes and metabolic acids. The most prominent effect of these changes is on the musculoskeletal system. In a condition called chronic renal tubular acidosis, glomerular function is normal, but the tubular secretion of H+ or reabsorption of HCO3− is abnormal.27

**Increased Bicarbonate Losses.** Increased HCO3− losses occur with the loss of bicarbonate-rich body fluids or with impaired conservation of HCO3− by the kidney. Intestinal secretions have a high HCO3− concentration. Consequently, excessive loss of HCO3− occurs with severe diarrhea; small bowel, pancreatic, or biliary fistula drainage; ileostomy drainage; and intestinal suction. In diarrhea of microbial origin, HCO3− is also secreted into the bowel as a means of neutralizing the metabolic acids produced by the microorganisms causing the diarrhea. Creation of an ileal bladder, which is done for conditions such as neurogenic bladder or surgical removal of the bladder because of cancer, involves the implantation of the ureters into a short, isolated loop of ileum that serves as a conduit for urine collection. With this procedure, contact time between the urine and ileal bladder is normally too short for significant anion exchange, and HCO3− is lost in the urine.28

**Hyperchloremic Acidosis.** Hyperchloremic acidosis occurs when Cl− levels are increased. Because Cl− and HCO3− are exchangeable anions, the plasma HCO3− decreases when there is an increase in Cl−. Hyperchloremic acidosis can occur as the result of abnormal absorption of Cl− by the kidneys or as a result of treatment with chloride-containing medications (i.e., sodium chloride, amino acid–chloride hyperalimentation solutions, and ammonium chloride). Ammonium chloride is broken down into NH4+ and Cl−. The ammonium ion is converted to urea in the liver, leaving the Cl− free to react with H+ to form HCl. The administration of intravenous sodium chloride or parenteral hyperalimentation solutions that contain an amino acid–chloride combination can cause acidosis in a similar manner.15 With hyperchloremic acidosis, the anion gap remains within the normal range, whereas plasma Cl− levels are increased and HCO3− levels are decreased.

**Clinical Manifestations**

Metabolic acidosis is characterized by a decrease in pH (<7.35) and HCO3− levels (<22 mEq/L) due to a gain in H+ or a loss of HCO3−. Acidosis typically produces a compensatory increase in respiratory rate with a decrease in PCO2.

The manifestations of metabolic acidosis fall into three categories:

1. Signs and symptoms of the disorder causing the acidosis
2. Changes in body function related to recruitment of compensatory mechanisms
3. Alterations in cardiovascular, neurologic, and musculoskeletal function resulting from the decreased pH (see Table 40.2)

The signs and symptoms of metabolic acidosis usually begin to appear when the plasma HCO3− concentration falls to 20 mEq/L or less. A fall in pH to less than 7.1 to 7.2 can reduce cardiac output and predispose to potentially fatal cardiac arrhythmias.7

Metabolic acidosis is seldom a primary disorder. It usually develops during the course of another disease.4 The manifestations of metabolic acidosis frequently are superimposed on the symptoms of the contributing health problem. With diabetic ketoacidosis, which is a common cause of metabolic acidosis, there is an increase in blood and urine glucose and a characteristic smell of ketones to the breath. In the metabolic acidosis that accompanies chronic kidney disease, blood urea nitrogen levels are elevated and other tests of renal function yield abnormal results.

Clinical manifestations related to respiratory and renal compensatory mechanisms usually occur early in the course of metabolic acidosis. In situations of acute metabolic acidosis, the respiratory system compensates for a decrease in pH by increasing ventilation to reduce PCO2. This is accomplished through deep and rapid respirations. In diabetic ketoacidosis, this breathing pattern is referred to as Kussmaul breathing. For descriptive purposes, it can be said that Kussmaul breathing resembles the hyperpnea of exercise—the person breathes as though he or she had been running. There may be complaints of difficult breathing or dyspnea with exertion. With severe acidosis, dyspnea may be present even at rest. Respiratory compensation for acute acidosis tends to be somewhat greater than for chronic acidosis. When kidney function is normal, H+ excretion increases promptly in response to acidosis, and the urine becomes more acidic.

Changes in pH have a direct effect on body function that can produce signs and symptoms common to most types of metabolic acidosis, regardless of cause. People with metabolic acidosis often complain of weakness, fatigue, general malaise, and a dull headache. They also may have anorexia, nausea, vomiting, and abdominal pain. Tissue turgor is impaired, and the skin is dry when fluid deficit accompanies acidosis. In people with undiagnosed diabetes mellitus, the nausea, vomiting, and abdominal symptoms may be misinterpreted as being caused by gastrointestinal flu or other abdominal disease, such as appendicitis. Acidosis depresses neuronal excitability, and it decreases binding of calcium to plasma proteins, so that more free calcium is available to decrease neural activity. As acidosis progresses, the level of consciousness declines, and stupor and coma develop. The skin is often warm and flushed because blood vessels in the skin become less responsive to sympathetic nervous system stimulation and lose their tone.

When the pH falls to 7.1 to 7.2, cardiac contractility and cardiac output decrease, the heart becomes less responsive to catecholamines (i.e., epinephrine and norepinephrine), and arrhythmias, including fatal ventricular arrhythmias, can develop. A decrease in ventricular function may be particularly important in perpetuating shock-induced lactic acidosis, and partial correction of the acidemia may be necessary before tissue perfusion can be restored.12

Chronic acidemia, as in chronic kidney disease, can lead to a variety of musculoskeletal problems, some of which...
result from the release of calcium and phosphate during bone buffering of excess H\(^+\) ions.\(^\text{17}\) Of particular importance is impaired growth in children. In infants and children, acidaemia may be associated with a variety of nonspecific symptoms such as anorexia, weight loss, muscle weakness, and listlessness. Muscle weakness and listlessness may result from alterations in muscle metabolism.

**Treatment**

The treatment of metabolic acidosis focuses on correcting the condition that caused the disorder and restoring the fluids and electrolytes that have been lost from the body. The use of supplemental sodium bicarbonate (\(\text{NaHCO}_3\)) has been the mainstay of treatment for some forms of normal anion gap acidosis.\(^\text{17}\) However, its use in treatment of metabolic acidosis with an increased anion gap is controversial.\(^\text{17}\) In most people with circulatory shock, cardiac arrest, or sepsis, impaired oxygen delivery is the primary cause of lactic acidosis. In these situations, the administration of large amounts of \(\text{NaHCO}_3\) does not improve oxygen delivery. With lactic acidosis, treatment measures to improve tissue perfusion are necessary, and with sepsis-related acidosis, treatment of the infection is essential.\(^\text{17}\)

**Metabolic Alkalosis**

Metabolic alkalosis is a systemic disorder caused by an increase in plasma pH due to a primary excess in HCO\(_3^-\).\(^\text{1,8,15}\) It is reported to be the second most common acid–base disorder in hospitalized adults, accounting for about 32% of all acid–base disorders.\(^\text{7}\)

**Etiology**

Metabolic alkalosis can be caused by factors that generate a loss of fixed acids or a gain of bicarbonate and those that maintain the alkalis by interfering with excretion of the excess bicarbonate (Table 40.3). They include

1. A gain of base through the oral or intravenous route
2. Loss of fixed acids from the stomach
3. Maintenance of the increased bicarbonate levels by contraction of the ECF volume, hypokalemia, and hypochloremia

**Excess Base Loading.** Because the normal kidney is extremely efficient at excreting bicarbonate, excess base intake is rarely a cause of significant chronic metabolic alkalosis. Transient acute alkalosis, on the other hand, is a rather common occurrence during or immediately after excess oral ingestion of bicarbonate-containing antacids (e.g., Alka-Seltzer) or intravenous infusion of \(\text{NaHCO}_3\) or base equivalent (e.g., acetate in hyperalimentation solutions, lactate in Ringer’s lactate, and citrate in blood transfusions). A condition called the *milk-alkali syndrome* is a condition in which the chronic ingestion of milk or calcium carbonate antacids leads to hypercalcemia and metabolic alkalosis. In this case, the antacids raise the plasma HCO\(_3^-\) concentration, whereas

the hypercalcemia prevents the urinary excretion of HCO₃⁻. The most common cause at present is the administration of calcium carbonate as a phosphate binder to persons with chronic kidney disease.²⁹

**Loss of Fixed Acid.** The loss of fixed acids occurs mainly through the loss of acid from the stomach and the loss of chloride in the urine. Vomiting and removal of gastric secretions by nasogastric suction are common causes of metabolic alkalosis in acutely ill or hospitalized people. Gastric secretions contain high concentrations of HCl and lesser concentrations of potassium chloride (KCl). As Cl⁻ is taken from the blood and secreted into the stomach, it is replaced by HCO₃⁻. Thus, the loss of gastric secretions through vomiting or gastric suction is a common cause of metabolic alkalosis. The accompanying ECF volume depletion, hypochloremia, and hypokalemia serve to maintain the metabolic alkalosis by increasing HCO₃⁻ reabsorption by the kidneys (Fig. 40.7). The loop (e.g., furosemide [Lasix]) and thiazide (e.g., hydrochlorothiazide) diuretics are commonly associated with metabolic alkalosis, the severity of which varies directly with the degree of diuresis. The volume contraction and loss of H⁺ in the urine contribute to the problem. The latter is primarily due to the enhanced H⁺ secretion in the distal tubule that results from an interplay between the diuretic-induced increase in Na⁺ delivery to the distal tubule and collecting duct, where an accelerated excretion of H⁺ and K⁺ takes place, and an increase in aldosterone secretion resulting from the volume contraction. Although aldosterone blunts the loss of Na⁺, it also accelerates the secretion of K⁺ and H⁺. The resulting loss of K⁺ also accelerates HCO₃⁻ reabsorption.

Metabolic alkalosis can also occur with abrupt correction of respiratory acidosis in people with chronic respiratory acidosis. Chronic respiratory acidosis is associated with a compensatory loss of H⁺ and Cl⁻ in the urine along with HCO₃⁻ retention. When respiratory acidosis is corrected abruptly, as with mechanical ventilation, a “posthypercapnic” metabolic alkalosis may develop because although the PCO₂ drops rapidly, the plasma HCO₃⁻, which must be eliminated through the kidney, remains elevated.

**Maintenance of Metabolic Alkalosis.** Maintenance of metabolic alkalosis resides within the kidney and its inability to rid the body of excess HCO₃⁻. Many of the conditions that accompany the development of metabolic alkalosis, such as contraction of the ECF volume, hypochloremia, and hypokalemia, also increase reabsorption of HCO₃⁻ by the kidney, thereby contributing to its maintenance.

Depletion of the ECF causes a decline in the glomerular filtration rate with a subsequent increase in Na⁺ and H₂O reabsorption. When there is Cl⁻ depletion from loss of HCl, the available anion for reabsorption with Na⁺ is HCO₃⁻. Hypokalemia, which generally accompanies metabolic alkalosis, also increases reabsorption of HCO₃⁻ by the kidney, thereby contributing to its maintenance. This is due partly to the direct effect of alkalosis on potassium excretion by the kidney and partly to a secondary hyperaldosteronism resulting from volume depletion. In hypokalemia, the distal tubular reabsorption of K⁺ is accompanied by an increase in H⁺ secretion.³⁰ The secondary hyperaldosteronism, in turn, promotes extensive reabsorption of Na⁺ from the distal and collecting tubules and at the same time stimulates the secretion of H⁺ from cells in the collecting tubules. Hypokalemia induced in this manner further worsens the metabolic alkalosis by increasing HCO₃⁻ reabsorption in the proximal tubule and H⁺ secretion in the distal tubule.

**Clinical Manifestations**

Metabolic alkalosis is characterized by a pH above 7.45, HCO₃⁻ above 26 mEq/L (26 mmol/L), and base excess above 2 mEq/L (2 mmol/L; see Table 40.3). People with metabolic alkalosis often are asymptomatic or have signs related to ECF volume depletion or hypokalemia. Neurologic signs and symptoms (e.g., hyperexcitability) occur less frequently with metabolic alkalosis than with other acid–base disorders because HCO₃⁻ enters the CSF more slowly than CO₂. When neurologic manifestations do occur, as in acute and severe metabolic alkalosis, they include mental confusion,
hyperactive reflexes, tetany, and carpopedal spasm. Metabolic alkalosis also leads to a compensatory hypoventilation with development of various degrees of hypoxemia and respiratory acidosis. Significant morbidity occurs with severe metabolic alkalosis (pH > 7.55), including respiratory failure, cardiac arrhythmias, seizures, and coma.

**Treatment**

The treatment of metabolic alkalosis usually is directed toward correcting the cause of the condition. A chloride deficit requires correction. Potassium chloride usually is the treatment of choice when there is an accompanying K+ deficit. When KCl is used as a therapy, the Cl\(^-\) anion replaces the HCO\(_3\)^- anion and the K\(^+\) corrects the potassium deficit, allowing the kidneys to retain H\(^+\) while eliminating K\(^+\). Fluid replacement with normal saline or one-half normal saline often is used in treatment of volume contraction alkalosis.

**Respiratory Acidosis**

Respiratory acidosis occurs in conditions that impair alveolar ventilation and cause an increase in plasma PCO\(_2\), also known as hypercapnia, along with a decrease in pH. Respiratory acidosis can occur as an acute or chronic disorder, but occurs most often as a result of decreased ventilation. Acute respiratory failure is associated with a rapid rise in arterial PCO\(_2\) with a minimal increase in plasma HCO\(_3\)^- and large decrease in pH. Chronic respiratory acidosis is characterized by a sustained increase in arterial PCO\(_2\), resulting in renal adaptation with a more marked increase in plasma HCO\(_3\)^- and a lesser decrease in pH.

**Etiology**

Respiratory acidosis occurs in acute or chronic conditions that impair effective alveolar ventilation and cause an accumulation of CO\(_2\) (Table 40.4). Impaired ventilation can occur as the result of decreased respiratory drive, lung disease, or disorders of chest wall and respiratory muscles. Less commonly, it results from excess CO\(_2\) production.

**Acute Disorders of Ventilation.** Acute respiratory acidosis can be caused by impaired function of the respiratory center in the medulla (as in narcotic overdose), lung disease, chest injury, weakness of the respiratory muscles, or airway obstruction. Almost all people with acute respiratory acidosis are hypoxicemic if they are breathing room air. In many cases, signs of hypoxemia develop before those of respiratory acidosis because CO\(_2\) diffuses across the alveolar capillary membrane 20 times more rapidly than oxygen.

**Chronic Disorders of Ventilation.** Chronic respiratory acidosis is a relatively common disturbance in people with chronic obstructive lung disease. In these people, the persistent elevation of PCO\(_2\) stimulates renal H\(^+\) secretion and

HCO$_3^-$ reabsorption. The effectiveness of these compensatory mechanisms can often return the pH to near-normal values as long as oxygen levels are maintained within a range that does not unduly suppress chemoreceptor control of respirations.

An acute episode of respiratory acidosis can develop in people with chronic lung disease who receive oxygen therapy at a flow rate that is sufficient to raise their PO$_2$ to a level that produces a decrease in ventilation. In these people, the medullary respiratory center has adapted to the elevated levels of CO$_2$ and no longer responds to increases in PCO$_2$. Instead, a decrease in the PO$_2$ becomes the major stimulus for respiration. If oxygen is administered at a flow rate that is sufficient to suppress this stimulus, the rate and depth of respiration decrease, and the PCO$_2$ increases. Any person who is in need of additional oxygen should it administered, albeit at a flow rate that does not depress the respiratory drive.

**Increased Carbon Dioxide Production.** Carbon dioxide is a product of the body’s metabolic processes, generating a substantial amount of acid that must be excreted by the lungs or kidneys to prevent acidosis. An increase in CO$_2$ production can result from numerous processes, including exercise, fever, sepsis, and burns. Nutrition also affects the production of carbon dioxide. A carbohydrate-rich diet produces larger amounts of CO$_2$ than one containing reasonable amounts of protein and fat. Although excess CO$_2$ production can lead to an increase in PCO$_2$, it seldom does. In healthy people, an increase in CO$_2$ is usually matched by an increase in CO$_2$ elimination by the lungs. In contrast, people with respiratory diseases may be unable to eliminate the excess CO$_2$.

**Clinical Manifestations**
Respiratory acidosis is associated with a pH below 7.35 and a PCO$_2$ above 45 mm Hg (see Table 40.4). The clinical manifestations of respiratory acidosis depend on the rapidity of onset and whether the condition is acute or chronic. Because respiratory acidosis often is accompanied by hypoxemia, the manifestations of respiratory acidosis often are intermixed with those of oxygen deficit. Carbon dioxide readily crosses the blood–brain barrier, exerting its effects by changing the pH of brain fluids. Elevated levels of CO$_2$ produce vasodilation of cerebral blood vessels, causing headache, blurred vision, irritability, muscle twitching, and psychological disturbances. If the condition is severe and prolonged, it can cause an increase in CSF pressure and papilledema. Impaired consciousness, ranging from lethargy to coma, develops as the PCO$_2$ rises to extreme levels. Paralysis of the extremities may occur, and there may be respiratory depression. Less severe forms of acidosis often are accompanied by warm and flushed skin, weakness, and tachycardia.

**Treatment**
The treatment of acute and chronic respiratory acidosis is directed toward improving ventilation. In severe cases, mechanical ventilation may be necessary.

**KEY POINTS**

**Respiratory Acidosis**
Respiratory acidosis is a systemic acid–base disorder characterized by a primary decrease in plasma PCO$_2$, also referred to as hypocapnia, which produces an elevation in pH and a subsequent decrease in HCO$_3^-$.

**Respiratory Alkalosis**
Respiratory alkalosis is caused by hyperventilation or a respiratory rate in excess of that needed to maintain normal plasma PCO$_2$ levels (Table 40.5). It may occur as the result of central stimulation of the medullary respiratory center or stimulation of peripheral (e.g., carotid chemoreceptor) pathways to the medullary respiratory center, but rarely does it occur as a result of a physical pathological condition.

Mechanical ventilation may produce respiratory alkalosis if the rate and tidal volume are set, so that CO$_2$ elimination exceeds CO$_2$ production. Carbon dioxide crosses the alveolar capillary membrane 20 times more rapidly than oxygen. Therefore, increased minute ventilation may be necessary to maintain adequate oxygen levels while producing a concomitant decrease in CO$_2$ levels. Respiratory alkalosis is seen as a treatment with the ventilator with intubated people experiencing high intracranial pressure (ICP) in order to attempt to lower the ICP.

Central stimulation of the medullary respiratory center occurs with anxiety, pain, pregnancy, febrile states, sepsis, encephalitis, and salicylate toxicity. Respiratory alkalosis has long been recognized as an acid–base disorder in people who are critically ill, and is a consistent finding in pulmonary embolism and congestive heart failure. Women can develop substantial hypocapnia during pregnancy, most notably during the last trimester.

One of the most common causes of respiratory alkalosis is hyperventilation, which is characterized by recurring episodes of overbreathing often associated with anxiety. People
-experiencing panic attacks frequently present in the emergency department with manifestations of acute respiratory alkalosis.

A physiologic type of respiratory alkalosis can occur when a person climbs to high altitudes. The lower oxygen content in the air stimulates the respiratory rate. This increased rate causes loss of CO\textsubscript{2} and results in a mild form of respiratory alkalosis. Typically, the body will compensate for this through the kidneys to increase HCO\textsubscript{3}\textsuperscript{−} excretion. Hypoxemia exerts its effect on pH through the peripheral chemoreceptors in the carotid bodies. Stimulation of peripheral chemoreceptors occurs in conditions that cause hypoxemia with relatively unimpaired CO\textsubscript{2} transport, such as exposure to high altitudes.

**Clinical Manifestations**

Respiratory alkalosis manifests with a decrease in PCO\textsubscript{2} and a deficit in H2CO\textsubscript{3} (see Table 40.5). In respiratory alkalosis, the pH is above 7.45, PCO\textsubscript{2} is below 35 mm Hg, and HCO\textsubscript{3}\textsuperscript{−} levels usually are below 22 mEq/L (22 mmol/L).

The signs and symptoms of respiratory alkalosis are associated with hyperexcitability of the nervous system and a decrease in cerebral blood flow. Alkalosis increases protein binding of extracellular calcium. This reduces ionized calcium levels, causing an increase in neuromuscular excitability. A decrease in the CO\textsubscript{2} content of the blood causes constriction of cerebral blood vessels. Because CO\textsubscript{2} crosses the blood–brain barrier rather quickly, the manifestations of acute respiratory alkalosis are usually of sudden onset. The person often experiences light-headedness, dizziness, tingling, and numbness of the fingers and toes. Sweating, palpitations, panic, air hunger, and dyspnea may accompany these manifestations. Chvostek and Trousseau signs may be positive and tetany and convulsions may occur. Because CO\textsubscript{2} provides the stimulus for short-term regulation of respiration, short periods of apnea may occur in people with acute episodes of hyperventilation.

**Cardiovascular Function**

Cardiac arrhythmias

**Treatment**

Since respiratory alkalosis is typically a compensatory state, it is should not be treated directly. Thus, the treatment of respiratory alkalosis focuses on measures to correct the underlying cause. Hypoxia may be corrected by administration of supplemental oxygen. Changing ventilator settings may be used to prevent or treat respiratory alkalosis in persons who are being mechanically ventilated. People with hyperventilation may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to the psychological stress.

**IN SUMMARY**

Acidosis describes a decrease in pH and alkalosis an increase in pH. Acid–base disorders may be caused by alterations in the body’s volatile acids (i.e., respiratory acidosis or respiratory alkalosis) or nonvolatile or fixed acids (i.e., metabolic acidosis or metabolic alkalosis). Acidosis and alkalosis typically involve a primary or initiating event and a compensatory or adaptive state that results from homeostatic mechanisms that attempt to prevent or correct large changes in pH. A mixed acid–base disorder is one in which there is both a primary and a compensatory change in acid–base balance.

Metabolic acidosis is defined as a decrease in pH due to a decrease in the HCO\textsubscript{3}\textsuperscript{−} level, and metabolic alkalosis as an increase in pH due to an increase in the HCO\textsubscript{3}\textsuperscript{−} level. It is caused by an increased production of nonvolatile metabolic acids such as lactic acid or ketoacids, decreased acid excretion by the kidney, excessive loss of HCO\textsubscript{3}\textsuperscript{−} as in diarrhea, or an increase in Cl\textsuperscript{−}. Metabolic acidosis may present with an increased anion gap in which sodium bicarbonate is replaced by the sodium salt.
of the offending anion, or with a normal anion gap when $\text{HCO}_3^-$ is replaced by $\text{Cl}^-$. Metabolic alkalosis involves generation of the increased pH and $\text{HCO}_3^-$ levels through a loss of $\text{H}^+$ or gain of $\text{HCO}_3^-$, and the maintenance of the alkalotic state because of the kidney’s failure to eliminate the excess $\text{HCO}_3^-$ owing to an accompanying ECF volume contraction, increased aldosterone levels, and decreased $\text{Cl}^-$ and $\text{K}^+$ levels.

Respiratory acidosis reflects an increase in $\text{PCO}_2$ levels and is caused by conditions that impair alveolar ventilation. It can occur as an acute disorder in which there is a rapid rise in $\text{PCO}_2$, a minimal increase in plasma $\text{HCO}_3^-$, and a large decrease in pH. Respiratory alkalosis is caused by conditions that cause hyperventilation and a reduction in $\text{PCO}_2$ levels. Because respiratory alkalosis often occurs suddenly, a compensatory decrease in $\text{HCO}_3^-$ levels may not occur before corrections have been accomplished.

The signs and symptoms of acidosis and alkalosis reflect alterations in body function associated with the disorder causing the acid–base disturbance, the effect of the change of pH on body function, and the body’s attempt to correct and maintain the pH within a normal physiologic range. In general, neuromuscular excitability is decreased in acidosis and increased in alkalosis.

### REVIEW EXERCISES

1. A 34-year-old woman with diabetes is admitted to the emergency department in a stuporous state. Her skin is flushed and warm, her breath has a sweet odor, her pulse is rapid and weak, and her respirations are rapid and deep. Her initial laboratory tests indicate a blood sugar of 320 mg/dL, serum $\text{HCO}_3^-$ of 12 mEq/L (normal, 22 to 26 mEq/L), and a pH of 7.1 (normal, 7.35 to 7.45).
   
   A. What is the most likely cause of her lowered pH and bicarbonate levels?
   
   B. How would you account for her rapid and deep respirations?
   
   C. Using the Henderson-Hasselbalch equation and the solubility coefficient for CO$_2$ given in this chapter, what would you expect her PCO$_2$ to be?
   
   D. How would you explain her warm, flushed skin and stuporous mental state?

2. Explain the use of the urine anion gap to determine the kidney’s ability to compensate for acid–base disorders by secreting and eliminating $\text{H}^+$ ions.

3. A 16-year-old girl is seen by her primary care provider because of her parents’ concern over her binge eating and their recent discovery that she engages in self-induced vomiting. A tentative diagnosis of bulimia nervosa is made. Initial laboratory tests reveal a plasma $\text{K}^+$ of 3 mEq/L (normal, 3.5 to 5.0 mEq/L) and a $\text{Cl}^-$ of 93 mEq/L (normal, 98 to 106 mEq/L).
   
   A. Explain her low $\text{K}^+$ and $\text{Cl}^-$. 
   
   B. What type of acid–base abnormality would you expect her to have?

4. A 65-year-old man with chronic obstructive lung disease has been using low-flow oxygen therapy because of difficulty in maintaining adequate oxygenation of his blood. He has recently had a severe respiratory tract infection and has had difficulty breathing. He is admitted to the emergency department because he became increasingly lethargic and his wife has had trouble arousing him. His respirations are 12 breaths/minute. She relates that he had “turned his oxygen way up” because of difficulty breathing.
   
   A. What is the most likely cause of this man’s problem?
   
   B. How would you explain the lethargy and difficulty in arousal?
   
   C. Arterial blood gases, drawn on admission to the emergency department, indicated a PO$_2$ of 85 mm Hg (normal, 90 to 95 mm Hg) and a PCO$_2$ of 90 mm Hg (normal, 40 mm Hg). His serum $\text{HCO}_3^-$ was 34 mEq/L (normal, 22 to 26 mEq/L). What is his pH?
   
   D. What would be the main goal of treatment for this man in terms of acid–base balance?

Kidney disease continues to be a major cause of work loss, physician visits, and hospitalization among both men and women. In America, kidney stones account for half a million emergency department visits every year. Approximately one in ten Americans have a kidney stone at some time of their life. Urinary tract infections (UTIs) result in nearly 10 million office visits every year. The kidneys filter blood from all parts of the body. Although many forms of kidney disease originate in the kidneys, others develop secondary to disorders such as hypertension, diabetes mellitus, and systemic lupus erythematosus (SLE). The content in this chapter focuses on congenital disorders of the kidneys, obstructive disorders, UTIs, disorders of glomerular function, tubulointerstitial disorders, and neoplasms of the kidneys.
Congenital Disorders of the Kidneys

The kidneys begin to develop early in the fifth week of gestation and start to function approximately 3 weeks later. Formation of urine is thought to begin in the 9th to 12th weeks of gestation. By the 32nd week, fetal production of urine reaches approximately 28 mL/hour. The urine that is produced is excreted into the amniotic cavity and is the main constituent of amniotic fluid. Thus, the relative amount of amniotic fluid can provide information about the status of fetal renal function. In pregnancies that involve infants with nonfunctional kidneys or outflow obstruction of urine from the kidneys, the amount of amniotic fluid is small. This condition is called oligohydramnios. It causes compression of the developing fetus and is often associated with impaired development of lungs and other fetal structures.

Anomalies in shape and position are the most common congenital kidney problems. Less common are disorders involving a decrease in renal mass (e.g., agenesis, hypogenesis) or a change in renal structure (e.g., renal dysplasia). The kidneys can be visualized as early as 12 weeks gestation by ultrasonography, allowing many fetal urinary abnormalities to be detected before birth.

Agenesis and Hypoplasia

The term dysgenesis refers to a failure of an organ to develop normally. Agenesis refers to failure of an organ to develop at all. Unilateral renal agenesis is relatively common. It occurs in about 1 of 1000 to 2000 newborn infants. Boys are affected more often than girls. Unilateral agenesis usually does not cause symptoms. It is often not discovered during infancy because the other kidney usually undergoes compensatory hypertrophy and performs the function of the missing kidney.

Total agenesis of both kidneys is incompatible with extrauterine life. Infants are stillborn or die shortly after birth of pulmonary hypoplasia. Newborns with renal agenesis often have characteristic facial features, sometimes called Potter syndrome, resulting from the effects of oligohydramnios. The eyes are widely separated and have epicanthic folds, the ears are low set, the nose is broad and flat, the chin is receding, and limb defects often are present.

In renal hypoplasia, the kidneys do not develop to normal size. Like agenesis, hypoplasia more commonly affects only one kidney. When both kidneys are affected, there is progressive development of renal failure. It has been suggested that true hypoplasia is extremely rare. Most cases probably represent acquired scarring due to vascular, infectious, or other kidney diseases rather than an underlying developmental failure.

Renal Dysplasia

Renal dysplasia is caused by an abnormality in the differentiation of kidney structures during embryonic development. It is characterized by undifferentiated tubular structures surrounded by primitive embryonic tissue. The disorder may result in small, aplastic kidneys or cysts that form from the abnormal tubules. If cysts are present, the condition is referred to as cystic dysplasia. One or both kidneys may be involved, and the affected kidney may be abnormally large or abnormally small. Many forms of dysplasia are accompanied by other urinary tract abnormalities, especially disorders that cause obstruction to urine flow (e.g., ureteral agenesis or atresia, ureteropelvic junction obstruction).

A multicystic kidney is one in which the kidney is replaced by cysts and does not function. The kidney does not have the usual kidney shape, but is rather a mass of cysts. Unilateral multicystic renal dysplasia is the most common cause of an abdominal mass in newborns. The function of the opposite kidney is usually normal, and these children have an excellent prognosis after surgical removal of the affected kidney. Bilateral renal dysplasia causes oligohydramnios and the resultant Potter facies, pulmonary hypoplasia, and renal failure.

Alterations in Kidney Position and Form

The development of the kidneys during embryonic life can result in ectopic kidneys that lie outside their normal position. One or both kidneys may be in an abnormal position. Most ectopic kidneys are located just above the pelvic brim or within the pelvis, but some lie in the inferior part of the abdomen. Because of the abnormal position, kinking of the ureters and obstruction of urinary flow may occur.

One of the most common alterations in kidney form is an abnormality called a horseshoe kidney. This abnormality occurs in approximately 1 of every 500 to 1000 people. In this disorder, the upper or lower poles of the two kidneys are fused, producing a horseshoe-shaped structure that is continuous along the midline of the body anterior to the great vessels. Most horseshoe kidneys are fused at the lower pole (Fig. 41.1). The condition usually does not cause problems unless there is an associated defect in the renal pelvis or other urinary structures that obstructs urinary flow.

Inherited Cystic Kidney Diseases

The inherited cystic kidney diseases, which are single-gene disorders and are inherited as mendelian traits, include autosomal dominant and recessive polycystic kidney disease, and nephronophthisis–medullary cystic disease. Polycystic
Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease, also known as adult polycystic disease, is the most common form of renal cystic disease. The disorder, which is inherited as an autosomal trait, results in the formation of destructive fluid-filled cysts in the kidney and other organs. ADPD affects more than 1:400 to 1:1000 people in the United States. Half of these people eventually develop end-stage renal disease (ESRD). The disease accounts for 5% of all cases of chronic renal disease that require dialysis or transplantation.

Remember Mr. Reterez, the man with the polycystic kidney disease you were introduced to in Chapter 30? It is very likely that he has the ADPD since his mother, maternal uncles, and maternal grandfather died from this disease. When so many people in one family die from a similar problem or from multiple problems related to one specific part of the human body, that person, or his or her children, should seek genetic counseling and screening.
There are two types of ADPD:

1. Type I, which is caused by mutations in the PKD1 gene and accounts for 85% of cases
2. Type II, which is caused by mutations in the PKD2 gene and accounts for most of the remaining 15% of cases.

The products of these genes, polycystin-1 and polycystin-2, are found in the primary cilia that line the apical surface of the tubular epithelium. These primary cilia are thought to act as sensors of urinary flow and as signal transducers for tubular cell proliferation, differentiation, and apoptosis.

**Clinical Manifestations.** Typically, the progress of the kidney disease is slow, and ESRD is uncommon for adults before 40 years of age. Initially, cysts are generally asymptomatic, and (kidney and) liver function are normal.

As the kidney disease progresses, the manifestations of ADPD include pain from the enlarging cysts that may reach debilitating levels, episodes of gross hematuria from bleeding into a cyst, infected cysts from ascending UTIs, and hypertension resulting from compression of intrarenal blood vessels with activation of the renin–angiotensin mechanism.

The kidneys are usually enlarged in people with ADPD and may achieve enormous sizes (Fig. 41.3). The external contours of the kidneys are distorted by numerous cysts, some as large as 5 cm in diameter, which are filled with straw-colored fluid. Cysts also may be found in the liver and, less commonly, in the pancreas and spleen.

As the disease continues to progress, extrarenal manifestations such as aneurysms are frequent, underscoring the systemic nature of the disease. Approximately 20% of people with polycystic kidney disease have an associated aneurysm, and subarachnoid hemorrhage is a frequent cause of death.

Mr. Reterez is experiencing abdominal and flank discomfort, which could be caused by enlarging or bleeding cysts or by a urinary tract infection. His abdominal girth is abnormally large, reflecting the presence of multiple fluid-filled cysts. He also has evidence of significant renal dysfunction (approaching ESRD), including 1+ pedal edema, nausea, anorexia, fatigue, and hypertension (blood pressure, 140/92 mm Hg).

The death of Mr. Reterez’s nephrons reduces the production of erythropoietin (EPO) by his kidneys. EPO promotes red blood cell (RBC) production by the bone...
Diagnosis and Treatment. Serum creatinine levels have not been found to be an effective predictor marker for worsening ADPD, but urine albumin excretion (UAE) has been determined a reliable predictor, as have increased electrolytes and hematuria. Ultrasonography usually is the preferred technique for diagnosis of ADPD in symptomatic people and for screening of asymptomatic family members. Computed tomography (CT) may be used for detection of small cysts. Genetic linkage studies are used for diagnosis of ADPD, but are usually reserved for cases in which radiographic imaging is negative and the need for a definitive diagnosis is essential, such as when screening family members for potential kidney donation.

The blood and urine tests provide evidence of the destruction of Mr. Reterez’s kidney tissue. He has elevated blood urea nitrogen (BUN) and blood sodium concentrations, and albumin and red blood cells are present in his urine. These indicators of kidney function will likely worsen as he moves along the continuum toward complete renal failure. The finding of hematuria (blood in the urine) will need a comprehensive workup, because it can also indicate problems unrelated to his kidney disease.

The treatment of ADPD is largely supportive and aimed at delaying progression of the disease. The drug, Tolvaptan, which is a selective vasopressin V2 receptor antagonist, has been studied and found to inhibit cyst growth and preserve kidney function. Control of hypertension and prevention of ascending UTIs are important. Pain is a common complaint of people with ADPD. Therefore, a systematic approach is needed to differentiate the etiology of the pain and define an approach for management. Dialysis and kidney transplantation are reserved for those who progress to kidney failure. However, it is important to note that prolonged dialysis will increase cyst formation even in people without ADPD.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease is characterized by cystic dilation of the cortical and medullary collecting tubules (see Fig. 41.2). It is rare compared with ADPD. ARPD is caused by mutations in the PKHD1 gene. The gene product, fibrocystin, is found in the kidney, liver, and pancreas and appears to be involved in the regulation of cell proliferation and adhesion.

Clinical Manifestations. The typical infant with ARPD presents with bilateral flank masses, accompanied by severe renal failure, signs of impaired lung development, and variable degrees of liver fibrosis and portal hypertension. Pottery facies and other defects associated with oligohydramnios may be present. Hypertension is usually noted within the first few weeks of life and is often severe. Many infants die during the perinatal period, often of pulmonary hypoplasia. Exceptional cases of ARPD manifest in older children and adults.

Treatment. The treatment of ARPD is largely supportive. Aggressive ventilatory support is often necessary in the neonatal period because of pulmonary hypoplasia and hyperventilation. Modern neonatal respiratory techniques and renal replacement therapy have increased the 10-year survival rate of children surviving beyond the first year of life. Morbidity and mortality in the older child is related to complications from chronic renal failure and liver disease.

Nephronophthisis–Medullary Cystic Disease Complex

The nephronophthisis–medullary cystic disease complex is a group of renal disorders that have their onset in childhood. Common characteristics are small and shrunken kidneys and the presence of a variable number of cysts, usually concentrated at the corticomedullary junction. The initial insult involves the distal tubules, with tubular basement membrane disruption followed by chronic and progressive tubular atrophy involving both the medulla and cortex. Although the presence of medullary cysts is important, the cortical and tubular damage is the eventual cause of chronic kidney disease and failure.

As a complex, the disorders account for 10% to 25% of renal failure in childhood. Affected children present first with polyuria, polydipsia, and enuresis (bed-wetting), which reflect impaired ability of the kidneys to concentrate urine. Other manifestations of the disorders include salt wasting, growth retardation, anemia, and progressive renal insufficiency. Some juvenile forms of nephronophthisis have extrarenal complications, including ocular motor abnormalities, retinitis pigmentosa, liver fibrosis, and cerebellar abnormalities. Progressive azotemia and renal failure follow, usually within 5 to 10 years.

Simple and Acquired Renal Cysts

Simple cysts are a common disorder of the kidney. The cysts may be single or multiple, unilateral or bilateral, and they usually are less than 1 cm in diameter, although they may grow larger. Most simple cysts do not produce signs or symptoms or compromise renal function. When symptomatic, the cysts may cause flank pain, hematuria, infection, and hypertension related to ischemia-produced stimulation of the renin–angiotensin system. They are most common in older adults. Although the cysts are benign, they may be confused clinically with renal cell carcinoma.

An acquired form of renal cystic disease occurs in people with end stage renal failure (ESRF) who have undergone prolonged dialysis treatment. Although the condition is largely asymptomatic, the cysts may bleed, causing hematuria. Tumors, usually adenomas but occasionally adenosarcomas, may develop in the walls of these cysts.
Approximately 10% of infants are born with potentially significant malformations of the urinary system. These abnormalities can range from bilateral renal agenesis, which is incompatible with life, to hypogenesis of one kidney, which usually causes no problems unless the function of the remaining kidney is impaired. Renal dysplasia is caused by an abnormality in the differentiation of kidney structures during embryonic development. A dysplastic multicystic kidney is one in which the kidney is replaced by cysts and does not function. The horseshoe kidney is a developmental disorder in which the upper or lower poles of the two kidneys are fused, producing a horseshoe-shaped structure.

Renal cystic disease is a condition in which there is dilation of tubular structures with cyst formation. Cysts may be single or multiple. Polycystic kidney disease is an inherited form of renal cystic disease; it can be inherited as an autosomal dominant or recessive trait. The autosomal dominant form of the disease (ADPD) results in the formation of numerous fluid-filled cysts in the tubular structures of both kidneys with the threat of progression to chronic renal failure. Other manifestations of the disease include hypertension, cardiovascular abnormalities, cerebral aneurysms, and cysts in other organs such as the liver and pancreas. The ARPD is characterized by cystic transformation of the collecting ducts. It is rare compared with ADPD, and usually presents as severe renal dysfunction during infancy. The nephronophthisis–medullary cystic disease complex is a group of hereditary disorders that usually have their onset during childhood and are characterized by the presence of cysts in the medullary portion of the kidney, renal atrophy, and eventual kidney failure. Single or multiple simple renal cysts most commonly occur in persons older than 50 years of age.

Urinary obstruction can occur in people of any age and can involve any level of the urinary tract, from the urethra to the renal pelvis (Fig. 41.4). Obstruction may be sudden or insidious, partial or complete, and unilateral or bilateral. The conditions that cause urinary tract obstruction include congenital anomalies, urinary calculi (i.e., stones), pregnancy, benign prostatic hyperplasia, scar tissue resulting from infection and inflammation, tumors, and neurologic disorders such as spinal cord injury. The causes of urinary tract obstructions are summarized in Table 41.1.

Obstructive uropathy is usually classified according to site, degree, and duration of obstruction. Lower urinary tract

Obstructions are located below the ureterovesical junction and are bilateral in nature. Upper urinary tract obstructions are located above the ureterovesical junction and are usually unilateral. The condition causing the obstruction can cause complete or partial occlusion of urine outflow. When the obstruction is of short duration (i.e., less than a few days), it is said to be acute and is usually caused by conditions such as renal calculi. An obstruction that develops slowly and is longer lasting is said to be chronic and is usually caused by conditions such as congenital ureterovesical abnormalities. Bilateral acute urinary tract obstruction causes acute renal failure. Because many causes of acute obstruction are reversible, prompt recognition is important. When left untreated, an obstructed kidney undergoes atrophy, and in the case of bilateral obstruction, results in chronic renal failure.

**Mechanisms of Renal Damage**

The destructive effects of urinary obstruction on kidney structures are determined by the degree and the duration of the obstruction. The two most damaging effects of urinary obstruction are:

1. **Stasis of urine, which predisposes to infection and stone formation.**
2. **Progressive dilation of the renal collecting ducts and renal tubular structures, which causes destruction and atrophy of renal tissue.**

A common complication of urinary tract obstruction is infection. Stagnation of urine predisposes to infection, which may spread throughout the urinary tract. Once established, the infection is difficult to treat. Urea-splitting organisms (e.g., *Proteus*, *staphylococci*) that increase ammonia production and cause the urine to become alkaline often cause infection. When present, urinary calculi serve as foreign bodies and contribute to the infection. Calcium salts precipitate more readily in stagnant alkaline urine; thus, urinary tract obstructions also predispose to stone formation.

In situations of severe partial or complete obstruction, the impediment to the outflow of urine causes dilation of the renal pelvis and calices associated with progressive atrophy of the kidney. Even with complete obstruction, glomerular filtration continues for sometime. Because of the continued filtration, the calices and pelvis of the affected kidney become dilated, often markedly so. The high pressure in the renal pelvis is transmitted back through the collecting ducts of the kidney, compressing renal vasculature and causing renal atrophy. Initially, the functional alterations are largely tubular, manifested primarily by impaired urine-concentrating ability. Only later does the glomerular filtration rate (GFR) begin to diminish.

**Hydronephrosis**

*Hydronephrosis* refers to urine-filled dilation of the renal pelvis and calices associated with progressive atrophy of the kidney due to obstruction of urine outflow. The degree of hydronephrosis depends on the duration, degree, and level of obstruction. In far-advanced cases, the kidney may be transformed into a thin-walled cystic structure with parenchymal atrophy, total obliteration of the pyramids, and thinning of the cortex (Fig. 41.5). The condition is usually unilateral. Bilateral hydronephrosis occurs only when the obstruction is below the level of the ureterovesical junction. When the obstruction affects the outflow of urine from the distal ureter, the increased pressure dilates the ureter, a condition called *hydroureter* (Fig. 41.6). Bilateral hydroureter may develop as a complication of bladder outlet obstruction due to prostatic hyperplasia.

**Clinical Manifestations**

The manifestations of urinary obstruction depend on the site of obstruction, the cause, and the rapidity with which the condition developed. The underlying pathologic process produces most of the early symptoms. Urinary tract obstruction encourages the growth of microorganisms and should be suspected in people with recurrent UTIs.

Complete or partial unilateral hydronephrosis may remain silent for long periods because the unaffected kidney can maintain adequate kidney function. Obstruction may provoke pain due to distention of the collecting system and renal capsule. Acute supravesical obstruction, such as that due to a kidney stone lodged in the ureter, is associated with excruciatingly severe pain. By contrast, more insidious causes of obstruction, such as narrowing of the ureteropelvic junction, generally produce little pain but totally destroy the kidney.

Complete bilateral obstruction results in oliguria and anuria and renal failure. Acute bilateral obstruction may mimic prerenal failure. With partial bilateral obstruction, the earliest manifestation is an inability to concentrate urine, reflected by polyuria and nocturia. Hypertension is an occasional...
Renal Calculi

The most common cause of upper urinary tract obstruction is urinary calculi. Although stones can form in any part of the urinary tract, most develop in the kidneys. Renal calculi or kidney stones are a common diagnosis occurring in the urinary tract, exceeded only by UTIs and prostate disorders. Kidney stones are polycrystalline aggregates composed of materials that the kidneys normally excrete in the urine.

Etiology and Pathogenesis

The etiology of urinary stone formation is complex. It is thought to encompass a number of factors, including increases in blood and urinary levels of stone components and interactions among the components, anatomic changes in urinary tract structures, metabolic and endocrine influences, dietary and intestinal absorption factors, and UTIs. Several factors are used to explain stone formation, including a supersaturated urine, presence of a nucleus for crystal formation, and deficiency of inhibitors of stone formation.

Kidney stone formation requires a supersaturated urine and an environment that allows the stone to grow. The risk for stone formation is increased when the urine is supersaturated with stone components (e.g., calcium salts, uric acid, magnesium ammonium phosphate, cystine). Supersaturation depends on urinary pH, solute concentration, ionic strength, and complexation. The greater the concentration of two ions, the more likely they are to precipitate. Complexation influences the availability of specific ions. For example, oxalate complexes with sodium and decreases the availability of its free ionic form that participates in stone formation.

In addition to a supersaturated urine, kidney stone formation requires a nidus or nucleus that facilitates crystal aggregation. In supersaturated urine, stone formation begins with small clusters of crystals such as calcium oxalate. Most small clusters tend to disperse because the internal forces that hold them together are too weak to overcome the random tendency of ions to move apart. Larger ion clusters form nuclei and remain stable because the attraction forces balance surface losses. Once they are stable, nuclei can grow at levels of supersaturation below that needed for their creation.

Diagnosis and Treatment

Early diagnosis of urinary tract obstruction is important because the condition usually is treatable and a delay in therapy may result in permanent damage to the kidneys. Diagnostic methods vary with the symptoms. Ultrasonography has proved to be the single most useful noninvasive diagnostic modality for urinary obstruction. Radiologic methods, CT scans, and intravenous urography may also be used. Other diagnostic methods, such as urinalysis, are used to determine the extent of renal involvement and the presence of infection.

Treatment of urinary tract obstruction depends on the cause. Urinary stone removal may be necessary, or surgical treatment of structural defects may be indicated. Treatment of a complicated UTI due to urinary stasis is also important.
ion to become an ammonium ion, increasing the pH of the urine so that it becomes more alkaline. Because phosphate levels are increased in alkaline urine and because magnesium always is present in the urine, struvite stones form. These stones enlarge as the bacterial count grows, and they can increase in size until they fill an entire renal pelvis (Fig. 41.7). Because of their shape, they often are called *staghorn stones*. They almost always are associated with UTIs and represent about 15% of all kidney stones. Because these stones act as a foreign body, treatment of the infection often is difficult. Struvite stones usually are too large to be passed and require lithotripsy or surgical removal.

Uric acid stones develop in conditions of gout and high concentrations of uric acid in the urine and account for about 7% of all stones. Hyperuricosuria also may contribute to calcium stone formation by acting as a nucleus for calcium oxalate stone formation. Unlike radiopaque calcium stones, uric acid stones are not visible on x-ray films. Uric acid stones form most readily in acidic urine. Thus, these stones can be treated by raising the urinary pH to 6 to 6.5 with potassium alkali salts.

Cystine stones account for less than 1% to 3% of kidney stones overall, but represent a significant proportion of childhood calculi. They are seen in cystinuria, which results from an autosomal recessive genetic defect in renal transport of cystine so there is a decrease in cystine tubular absorption. These stones resemble struvite stones except that infection is unlikely to be present.

**Clinical Manifestations**

One of the major manifestations of kidney stones is pain. Depending on location, there are two types of pain associated with kidney stones: renal colic and noncolicky renal pain. *Renal colic* is the term used to describe the colicky pain that

**KEY POINTS**

**KIDNEY STONES**

- Stones require a nidus to form and a urinary environment that supports continued crystallization of stone components.
- The development of kidney stones is influenced by the concentration of stone components in the urine, the ability of the stone components to complex and form stones, and the presence of substances that inhibit stone formation.
accompanies stretching of the collecting system or ureter. The symptoms of renal colic are caused by stones 1 to 5 mm in diameter that can move into the ureter and obstruct flow. Classic ureteral colic is manifested by acute, intermittent, and excruciating pain in the flank and upper outer quadrant of the abdomen on the affected side. The pain may radiate to the lower abdominal quadrant, bladder area, perineum, or scrotum in the man. The skin may be cool and clammy, and nausea and vomiting are common. Noncolicky pain is caused by stones that produce distention of the renal calyces or renal pelvis. The pain usually is a dull, deep ache in the flank or back that can vary in intensity from mild to severe. The pain is often exaggerated by drinking large amounts of fluid.

Diagnosis and Treatment

People with kidney stones often present with acute renal colic, and the diagnosis is based on symptomatology and diagnostic tests, which include urinalysis, plain film radiography, intravenous pyelography (IVP), and abdominal ultrasonography. Urinalysis provides information related to hematuria, infection, the presence of stone-forming crystals, and urine pH. Most stones are radioopaque and readily visible on a plain radiograph of the abdomen. The noncontrast spiral CT scan is the imaging modality of choice in people with acute renal colic. IVP uses an intravenously injected contrast medium that is filtered in the glomeruli to visualize the collecting system of the kidneys and ureters. Abdominal ultrasonography is highly sensitive to hydronephrosis, which may be a manifestation of ureteral obstruction. A new imaging technique called nuclear scintigraphy uses bisphosphonate markers as a means of imaging stones. The method has been credited with identifying stones that are too small to be detected by other methods.

Treatment of acute renal colic usually is supportive. Pain relief may be needed during acute phases of obstruction, and antibiotic therapy may be necessary to treat UTIs. Most stones that are less than 5 mm in diameter pass spontaneously. All urine should be strained during an attack in the hope of retrieving the stone for chemical analysis and determination of type. This information, along with a careful history and laboratory tests, provides the basis for long-term preventive measures.

A major goal of treatment in people who have passed kidney stones or have had them removed is to prevent their recurrence. Prevention requires investigation into the cause of stone formation using urine tests, blood chemistries, and stone analysis. Underlying disease conditions, such as hyperparathyroidism, are treated. Adequate fluid intake reduces the concentration of stone-forming crystals in the urine and needs to be encouraged. Depending on the type of stone that is formed, dietary changes, medications, or both may be used to alter the concentration of stone-forming elements in the urine. For example, people who form calcium oxalate stones may need to decrease their intake of foods that are high in oxalate (e.g., spinach, Swiss chard, cocoa, chocolate, pecans, peanuts). More children who have a vegetarian diet and rely on plant sources for the majority of their protein are being diagnosed with kidney stones. Therefore, they may need to use other sources of protein to supplement the diet. Also, it is important to realize that gallstones and kidney stones have been correlated with insulin resistance. However, only gallstones have been identified as a possible risk factor for developing type 2 diabetes mellitus.

Calcium supplementation with calcium salts such as calcium carbonate and calcium phosphate also may be used to bind oxalate in the intestine and decrease its absorption. Thiazide diuretics lower urinary calcium by increasing tubular reabsorption so that less remains in the urine. Drugs that bind calcium in the gut (e.g., cellulose phosphate) may be used to inhibit calcium absorption and urinary excretion.

Measures to change the pH of the urine also can influence kidney stone formation. In persons who lose the ability to lower the pH of (or acidify) their urine, there is an increase in the divalent and trivalent forms of urine phosphate that combine with calcium to form calcium phosphate stones. The formation of uric acid stones is increased in acid urine; stone formation can be reduced by raising the pH of urine to 6.0 to 6.5 with potassium alkali (e.g., potassium citrate) salts. Table 41.2 summarizes measures for preventing the recurrence of different types of kidney stones.

In some cases, stone removal may be necessary. Several methods are available for removing kidney stones—ureteroscopic removal, percutaneous removal, and extracorporeal lithotripsy. All these procedures eliminate the need for an open surgical procedure, which is another form of treatment.
Open stone surgery may be required to remove large calculi or those that are resistant to other forms of removal.

Ureteroscopic removal involves the passage of an instrument through the urethra into the bladder and then into the ureter. The development of high-quality optics has improved the ease with which this procedure is performed and its outcome. The procedure, which is performed under fluoroscopic guidance, involves the use of various instruments for dilating the ureter and for grasping, fragmenting, and removing the stone. Preprocedure radiologic studies using a contrast medium (i.e., excretory urography) are done to determine the position of the stone and direct the placement of the ureteroscope.17

Percutaneous nephrolithotomy is the treatment of choice for removal of renal or proximal ureteral calculi.17 It involves the insertion through the flank of a small-gauge needle into the collecting system of the kidney. The needle tract is then dilated, and an instrument called a nephroscope is inserted into the renal pelvis. The procedure is performed under fluoroscopic guidance. Preprocedure radiologic and ultrasonographic examinations of the kidney and ureter are used to determine the placement of the nephroscope. Stones up to 1 cm in diameter can be removed through this method. Larger stones must be broken up with an ultrasonic lithotripter (i.e., stone breaker).

A nonsurgical treatment, called extracorporeal shock-wave lithotripsy, uses acoustic shock waves to fragment calculi into sandlike particles that are passed in the urine over the next few days. Because of the large amount of stone particles that are generated during the procedure, a ureteral stent (i.e., a tubelike device used to hold the ureter open) may be inserted to ensure adequate urine drainage.

IN SUMMARY

Obstruction of urine flow can occur at any level of the urinary tract. Among the causes of urinary tract obstruction are developmental defects, pregnancy, infection and inflammation, kidney stones, neurologic defects, and prostatic hypertrophy. Obstructive disorders produce stasis of urine, increase the risk for infection and calculi formation, and produce progressive dilation of the renal collecting ducts and renal tubular structures, which causes renal atrophy.

Hydronephrosis refers to urine-filled dilation of the renal pelvis and calices associated with progressive atrophy of the kidney due to obstruction of urine outflow. Unilateral hydronephrosis may remain silent for long periods because the unaffected kidney can maintain adequate kidney function. With partial bilateral obstruction, the earliest manifestation is an inability to concentrate urine, reflected by polyuria and nocturia. Complete bilateral obstruction results in oliguria and anuria and renal failure.

Kidney stones are a major cause of upper urinary tract obstruction. There are four types of kidney stones: calcium (i.e., oxalate and phosphate) stones, which are associated with increased serum calcium levels; magnesium ammonium phosphate (i.e., struvite) stones, which are associated with UTIs; uric acid stones, which are related to elevated uric acid levels; and cystine stones, which are seen in cystinuria. A major goal of treatment for persons who have passed kidney stones or have had them removed is to identify stone composition and prevent their recurrence. Treatment measures depend on stone type and include adequate fluid intake to prevent urine saturation, dietary modification to decrease intake of stone-forming constituents, treatment of UTI, measures to change urine pH, and the use of diuretics that decrease the calcium concentration of urine.

URINARY TRACT INFECTIONS

After completing this section of the chapter, you should be able to meet the following objectives:

- List three physiologic mechanisms that protect against UTIs.
- Describe factors that predispose to UTIs in children, sexually active women, pregnant women, and older adults.
- Cite measures used in the diagnosis and treatment of UTIs.

UTIs are a frequent type of bacterial infection seen by health care providers. UTIs include several distinct entities, including asymptomatic bacteriuria, symptomatic infections, lower UTIs such as cystitis, and upper UTIs such as pyelonephritis. Because of their ability to cause renal damage, upper UTIs are considered more serious than lower UTIs. Acute pyelonephritis represents an infection of the renal parenchyma and renal pelvis. Improperly treated, it can lead to sepsis, renal abscesses, chronic pyelonephritis, and chronic renal failure. Approximately 7 million visits to a primary care provider are made each year for treatment of lower UTIs.15

KEY POINTS

URINARY TRACT INFECTIONS

- Infection is facilitated by host conditions that disrupt washout of the agent from the UT through urine flow, change the protective properties of the mucin lining of the UT, disrupt the protective function of the normal bacterial flora, or impair the function of the immune system.
- Virulence of the agent is derived from its ability to gain access to and thrive in the UT environment, adhere to the tissues of the lower or upper UT, evade the destructive effects of the host's immune system, and develop resistance to antimicrobial agents.
Etiology and Pathogenesis

Most uncomplicated lower UTIs are caused by *Escherichia coli*.

Other uropathic pathogens include *Staphylococcus saprophyticus* in uncomplicated UTIs, and both non- *E. coli* gram-negative rods (*Proteus mirabilis*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa*) and gram-positive cocci (*Staphylococcus aureus*) in complicated UTIs. Most UTIs are caused by bacteria that enter through the urethra. Bacteria can also enter through the bloodstream usually in immunocompromised people and neonates. Although the distal portion of the urethra often contains pathogens, the urine formed in the kidneys and found in the bladder normally is sterile or free of bacteria. This is because of the washout phenomenon, in which urine from the bladder normally washes bacteria out of the urethra. When a UTI occurs, it is usually from bacteria that have colonized the urethra, vagina, or perianal area.

There is an increased risk for UTIs in people with urinary obstruction and reflux, in people with neurogenic disorders that impair bladder emptying, in women who are sexually active, in postmenopausal women, in men with diseases of the prostate, and in older adults. Instrumentation and urinary catheterization are the most common predisposing factors for nosocomial UTIs. UTIs occur more commonly in women with diabetes than in women without the disease (due to their alkaline urine). People with diabetes are also at increased risk for complications associated with UTIs, including pyelonephritis, and they are more susceptible to fungal infections specifically women between the ages of 16 and 35 years, at approximately 50 years of age. After this age, prostatic hypertrophy provides some protection from ascending UTIs until approximately 50 years of age. After this age, prostatic hypertrophy becomes more common, and with it may come obstruction and increased risk for UTI. For older adults with urinary catheters, a biofilm builds up and promotes more bacterial growth. Therefore, these older adults with decreased immunological function need meticulous surveillance for signs of infection.

Host Defenses. In the development of a UTI, host defenses are matched against the virulence of the pathogen. The host defenses of the bladder include:

- The washout phenomenon, whereby bacteria are removed from the bladder and urethra during voiding.
- The bladder lining, which assists in providing a barrier to protect against bacterial invasion.
- The body’s immune response.

In the ureters, peristaltic movements facilitate the movement of urine from the renal pelvis through the ureters and into the bladder. Immune mechanisms, particularly secretory immunoglobulin (Ig) A, appear to provide an important antibacterial defense. Phagocytic blood cells further assist in the removal of bacteria from the urinary tract.

Other important host factors include the normal flora of the periurethral area in women and prostate secretions in men. In women, the normal flora of the periurethral area, which consists of organisms such as *Lactobacillus*, provides defense against the colonization of uropathic bacteria. Alterations in the periurethral environment, such as that occurring with a decrease in estrogen levels during menopause or the use of antibiotics, can alter the protective periurethral flora, allowing uropathogens to colonize and enter the urinary tract. In men, the prostatic fluid has antimicrobial properties that protect the urethra from colonization.

Pathogen Virulence. Not all bacteria are capable of adhering and infecting the urinary tract. Of the many strains of *E. coli*, only those with increased ability to adhere to the epithelial cells of the urinary tract are able to produce UTIs. These bacteria have fine protein filaments, called pili or fimbriae, that help them adhere to receptors on the lining of urinary tract structures. The two main types of pili (types 1 and P) found on *E. coli* that cause UTIs are morphologically similar, but differ in their ability to mediate hemagglutination in the presence of mannose. Type P pili are mannose resistant and were named because of their high incidence in *E. coli* that cause pyelonephritis and because of their association with the P blood group system. P pili have been observed in over 90% of *E. coli* strains causing pyelonephritis but less than 20% of strains causing lower UTIs. Evidence suggests that probiotic therapies may be helpful instead of empirically administering antibiotics for every lower UTI, with this information regarding P pili.

Obstruction and Reflux

Obstruction and reflux are other contributing factors in the development of UTIs. Any microorganisms that enter the bladder normally are washed out during voiding. When outflow is obstructed, urine remains in the bladder and acts as a medium for microbial growth. The microorganisms in the contaminated urine can then ascend along the ureters to infect the kidneys. The presence of residual urine correlates closely with bacteriuria and with its recurrence after treatment. Another aspect of bladder outflow obstruction and bladder distention is increased intravesical pressure, which compresses blood vessels in the bladder wall, leading to a decrease in the mucosal defenses of the bladder.

In UTIs associated with stasis of urine flow, the obstruction may be anatomic or functional. Anatomic obstructions include urinary tract stones, prostatic hyperplasia, pregnancy, and malformations of the ureterovesical junction. Functional obstructions include neurogenic bladder, infrequent voiding, detrusor (bladder) muscle instability, and constipation.
Catheter-associated bacteriuria remains the most frequent cause of gram-negative septicemia in hospitalized patients. Studies have shown that bacteria adhere to the surface of the catheter and initiate the growth of a biofilm that then covers the surface of the catheter. The biofilm tends to protect the bacteria from the action of antibiotics and makes treatment difficult. A closed drainage system (i.e., closed to air and other sources of contamination) and careful attention to perineal hygiene (i.e., cleaning the area around the urethral meatus) help to prevent infections in persons who require an indwelling catheter. Careful hand washing and early detection and treatment of UTIs also are essential.

Clinical Manifestations

The manifestations of UTI depend on whether the infection involves the lower (bladder) or upper (kidney) urinary tract and whether the infection is acute or chronic. The majority of UTIs are acute uncomplicated bladder infections that occur in women. Upper UTIs affect the parenchyma and pelvis of the kidney (pyelonephritis). They are less common and occur more frequently in children and adults with urinary tract obstructions or other predisposing conditions such as diabetes.

An acute episode of cystitis (bladder infection) is characterized by frequency of urination, lower abdominal or back discomfort, and burning and pain on urination (i.e., dysuria). Occasionally, the urine is cloudy and foul smelling. In adults, fever and other signs of infection usually are absent. If there are no complications, the symptoms disappear within 48 hours.
of treatment. The symptoms of cystitis also may represent urethritis caused by Chlamydia trachomatis, Neisseria gonorrhoeae, or herpes simplex virus, or vaginitis attributable to Trichomonas vaginalis or Candida species.1

**Diagnosis and Treatment**

The diagnosis of UTI usually is based on symptoms and on examination of the urine for the presence of microorganisms. When necessary, x-ray films, ultrasonography, and CT and renal scans are used to identify contributing factors, such as obstruction.

Urine tests are used to establish the presence of bacteria in the urine and for a diagnosis of UTI. A commonly accepted criterion for diagnosis of a UTI is the presence of 100,000 colony-forming units (CFU) or more bacteria per milliliter (mL) of urine.17 Colonization usually is defined as the multiplication of microorganisms in or on a host without apparent evidence of invasiveness or tissue injury.17 Pyuria (the presence of less than five to eight leukocytes per high-power field) indicates a host response to infection rather than asymptomatic bacterial colonization.17 A Gram stain may be done to determine the type (gram positive or gram negative) of organism that is present. A urine culture may be done to confirm the presence of pathogenic bacteria in urine specimens, allow for their identification, and permit the determination of their sensitivity to specific antibiotics.

Chemical screening (urine dipstick) for markers of infection may provide useful information but is less sensitive than microscopic analysis.12,15 These tests are relatively inexpensive, easy to perform, and can be done in the clinic setting or even in the home. Bacteria reduce nitrates in the urine to nitrites, providing a means for chemical analysis. Similarly, activated leukocytes secrete leukocyte esterase, which can be detected chemically. Leukocyte esterase is specific (94% to 98%) and reliably sensitive (75% to 96%) for detecting uropathogens equivalent to 100,000 CFU/mL urine.17 Nitrite tests may be negative if the causative organism is not nitrate producing (e.g., enterococci, S. saprophyticus). The nitrite test can also be negative if the urine specimen is too diluted.

The treatment of UTI is based on the pathogen causing the infection, and the presence of contributing host–agent factors. Other considerations include whether the infection is acute, recurrent, or chronic. Most acute lower UTIs, which occur mainly in women and are generally caused by E. coli, are treated successfully with a short course of antimicrobial therapy. Forcing fluids may relieve signs and symptoms, and this approach is used as an adjunct to antimicrobial treatment.

Recurrent lower UTIs are those that recur after treatment. They are due either to bacterial persistence or reinfec tion. Bacterial persistence usually is curable by removal of the infectious source (e.g., urinary catheter or infected bladder stones). Reinfec tion is managed principally through education regarding pathogen transmission prevention measures. Cranberry juice has been suggested as a preventive measure for women with recurrent UTIs. Evidence suggests that cranberry juice reduces bacterial adherence to the epithelial lining of the urinary tract.27 Because of its mechanism of action, the juice is also being studied with periodontal disease and Helicobacter pylori-associated gastritis and has been documented as an antioxidant and possible cholesterol-lowering therapy.27

Chronic UTIs are more difficult to treat. Because they often are associated with obstructive uropathy or reflux flow of urine, diagnostic tests usually are performed to detect such abnormalities.12 When possible, the condition causing the reflux flow or obstruction is corrected. Men, in particular, should be investigated for obstructive disorders or a prostatic focus of infection.

**Infections in Special Populations**

UTIs affect persons of all ages. In infants, they occur more often in boys than in girls. After the first year of life, UTIs occur more often in girls. This is because of the shorter length of the female urethra and because the vaginal vestibule can be easily contaminated with fecal flora. Approximately half of all adult women have at least one UTI during their lifetime.15 The major risk factors for women of 16 to 35 years of age are related to sexual intercourse and use of spermicidal agents.15 The anterior urethra usually is colonized with bacteria; urethral massage or sexual intercourse can force these bacteria back into the bladder.

**Urinary Tract Infections in Pregnant Women**

Pregnant women are at increased risk for UTIs. Normal changes in the functioning of the urinary tract that occur during pregnancy predispose to UTIs.28 These changes involve the collecting system of the kidneys and include dilation of the renal calyces, pelves, and ureters that begin during the first trimester and become most pronounced during the third trimester. This dilation of the upper urinary system is accompanied by a reduction in the peristaltic activity of the ureters that is thought to result from the muscle-relaxing effects of progesterone-like hormones and mechanical obstruction from the enlarging uterus. In addition to the changes in the kidneys and ureters, the bladder becomes displaced from its pelvic position to a more abdominal position, producing further changes in ureteral position.

Asymptomatic UTIs are common, with a prevalence of 2% to 14% in pregnant women.28 The complications of asymptomatic UTIs during pregnancy include persistent bacteriuria, acute and chronic pyelonephritis, and preterm delivery of infants with low birth weight. Evidence suggests that few women become bacteriuric during pregnancy. Rather, it appears that symptomatic UTIs during pregnancy reflect pre-existing asymptomatic bacteriuria and that changes occurring during pregnancy simply permit the prior urinary colonization to progress to symptomatic infection and invasion of the kidneys.
**Urinary Tract Infections in Children**

UTIs occur most frequently during the first 6 months of life. After that, occurrence greatly decreases, especially in boys. Children who are at increased risk for bacteriuria or symptomatic UTIs are premature infants discharged from neonatal intensive care units, children with systemic or immunologic disease or urinary tract abnormalities such as neurogenic bladder or vesicoureteral reflux, those with a family history of UTI or urinary tract anomalies with reflux, and girls younger than 5 years of age with a history of UTI.

UTIs in children frequently involve the upper urinary tract (pyelonephritis). In children in whom renal development is not complete, pyelonephritis can lead to hypertension, renal scarring, and permanent kidney damage. The incidence of scarring is greatest in children with gross vesicoureteral reflux or obstruction, in children with recurrent UTIs, and in those with a delay in treatment.

**Clinical Manifestations.** Unlike adults, children frequently do not present with the typical signs of a UTI. Many neonates with UTIs have bacteremia and may show signs and symptoms of septicemia, including fever, hypothermia, apneic spells, poor skin perfusion, abdominal distention, diarrhea, vomiting, lethargy, and irritability. Older infants may present with feeding problems, failure to thrive, diarrhea, vomiting, fever, and foul-smelling urine. Toddlers often present with abdominal pain, vomiting, diarrhea, abnormal voiding patterns, foul-smelling urine, fever, and poor growth. In older children with lower UTIs, the classic features—enuresis, frequency, dysuria, and suprapubic discomfort—are more common. Fever is a common sign of UTI in children, and the possibility of UTI should be considered in any child with unexplained fever.

**Diagnosis and Treatment.** Diagnosis is based on a careful history of voiding patterns and symptomatology; physical examination to determine fever, hypertension, abdominal or suprapubic tenderness, and other manifestations of UTI; and urinalysis to determine bacteriuria, pyuria, proteinuria, and hematuria. A positive urine culture that is obtained correctly is essential for the diagnosis. Additional diagnostic methods may be needed to determine the cause of the disorder. Vesicoureteral reflux is the most commonly associated abnormality in UTIs, and reflux nephropathy is an important cause of end-stage renal disease in children and adolescents. Children with a relatively uncomplicated first UTI may turn out to have significant reflux. Therefore, even a single documented UTI in a child requires careful diagnosis. Urinary symptoms in the absence of bacteriuria suggest vaginitis, urethritis, sexual molestation, the use of irritating bubble baths, pinworms, or viral cystitis. In adolescent girls, a history of dysuria and vaginal discharge makes vaginitis or vulvitis a consideration.

The approach to treatment is based on the clinical severity of the infection, the site of infection (i.e., lower versus upper urinary tract), the risk for sepsis, and the presence of structural abnormalities. The immediate treatment of infants and young children is essential. Most infants with symptomatic UTIs and many children with clinical evidence of acute upper UTIs require hospitalization, rehydration, and intravenous antibiotic therapy. Follow-up is essential for children with febrile UTIs to ensure resolution of the infection. Follow-up urine cultures often are done at the end of treatment to ensure the antibiotic was effective. Imaging studies often are recommended for all children after their first UTI to detect renal scarring, vesicoureteral reflux, or other abnormalities.

**Urinary Tract Infections in Older Adults**

UTIs are relatively common in older adults. They are the second most common form of infection, after respiratory tract infections, among otherwise healthy community-dwelling older adults.

Most of these infections follow invasion of the urinary tract by the ascending route. Several factors predispose older adults to UTIs, including immobility resulting in poor bladder emptying, bladder outflow obstruction caused by prostatic hyperplasia or kidney stones, bladder ischemia caused by urine retention, constipation, senile vaginitis, and diminished bactericidal activity of urine and prostatic secretions. Added to these risks are other health problems that necessitate instrumentation of the urinary tract.

Older adults with bacteriuria have varying symptoms, ranging from the absence of symptoms to the presence of typical UTI symptoms. Even when symptoms of lower UTIs are present, they may be difficult to interpret because older adults without UTIs commonly experience urgency, frequency, and incontinence. Alternatively, older adults may have vague symptoms such as anorexia, fatigue, weakness, or change in mental status. Even with more serious upper UTIs (e.g., pyelonephritis), the classic signs of infection such as fever, chills, flank pain, and tenderness may be altered or absent in older adults. Sometimes, no symptoms occur until the infection is far advanced.

**IN SUMMARY**

UTI is the second most common type of bacterial infection seen by health care professionals. Infections can range from asymptomatic bacteriuria to severe kidney infections that cause irreversible kidney damage. Predisposition to infection is determined by host defenses and pathogen virulence. Host defenses include the washout phenomenon associated with voiding, the protective mucin lining of the bladder, and the local immune defenses. Pathogen virulence is enhanced by the presence of pili that facilitate adherence to structures in the urinary tract, lipopolysaccharides that bind to host cells and elicit an inflammatory reaction, and enzymes that break down RBCs and make iron available for bacterial metabolism and multiplication.

Most UTIs ascend from the urethra and bladder. A number of factors interact in determining the predisposition to
The glomeruli are tufts of capillaries that lie between the afferent and efferent arterioles. The capillaries of the glomeruli are arranged in lobules and supported by a stalk consisting of mesangial cells and a basement membrane–like extracellular matrix (Fig. 41.9). The glomerular capillary membrane is composed of three structural layers: an endothelial cell layer that lines the inner surface of the capillary, a basement membrane made up of a network of matrix proteins, and a layer of epithelial cells that surrounds the outer surface of the capillary and lines the inner surface of the Bowman capsule.

The development of UTIs, including urinary tract obstruction, urine stasis and reflux, pregnancy-induced changes in urinary tract function, age-related changes in the urinary tract, changes in the protective mechanisms of the bladder and ureters, impaired immune function, and virulence of the pathogen. Urinary tract catheters and urinary instrumentation contribute to the incidence of UTIs. Early diagnosis and treatment of UTI are essential to preventing permanent kidney damage.

**DISORDERS OF GLOMERULAR FUNCTION**

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Describe the two types of immune mechanisms involved in glomerular disorders.
- Use the terms proliferation, sclerosis, membranous, diffuse, focal, segmental, and mesangial to explain changes in glomerular structure that occur with glomerulonephritis.
- Briefly describe the difference among the nephritic syndromes, rapidly progressive glomerulonephritis, nephrotic syndrome, asymptomatic glomerular disorders, and chronic glomerulonephritis.

**Etiology and Pathogenesis of Glomerular Injury**

The causative agents or triggering events that produce glomerular injury include immunologic, nonimmunologic, and hereditary mechanisms. Most cases of primary and many cases of secondary glomerular disease probably have an immune origin. Although many glomerular diseases are driven by immunologic events, a variety of nonimmunologic metabolic (e.g., diabetes), hemodynamic (e.g., hypertension), and toxic (e.g., drugs, chemicals) stresses can induce glomerular injury, either alone or along with immunologic mechanisms. Hereditary glomerular diseases such as Alport syndrome, although relatively rare, are an important category of glomerular disease because of their association with progressive loss of renal function and transmission to future generations.

**FIGURE 41.9** • Schematic representation of three glomerular capillaries depicting the sites of immune complex formation. Subepithelial deposits are seen in postinfectious glomerulonephritis (1) and membranous nephropathy (2) and are likely to be assembled locally by an in situ mechanism. Subendothelial deposits (3) and mesangial deposits (4) may also form locally but are more often the result of passive entrapment of preformed circulating immune complexes. Anti-GBM antibodies bind in a linear pattern to the GBM (5), and since the specific antigen is part of the heavily cross-linked basement membrane, electron-dense deposits at the ultrastructural level are missing. EN, endothelial cell; EP, visceral epithelial cell or podocyte; MC, mesangial cell; MM, mesangial matrix. (From Rennke H. G., Denker B. M. (2010). Renal pathophysiology: The essentials (3rd ed., p. 244). Philadelphia, PA: Lippincott Williams & Wilkins.)
Antigens responsible for development of the immune response may be of endogenous origin, such as autoantibodies to deoxyribonucleic acid (DNA) in SLE, or they may be of exogenous origin, such as streptococcal membrane antigens in poststreptococcal glomerulonephritis. Frequently, the source of the antigen is unknown.

Two types of immune mechanisms have been implicated in the development of glomerular disease:

1. Injury resulting from antibodies reacting with fixed glomerular antigens or antigens planted within the glomerulus
2. Injury resulting from circulating antigen–antibody complexes that become trapped in the glomerular membrane (Fig. 41.11)

Antigens responsible for development of the immune response may be of endogenous origin, such as autoantibodies to deoxyribonucleic acid (DNA) in SLE, or they may be of exogenous origin, such as streptococcal membrane antigens in poststreptococcal glomerulonephritis. Frequently, the source of the antigen is unknown.

The cellular changes that occur with glomerular disease include increases in glomerular or inflammatory cell

**FIGURE 41.10** Algorithm demonstrating the integration of pathologic findings with clinical data to make a diagnosis of a specific form of primary or secondary glomerulonephritis. An important initial categorization is an anti-GBM, immune complex or antineutrophil cytoplasmic autoantibody (ANCA) glomerulonephritis. Once this determination is made, more specific diagnoses depend on additional clinical or pathologic observations. (From Rubin R., Strayer D. (Eds.) (2012). Rubin's pathology: Clinicopathologic foundations of medicine (6th ed., p. 765). Philadelphia, PA: Lippincott Williams & Wilkins.)

**FIGURE 41.11** Immune mechanisms of glomerular disease. (A) Antiglomerular membrane antibodies leave the circulation and interact with antigens that are present in the basement membrane of the glomerulus. (B) Antigen–antibody complexes circulating in the blood become trapped as they are filtered in the glomerulus.
number (proliferative or hypercellular), basement membrane thickening (membranous), and changes in noncellular glomerular components (sclerosis and fibrosis). An increase in cell numbers is characterized by one or more of the following: proliferation of endothelial and mesangial cells, leukocyte infiltration (neutrophils, monocytes, and in some cases, lymphocytes), and formation of crescents (half-moon–shaped collections of proliferating epithelial cells and infiltrating leukocytes) in the Bowman space. Basement membrane thickening involves deposition of dense noncellular material on the endothelial and epithelial sides of the basement membrane or within the membrane itself. Sclerosis refers to an increase in the amount of extracellular material in the mesangial, subendothelial, or subepithelial tissue of the glomerulus, and fibrosis refers to the deposition of collagen fibers. Glomerular changes can be diffuse, involving all glomeruli and all parts of the glomeruli; focal, in which only some glomeruli are affected and others are essentially normal; segmental, involving only a certain segment of each glomerulus; or mesangial, affecting only mesangial cells. Figure 41.9B illustrates the location of lesions associated with various types of glomerular disease.

Types of Glomerular Disease

The clinical manifestations of glomerular disorders generally fall into one of five categories:

1. Nephritic syndromes
2. Rapidly progressive glomerulonephritis
3. The nephrotic syndrome
4. Asymptomatic disorders of urinary sediment (i.e., hematuria, proteinuria)
5. Chronic glomerulonephritis

The nephritic syndromes produce a proliferative inflammatory response, whereas the nephrotic syndrome produces increased permeability of the glomerulus. Because most glomerular disorders can produce mixed nephritic and nephrotic syndromes, a definitive diagnosis often requires renal biopsy.

Acute Nephritic Syndrome

The acute nephritic syndrome is the clinical correlate of acute glomerular inflammation. In its most dramatic form, the acute nephritic syndrome is characterized by sudden onset of hematuria (either microscopic or grossly visible, with red cell casts), variable degrees of proteinuria, diminished GFR, oliguria, and signs of impaired renal function. Inflammatory processes that occlude the glomerular capillary lumen and damage the capillary wall cause it. This damage to the capillary wall allows RBCs to escape into the urine and produce hemodynamic changes that decrease the GFR. Extracellular fluid accumulation, hypertension, and edema develop because of the decreased GFR and enhanced tubular reabsorption of salt and water.

The acute nephritic syndrome may occur in such systemic diseases as SLE. Typically, however, it is associated with acute proliferative glomerulonephritis such as postinfectious glomerulonephritis.

Acute Postinfectious Glomerulonephritis. Acute postinfectious glomerulonephritis usually occurs after infection with certain strains of group A β-hemolytic streptococci and is caused by deposition of immune complexes of antibody and bacterial antigens. It also may occur after infections by other organisms, including staphylococci, a viral agent, such as hepatitis, and various parasites. Although the disease is seen primarily in children, people of any age can be affected.

The acute phase of postinfectious glomerulonephritis is characterized by diffuse glomerular enlargement and hypercellularity. The hypercellularity is caused by infiltration of leukocytes, both neutrophils and monocytes, and proliferation of endothelial and mesangial cells. There is also swelling of endothelial cells. The combination of proliferation, swelling, and leukocyte infiltration obliterates the glomerular capillary lumens. There may be interstitial edema and inflammation, and the tubules often contain RBCs. In the first weeks of disease, immunofluorescence microscopy typically reveals granular deposits of IgG and the complement component C3 in the mesangium and along the basement membrane (Fig. 41.12).

The classic case of poststreptococcal glomerulonephritis follows a streptococcal infection by approximately 7 to 12 days. This is the time needed for the development of antibodies. The primary infection usually involves the pharynx, but could be skin triggered. Oliguria, which develops as the GFR decreases, is one of the first symptoms. Proteinuria and hematuria follow because of increased glomerular capillary wall permeability. Materials in the urine degrade the RBCs, and cola-colored urine may be the first sign of the disorder. Sodium and water retention gives rise to edema (particularly of the face and hands) and hypertension. Important laboratory findings include an elevated antistreptococcal antibody (ASO) titer, a decline in serum concentrations of C3 and other components of the complement cascade, and cryoglobulins (i.e., large immune complexes) in the serum.
Disorders of Renal Function

1101

Goodpasture Syndrome. Goodpasture syndrome is an uncommon and aggressive form of glomerulonephritis that is caused by antibodies to the alveolar and glomerular basement membrane (GBM). The anti-GBM antibodies cross-react with the pulmonary alveolar basement membrane to produce the syndrome of pulmonary hemorrhage associated with renal failure. The pathologic hallmark of anti-GBM glomerulonephritis is diffuse linear staining of GBMs for IgG (Fig. 41.13). The cause of the disorder is unknown, although influenza infection, exposure to hydrocarbon solvent (found in paints and dyes), various drugs, and cancer have been implicated in some people. There is some thought that Goodpasture syndrome has a genetic predisposition, but this is not conclusive.

Treatment includes plasmapheresis to remove circulating anti-GBM antibodies and immunosuppressive therapy (i.e., corticosteroids and cyclophosphamide) to inhibit antibody production.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis is a clinical syndrome characterized by signs of severe glomerular injury that does not have a specific cause. As its name indicates, this type of glomerulonephritis is rapidly progressive, often within a matter of months. The disorder involves focal and segmental proliferation of glomerular cells and recruitment of monocytes and macrophages with formation of crescent-shaped structures that obliterate the Bowman space. Rapidly proliferative glomerulonephritis may be caused by a number of immunologic disorders, some systemic and others restricted to the kidney. Among the diseases associated with this form of glomerulonephritis are immune complex disorders such as SLE, small-vessel vasculitides (e.g., microscopic polyangiitis), and an immune disorder called Goodpasture syndrome.

Nephrotic Syndrome

The nephrotic syndrome is characterized by massive proteinuria (>3.5 g/day) and lipiduria (e.g., free fat, oval bodies, fatty casts), along with an associated hypoalbuminemia (<3 g/dL), generalized edema, and hyperlipidemia (cholesterol > 300 mg/dL).

The nephrotic syndrome is not a specific glomerular disease, but a constellation of clinical findings that result from an increase in glomerular permeability and loss of plasma proteins in the urine (Fig. 41.14).

Pathogenesis. Any increase in glomerular membrane permeability allows proteins to escape from the plasma into the glomerular filtrate. Massive proteinuria results, leading to hypoalbuminemia. Generalized edema, which is a hallmark of the nephrotic syndrome, results from the loss of colloidal osmotic pressure of the blood with subsequent accumulation of fluid in the interstitial tissues. There is also salt and water retention, which aggravates the edema. This appears to be due to several factors, including a compensatory increase in aldosterone, stimulation of the sympathetic nervous system, and a reduction in secretion of natriuretic factors. Initially, the edema presents in dependent parts of the body such as the lower extremities, but becomes more generalized as the disease progresses. Dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise due to ascites can develop in persons with nephrotic syndrome.
The hyperlipidemia that occurs in people with nephrosis is characterized by elevated levels of triglycerides and low-density lipoproteins (LDLs). Levels of high-density lipoproteins (HDLs) usually are normal. Because of the elevated LDL levels, people with nephrotic syndrome are at increased risk for development of atherosclerosis.

The largest proportion of protein lost in the urine is albumin, but globulins also may be lost. As a result, people with nephrosis may be vulnerable to infections, particularly those caused by staphylococci and pneumococci. This decreased resistance to infection probably is related to loss of both immunoglobulins and low molecular weight complement components in the urine. Many binding proteins also are lost in the urine. Consequently, the plasma levels of many ions (iron, copper, zinc) and hormones (thyroid and sex hormones) may be low because of decreased binding proteins. Many drugs require protein binding for transport. Hypoalbuminemia reduces the number of available protein-binding sites, thereby producing a potential increase in the amount of free (active) drug that is available.

**Etiology.** The glomerular derangements that occur with nephrosis can develop as a primary disorder or secondary to changes caused by systemic diseases such as diabetes mellitus and SLE. Among the primary glomerular lesions leading to nephrotic syndrome are minimal-change disease (lipoid nephrosis), focal segmental glomerulosclerosis, and membranous glomerulonephritis. The relative frequency of these causes varies with age. In children younger than 15 years of age, nephrotic syndrome almost always is caused by primary idiopathic glomerular disease, whereas in adults, it often is a secondary disorder.

**Minimal-Change Disease (Lipoid Nephrosis).** Minimal-change disease is characterized by diffuse loss (through fusion) of the foot processes of cells in the epithelial layer of the glomerular membrane. It is most commonly seen in children, but may occasionally occur in adults. The cause of minimal-change nephrosis is unknown. Although minimal-change disease does not progress to renal failure, it can cause significant complications, including predisposition to infection with gram-positive organisms, a tendency toward thromboembolic events, hyperlipidemia, and protein malnutrition.

**Membranous Glomerulonephritis.** Membranous glomerulonephritis is the most common cause of primary nephrosis in adults, most commonly those in the fifth and sixth decades of life and almost always after 30 years of age. The disorder is caused by diffuse thickening of the GBM due to deposition of immune complexes. The disorder may be idiopathic or associated with a number of disorders, including autoimmune diseases such as SLE, infections such as chronic hepatitis B, and metabolic disorders such as diabetes mellitus. The presence of immunoglobulins and complement in the subendothelial deposits suggests that the disease represents a chronic immune complex–mediated disorder.

The disorder usually begins with an insidious onset of the nephrotic syndrome or, in a small percentage of people, with non-nephrotic proteinuria. Hematuria and mild hypertension may be present. The progress of the disease is variable. Some people experience a complete remission, others have repeated remissions and relapses, and still others progress to complete renal failure and even death. Spontaneous remissions and a relatively benign outcome occur more commonly in women and those with proteinuria in the non-nephrotic range. Treatment is controversial.

**Focal Segmental Glomerulosclerosis.** Focal segmental glomerulosclerosis is characterized by sclerosis (i.e., increased collagen deposition) of some, but not all glomeruli, in the affected glomeruli, only a portion of the glomerular tuft is involved. It is a particularly common cause of nephrotic syndrome in Hispanic and African Americans.

Although focal segmental sclerosis often is an idiopathic syndrome, it may be associated with reduced oxygen in the blood (e.g., sickle cell disease and cyanotic congenital heart disease), human immunodeficiency virus (HIV) infection, or intravenous drug abuse, or it may occur as a secondary event reflecting glomerular scarring due to other forms of glomerulonephritis.

The presence of hypertension and decreased renal function distinguishes focal sclerosis from minimal-change disease. In addition, research indicates that urinary excretion of CD80 (B7.1) is elevated with minimal-change disease, but not with focal segmental glomerulosclerosis. The disorder.
usually is treated with corticosteroids. Most people with the disorder progress to kidney failure within 5 to 10 years.

**Asymptomatic Hematuria or Proteinuria**

Many cases of glomerulonephritis result in mild asymptomatic illness that is not recognized or brought to the attention of a health care professional, and therefore remains undiagnosed. Population-based screening studies have shown that kidney damage as evidenced by proteinuria, hematuria, low GFR, or a combination of these features is present in the population. Disorders such as Henoch-Schönlein purpura often resolve without permanent kidney damage, whereas others, such as IgA nephropathy and Alport syndrome, can progress to chronic kidney disease and renal failure.

**Immunoglobulin A Nephropathy.** Immunoglobulin A nephropathy (i.e., Berger disease) is a primary glomerulonephritis characterized by the presence of glomerular IgA immune complex deposits. It can occur at any age, but most commonly, the peak age of diagnosis is between 15 and 30 years of age. The disease occurs more commonly in men than women and is the most common cause of glomerular nephritis in Asians. The disorder is characterized by the deposition of IgA-containing immune complexes in the mesangium of the glomerulus. Once deposited in the kidney, the immune complexes are associated with glomerular inflammation. The cause of the disorder is unknown and there is a need for more specific classifications of the stages of IgA nephropathy so more information can be interpreted. Therefore, the International IgA Nephropathy Network is developing IgAN classifications to assist providers in diagnosing this disease. Some people with the disorder have elevated serum IgA levels.

Early in the disease, many people with the disorder have no obvious symptoms and are unaware of the problem. In these people, IgA nephropathy is suspected during routine screening or examination for another condition. In other people, the disorder presents with gross hematuria that is preceded by upper respiratory tract infection, gastrointestinal tract symptoms, or a flulike illness. The hematuria usually lasts 2 to 6 days. Approximately one half of the people with gross hematuria have a single episode, whereas the remainder experience a gradual progression in the disease with recurrent episodes of hematuria and mild proteinuria. Progression usually is slow, extending over several decades.

Immunofluorescence microscopy is essential for diagnosis of IgA nephropathy. The diagnostic finding is mesangial staining for IgA more intense than staining for IgG or IgM (Fig. 41.15). At present, there are no satisfactory treatment measures for IgA nephropathy. The role of immunosuppressive drugs such as steroids and cytotoxic drugs is not clear. There has been recent interest in the use of omega-3 fatty acids in delaying the progression of the disease.

**Henoch-Schölein Purpura Nephritis.** Henoch-Schönlein purpura is a small-vessel vasculitis that causes a purpuric rash largely of the lower extremities, arthritis or arthralgia, abdominal pain, and renal involvement identical to that of IgA nephropathy. The disease is seen most commonly in children but can also occur in adults. Renal involvement is not always present initially, but its incidence increases with time and is more common in older children, who have associated abdominal pain and a persistent rash. Although hematuria and proteinuria are the most common presentation, some people present with manifestations of acute nephritis, and others may present with combined nephritis and nephrotic manifestations. Most people recover fully over a period of several weeks. Corticosteroids are the most effective treatment and have been found to decrease the duration and intensity of abdominal and joint pain.

**Alport Syndrome**

Alport syndrome represents a hereditary defect of the GBM that results in hematuria and may progress to chronic renal failure. It tends to be associated with defects in the ears or eyes. The syndrome is caused by type IV collagen mutations. Approximately 85% of cases are inherited as an X-linked autosomal dominant trait, whereas others have autosomal dominant and recessive patterns of inheritance. In X-linked pedigrees, boys are usually affected more seriously than girls. Affected boys usually progress to renal failure as adults, but progression may occur during adolescence. Although many girls never have more than mild hematuria with or without mild proteinuria, some have more significant disease and may even progress to kidney failure.

Diagnosis of Alport syndrome is often made after examination of the urine of a child from a family with multiple cases of hereditary nephritis. Children may initially present with heavy microscopic hematuria, followed by the development of proteinuria. Many, but not all, people with Alport syndrome have sensorineural deafness and various eye disorders, including lens dislocation, posterior cataracts, and
Corneal dystrophy. The hearing loss is bilateral and often is first detected during adolescence.

**Chronic Glomerulonephritis**

Chronic glomerulonephritis represents the chronic phase of a number of specific types of glomerulonephritis. Some forms of acute glomerulonephritis (e.g., poststreptococcal glomerulonephritis) undergo complete resolution, whereas others progress at variable rates to chronic glomerulonephritis. Some people who present with chronic glomerulonephritis have no history of glomerular disease. These cases may represent the end result of relatively asymptomatic forms of glomerulonephritis. Histologically, the condition is characterized by small kidneys with sclerosed glomeruli. In most cases, chronic glomerulonephritis develops insidiously and slowly progresses to chronic kidney disease over a period of years.

**Glomerular Lesions Associated with Systemic Disease**

Many immunologic, metabolic, or hereditary systemic diseases are associated with glomerular injury. In some diseases, such as SLE, diabetes mellitus, and hypertension, the glomerular involvement may be a major clinical manifestation.

**Systemic Lupus Erythematosus Glomerulonephritis**

Renal involvement is clinically evident in 40% to 85% of people with SLE and is seen more commonly in black women. The pathogenesis of SLE is uncertain, but seems to be related to dysregulated B-cell immunity with production of autoantibodies to a variety of nuclear, cytoplasmic, extracellular matrix, and cell membrane components. Most glomerular injury is triggered by the formation of immune complexes within the glomerular capillary wall.

**Clinical Manifestations.** The clinical manifestations of lupus nephritis depend on the site of immune complex–mediated injury. Immune complexes confined to the mesangium cause less inflammation than subendothelial immune complexes, which have greater exposure to inflammatory cells and mediators in the blood, and which therefore are more likely to produce inflammation. The World Health Organization (WHO) classifies the renal glomerular lesions of SLE as class I, normal; class II, mesangial proliferation; class III, focal and segmental proliferation; class IV, diffuse proliferation; and class V, membranous proliferation.

**Diagnosis and Treatment.** Because of the high risk for kidney disease, all people with SLE should undergo routine urinalysis to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are noted, renal biopsy is often performed. Treatment depends on the extent of glomerular involvement. People with class I or II glomerulonephritis usually require no treatment. Progression to higher classes is usually accompanied by an increase in lupus serology activity and evidence of deteriorating renal function (i.e., rising serum creatinine, and a decrease in calculated GFR). Oral corticosteroids and angiotensin-converting enzyme (ACE) inhibitors are the mainstays of treatment. People with more advanced disease may require treatment with immunosuppressive agents (e.g., intravenous cyclophosphamide or oral mycophenolate mofetil). Clinical trials using other immunosuppressant agents are ongoing.

**Diabetic Glomerulosclerosis**

Diabetic nephropathy is a major cause of chronic kidney disease and the most common cause of kidney failure treated by renal replacement therapy in the United States. It occurs in both types 1 and 2 diabetes mellitus. It is more prevalent among African Americans, Asians, and Native Americans than whites.

**Pathophysiology.** The lesions of diabetic nephropathy most commonly involve the glomeruli. Widespread thickening of the glomerular capillary basement membrane occurs in almost all people with diabetes and can occur without evidence of proteinuria. This is followed by a diffuse increase in mesangial matrix, with mild proliferation of mesangial cells. As the disease progresses, the mesangial cells impinge on the capillary lumen, reducing the surface area for glomerular filtration. In nodular glomerulosclerosis, also known as Kimmelstiel-Wilson syndrome, there is nodular deposition of hyaline in the mesangial portion of the glomerulus. As the sclerotic process progresses in the diffuse and nodular forms of glomerulosclerosis, there is complete obliteration of the glomerulus, with impairment of renal function.

Although the mechanisms of glomerular change in diabetes are uncertain, they are thought to represent enhanced or defective synthesis of the GBM and mesangial matrix with an inappropriate incorporation of glucose into the noncellular components of these glomerular structures. Alternatively, hemodynamic changes that occur secondary to elevated blood glucose levels may contribute to the initiation and progression of diabetic glomerulosclerosis. It has been hypothesized that elevations in blood glucose produce an increase in GFR and glomerular pressure that leads to enlargement of glomerular capillary pores by a mechanism that is, at least partly, mediated by angiotensin II. This enlargement results in an increase in the protein content of the glomerular filtrate, which in turn requires increased endocytosis of the filtered proteins by tubular endothelial cells, a process that ultimately leads to nephron destruction and progressive deterioration of renal function.

**Clinical Manifestations and Treatment.** The clinical manifestations of diabetic glomerulosclerosis are closely linked to those of diabetes. The increased GFR that occurs in people with early alterations in renal function is associated with microalbuminuria, which is defined as urinary albumin excretion of 30 to 300 mg in 24 hours. Microalbuminuria is an important predictor of future diabetic nephropathies. In many cases, these early changes in glomerular function can be reversed by
careful control of blood glucose levels. Inhibition of angiotensin by ACE inhibitors or angiotensin receptor blockers (ARBs) has been shown to have a beneficial effect, possibly by reversing increased glomerular pressure. Hypertension and cigarette smoking have been implicated in the progression of diabetic nephropathy.

**Hypertensive Glomerular Disease**

Mild to moderate hypertension causes sclerotic changes in renal arterioles and small arteries, referred to as benign nephrosclerosis. It is most prevalent and most aggressive among blacks. Among African Americans, hypertension is the leading cause of end-stage renal disease.

Hypertensive nephropathy is associated with a number of changes in kidney structure and function. The kidneys are smaller than normal and are usually affected bilaterally. On histologic examination, there is narrowing of the arterioles and small arteries, caused by thickening and scarring of the vessel walls. As the vascular structures thicken and perfusion diminishes, blood flow to the nephron decreases, causing patchy tubular atrophy, interstitial fibrosis, and a variety of changes in glomerular structure and function.

Although uncomplicated hypertensive nephrosclerosis is not usually associated with significant abnormalities in renal function, a few people may progress to end-stage renal disease. Three groups of people are at particular risk for development of renal failure—blacks, people with more severe BP elevations, and people with a second underlying disease, such as diabetes.

**IN SUMMARY**

Glomerulonephritis, an inflammatory process that involves glomerular structures, is the second leading cause of kidney failure worldwide and ranks third, after diabetes and hypertension, as a cause of chronic kidney disease in the United States. The disease may occur as a primary condition in which the glomerular abnormality is the only disease present, or it may occur as a secondary condition in which the glomerular abnormality results from another disease, such as diabetes mellitus or SLE. Most cases of primary and many cases of secondary glomerular disease probably have an immune origin.

The clinical manifestations of glomerular disorders generally fall into one of five categories: the nephritic syndrome, rapidly progressive glomerulonephritis, nephrotic syndrome, asymptomatic disorders (i.e., hematuria, proteinuria), and chronic glomerulonephritis. The nephritic syndrome evokes an inflammatory response in the glomeruli and is characterized by hematuria with red cell casts in the urine, a diminished GFR, azotemia, oliguria, and hypertension. The nephrotic syndrome affects the integrity of the glomerular capillary membrane and is characterized by massive proteinuria, hypalbuminemia, generalized edema, lipiduria, and hyperlipidemia. Asymptomatic hematuria and proteinuria represent glomerular disorders that are not recognized or brought to the attention of a health care professional, and therefore remain undiagnosed. Chronic glomerulonephritis represents the chronic phase of a number of specific types of glomerulonephritis. Secondary causes of glomerular kidney disease include SLE, diabetes mellitus, and hypertension.

**Renal Tubular Acidosis**

Renal tubular acidosis (RTA) refers to a group of tubular defects in reabsorption of bicarbonate ions (HCO₃⁻) or excretion of hydrogen ions (H⁺) that result in metabolic acidosis and its subsequent complications, including metabolic bone disease, kidney stones, and growth failure in children. Proximal tubular disorders that affect bicarbonate reabsorption, and distal tubular defects that affect the secretion of fixed metabolic acids are the two major types of RTA. A third type of RTA results from aldosterone deficiency or resistance to its action that leads to impaired reabsorption of sodium ions (Na⁺) with decreased elimination of H⁺ and potassium ions (K⁺). Renal acidosis also occurs in kidney failure.
Proximal Renal Tubular Acidosis

Proximal RTA involves a defect in proximal tubular reabsorption, the nephron site where 85% of filtered HCO$_3^-$ is reabsorbed. With the onset of impaired tubular HCO$_3^-$ reabsorption, there is a loss of HCO$_3^-$ in the urine that reduces plasma HCO$_3^-$ levels. The concomitant loss of Na$^+$ in the urine leads to contraction of the extracellular fluid volume with increased aldosterone secretion and a resultant decrease in serum K$^+$ levels. With proximal tubular defects in acid–base regulation, the distal tubular sites for secretion of the fixed acids into the urine continue to function, and the reabsorption of HCO$_3^-$ eventually resumes, albeit at a lower level of serum HCO$_3^-$. Whenever serum levels rise above this decreased level, HCO$_3^-$ is lost in the urine. People with proximal RTA generally have plasma HCO$_3^-$ levels greater than 15 mEq/L and seldom develop severe acidosis.

Proximal RTA may occur as a hereditary or acquired disorder and may involve an isolated defect in HCO$_3^-$ reabsorption or accompany other defects in proximal tubular function (Fanconi syndrome). Isolated defects in HCO$_3^-$ reabsorption are relatively rare. The term Fanconi syndrome is used to describe a generalized proximal tubular dysfunction in which the RTA is accompanied by impaired reabsorption of glucose, amino acids, phosphate, and uric acid. Children with Fanconi syndrome are likely to have growth retardation, rickets, osteomalacia, and abnormal vitamin D metabolism in addition to mild acidosis associated with proximal RTA.

Children and infants with proximal RTA require alkali therapy because of the high incidence of growth retardation due to acidemia. Potassium supplements are also needed because of increased loss of potassium that occurs with alkali therapy. Adults may also require alkali therapy. Vitamin D and phosphate are appropriate treatments for rickets and hypophosphatemia.

Distal Renal Tubular Acidosis

Distal RTA has its origin in the distal convoluted tubule and the collecting duct, where about 15% of the filtered bicarbonate is reabsorbed. The clinical syndrome of distal RTA includes hypokalemia, hyperchloremic metabolic acidosis, inability to acidify the urine, nephrocalcinosis, and nephrolithiasis. Additional features include osteomalacia or rickets.

Distal RTA results from a distal tubular defect in H+ secretion with failure to acidify the urine. Because the secretion of H$^+$ in the distal tubules is linked to sodium reabsorption, failure to secrete H$^+$ results in a net loss of sodium bicarbonate in the urine. This results in contraction of fluids in the extracellular fluid compartment, a compensatory increase in aldosterone levels, and development of hypokalemia. The persistent acidosis, which requires buffering by the skeletal system, causes calcium to be released from bone. Increased losses of calcium in the urine lead to increased levels of parathyroid hormone, osteomalacia, bone pain, impaired growth in children, and development of kidney stones and nephrocalcinosis.

Long-term treatment of distal RTA requires alkali supplementation. Greater amounts are needed for children because of the need for base deposition in growing bone and because bicarbonate wastage is greater in children than in adults. Alkali therapy generally allows for correction of potassium wasting and hypokalemia.

Pyelonephritis

Pyelonephritis refers to infection of the kidney parenchyma and renal pelvis. There are two forms of pyelonephritis—acute and chronic.

Acute Pyelonephritis

Acute pyelonephritis represents an upper UTI, specifically the renal parenchyma and renal pelvis. Risk factors for complicated acute pyelonephritis are those that increase the host’s susceptibility or reduce the host response to infection. People with diabetes mellitus are at increased risk. A less frequent and more serious type of acute pyelonephritis, called necrotizing pyelonephritis, is characterized by necrosis of the renal papillae. It is particularly common in people with diabetes and may also be a complication of acute pyelonephritis when there is significant urinary tract obstruction.

Etiology. Gram-negative bacteria, including E. coli and Proteus, Klebsiella, Enterobacter, and Pseudomonas species, are the most common causative agents. The infection usually ascends from the lower urinary tract, with the exception of S. aureus, which is usually spread through the bloodstream. Factors that contribute to the development of acute pyelonephritis are catheterization and urinary instrumentation, vesicoureteral reflux, pregnancy, and neurogenic bladder.

Hematogenous acute pyelonephritis occurs most often in debilitated, chronically ill people and those receiving immunosuppressive therapy. Immunosuppression favors the development of subclinical (silent) pyelonephritis and infections caused by nonenteric, aerobic, gram-negative rods, and Candida.

Clinical Manifestations. Acute pyelonephritis tends to present with an abrupt onset of chills, high fever, and an ache or tenderness in the costovertebral angle (flank area of the back) that is unilateral or bilateral. Lower urinary tract symptoms, including dysuria, frequency, and urgency, also are common. Nausea and vomiting may occur along with abdominal pain. Palpation or percussion over the costovertebral angle on the affected side usually causes pain. Pyuria occurs but is not diagnostic because it also occurs in lower UTIs. The development of necrotizing papillitis is associated with a much poorer prognosis.

Treatment. Acute pyelonephritis is treated with appropriate antimicrobial drugs and may also require intravenous hydration. Unless obstruction or other complications occur, the symptoms usually disappear within several days. Treatment with an appropriate antimicrobial agent usually is continued for 10 to 14 days. People with complicated acute pyelonephritis
and those who do not respond to outpatient treatment may require hospitalization.

**Chronic Pyelonephritis**

Chronic pyelonephritis represents a progressive process. There is scarring and deformation of the renal calyces and pelvis (Fig. 41.16). The disorder appears to involve a bacterial infection superimposed on obstructive abnormalities or vesicoureteral reflux. Chronic obstructive pyelonephritis is associated with recurrent bouts of inflammation and scarring, which eventually lead to chronic pyelonephritis. Reflux, which is the most common cause of chronic pyelonephritis, results from superimposition of infection on congenital vesicoureteral reflux or intrarenal reflux. Reflux may be unilateral with involvement of a single kidney or bilateral, leading to scarring and atrophy of both kidneys with the eventual development of chronic renal insufficiency.

**Clinical Manifestations.** Chronic pyelonephritis may cause many of the same symptoms as acute pyelonephritis, or its onset may be insidious. Often, there is a history of recurrent episodes of UTI or acute pyelonephritis. Loss of tubular function and the ability to concentrate urine give rise to polyuria, nocturia, and mild proteinuria. Severe hypertension often is a contributing factor in the progress of the disease. Chronic pyelonephritis is a significant cause of renal failure.

**Drug-Related Nephropathies**

Drug-related nephropathies involve functional or structural changes in the kidneys that occur after exposure to a drug. Because of their large blood flow and high filtration pressure, the kidneys are exposed to any substance that is in the blood. The kidneys also are active in the metabolic transformation of drugs and therefore are exposed to a number of toxic metabolites. The tolerance to drugs varies with age and depends on renal function, state of hydration, BP, and the pH of the urine. Older adults are particularly susceptible to kidney damage caused by drugs and toxins. The dangers of nephrotoxicity are increased when two or more drugs capable of producing kidney damage are given at the same time.

Drugs and toxic substances can damage the kidneys by causing a decrease in renal blood flow, obstructing urine flow, directly damaging tubulointerstitial structures, or producing hypersensitivity reactions. Some drugs, such as diuretics, high molecular weight radiocontrast media, the immunosuppressive drugs cyclosporine and tacrolimus, and the nonsteroidal anti-inflammatory drugs (NSAIDs), can cause acute prerenal failure by decreasing renal blood flow. Persons at particular risk are those who already have compromised renal blood flow. Other drugs such as sulfonamides and vitamin C (due to oxalate crystals) can form crystals that cause kidney damage by obstructing urinary flow in the tubules.

Acute drug-related hypersensitivity reactions produce tubulointerstitial nephritis, with damage to the tubules and interstitium. This condition was observed initially in persons who were sensitive to the sulfonamide drugs; currently, it is observed most often with the use of methicillin and other synthetic antibiotics, and with the use of furosemide and the thiazide diuretics in persons sensitive to these drugs. At the onset, there is fever, eosinophilia, hematuria, mild proteinuria, and in approximately one fourth of cases, a rash. In approximately 50% of cases, signs and symptoms of acute renal failure develop. Withdrawal of the drug commonly is followed by complete recovery, but there may be permanent damage in some persons, usually in older persons. Drug nephritis may not be recognized in its early stage because it is relatively uncommon.

**FIGURE 41.16** • Chronic pyelonephritis. (A) The cortical surface contains many irregular, depressed scars (reddish areas). (B) There is marked dilation of calices caused by inflammatory destruction of papillae, with atrophy and scarring of the overlying cortex. (From Rubin R., Strayer D. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 797). Philadelphia, PA: Lippincott Williams & Wilkins.)
NSAIDs also have the potential for damaging renal structures, including medullary interstitial cells. Prostaglandins (particularly PG12 and PGE2) contribute to the regulation of tubular blood flow. The deleterious effects of NSAIDs on the kidney are thought to result from their ability to inhibit prostaglandin synthesis. An important feature of Wilms tumor is its association with other congenital anomalies, including aniridia (absence of the iris), hemihyperplasia (enlargement of one side of the face or body), and other congenital anomalies, usually of the genitourinary system. Several chromosomal abnormalities have been associated with Wilms tumor. One Wilms tumor gene, WT1, which is located on chromosome 11, encodes a transcription factor that is critical for normal kidney development. Wilms tumor usually is a solitary mass that occurs in any part of the kidney. It usually is sharply demarcated and variably encapsulated (Fig. 41.17). The tumors grow to a large size, distorting kidney structure. The tumors usually are staged using the National Wilms’ Tumor Study Group classification:

- Stage I tumors are limited to the kidney and can be excised with the capsular surface intact.
- Stage II tumors extend into the renal capsule, but can be excised.
- Stage III tumors extend to the abdomen, but not beyond.
- Stage IV tumors have undergone hematogenous metastasis, most commonly involving the lung.

### IN SUMMARY

Tubulointerstitial diseases affect the tubules and the surrounding interstitium of the kidneys. These disorders include RTA, acute and chronic pyelonephritis, and the effects of drugs and toxins. RTA describes a form of systemic acidosis that results from tubular defects in bicarbonate reabsorption or hydrogen ion secretion. Pyelonephritis, or infection of the kidney and kidney pelvis, can occur as an acute or a chronic condition. Acute pyelonephritis typically is caused by ascending bladder infections or infections that come from the bloodstream; it usually is successfully treated with appropriate antimicrobial drugs. Chronic pyelonephritis is a progressive disease that produces scarring and deformation of the renal calyces and pelvis. Drug-induced impairment of tubulointerstitial structure and function usually is the result of direct toxic injury, decreased blood flow, or hypersensitivity reactions.

### MALIGNANT TUMORS OF THE KIDNEY

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize Wilms tumor in terms of age of onset, possible oncogenic origin, manifestations, and treatment.
- Cite the risk factors for renal cell carcinoma, describe its manifestations, and explain why the 5-year survival rate has been so low.

There are two major groups of malignant tumors of the kidney—embryonic kidney tumors (i.e., Wilms tumor), which occur during childhood, and renal cell carcinoma, which occurs in adults.

### Wilms Tumor

Wilms tumor (nephroblastoma) is one of the most common primary neoplasms of young children. It usually presents between 3 and 5 years of age and is the most common malignant abdominal tumor in children. It may occur in one or both kidneys. The incidence of bilateral Wilms tumor is 5% in sporadic cases and up to 20% in familial cases.

Histologically, the tumor is composed of elements that resemble normal fetal tissue—blastemic, stromal, and epithelial. An important feature of Wilms tumor is its association with other congenital anomalies, including aniridia (absence of the iris), hemihyperplasia (enlargement of one side of the face or body), and other congenital anomalies, usually of the genitourinary system. Several chromosomal abnormalities have been associated with Wilms tumor. One Wilms tumor gene, WT1, which is located on chromosome 11, encodes a transcription factor that is critical for normal kidney development.
The common presenting signs are a large asymptomatic abdominal mass and hypertension. The tumor is often discovered inadvertently, and it is not uncommon for the mother to discover it while bathing the child. Some children may present with abdominal pain, vomiting, or both.

Treatment involves surgery, chemotherapy, and sometimes radiation therapy. Long-term survival rates have increased to 90% for stages I through III.

Renal Cell Carcinoma

Cancer of the kidney incidence peaks in people in their sixties and seventies. The increased use of imaging procedures such as ultrasonography, CT scanning, and magnetic resonance imaging (MRI) has contributed significantly to earlier diagnosis and more accurate staging of kidney cancers. Renal cell carcinoma accounts for approximately 80% to 90% of kidney tumors. The tumor may arise from any portion of the kidney, but most commonly affects the poles, especially the upper pole.

Etiology and Pathogenesis

The cause of renal cell carcinoma remains unclear. Epidemiologic evidence suggests a correlation between heavy smoking and kidney cancer. Obesity also is a risk factor, particularly in women. The risk for renal cell carcinoma also is increased in people with acquired cystic kidney disease associated with chronic renal insufficiency.

There are pathologic variants of renal cell carcinoma that reflect differences in cellular pathology, genetic profile, and clinical features ranging from benign to highly malignant. Categories include clear cell carcinoma (70% to 85% of cases) (Fig. 41.18), papillary or chromophilic tumors (10% to 15%), and chromophobic tumors (5% to 10%). Clear cell tumors have a clear cytoplasm, usually show chromosome 3 deletions, and arise from proximal tubular epithelial cells. Papillary renal cell tumors tend to be bilateral and multifocal, show trisomy 7 or 17, and arise from proximal tubular cells. Chromophobic tumors are characterized by multiple chromosomal losses but do not exhibit 3 deletions or trisomy 7 or 17, and have an indolent clinical course. Collecting duct tumors arise from the collecting ducts within the renal medulla, are very rare, affect younger people, and are very aggressive. Oncocytomas do not exhibit chromosomal changes and are considered benign.

Clinical Manifestations

Kidney cancer is largely a silent disorder during its early stages, and symptoms usually denote advanced disease. Presenting features include hematuria, flank pain, and presence of a palpable flank mass. Gross or microscopic hematuria, which occurs in the majority of cases, is an important clinical clue. It is, however, intermittent and may be microscopic. As a result, the tumor may reach considerable size before it is detected. Because of the widespread use of ultrasonography and CT scanning for diverse indications, renal tumors are being detected incidentally in people with no urologic symptoms.

Diagnosis and Treatment

Kidney cancer is suspected when there are findings of hematuria and a renal mass. Ultrasonography and CT scanning are used to confirm the diagnosis. MRI may be used when involvement of the inferior vena cava is suspected. Renal cancer is commonly staged using the American Joint Committee on Cancer staging system (Tumor, Node, Metastasis system).

Surgery (radical nephrectomy with lymph node dissection) is the treatment of choice for all resectable tumors. Nephron-sparing surgery may be done when both kidneys are involved or when an associated disease such as hypertension or diabetes mellitus threatens the contralateral kidney. Single-agent and combination chemotherapy agents have been used with limited success.

IN SUMMARY

There are two major groups of renal neoplasms—embryonic kidney tumors (i.e., Wilms tumor) that occur during childhood and adult renal cell carcinomas. Wilms tumor is one of the most common malignant tumors of children. The most common presenting signs are a large abdominal mass and hypertension. Treatment is surgery, chemotherapy, and sometimes radiation therapy. The long-term survival rate for children with Wilms tumor is approximately 90%, with an aggressive plan of treatment.

Renal cancer accounts for about 3% of all cancers, with a peak incidence in people in their sixties and seventies. Renal cell carcinoma accounts for 80% to 90% of kidney
tumors. These tumors are characterized by a lack of early warning signs, diverse clinical manifestations, and resistance to chemotherapy and radiation therapy. Because of the widespread use of ultrasonography and CT scanning for diverse indications, renal tumors are being detected incidentally in people with no urologic symptoms. Diagnostic methods include ultrasonography and CT scans. The treatment of choice is surgical resection. Prognosis depends on the stage of the cancer. The 5-year survival rate is 90% if the tumor has not extended beyond the renal capsule, but drops considerably if metastasis has occurred.

3. A 26-year-old woman makes an appointment with her health care provider, complaining of urinary frequency, urgency, and burning. She reports that her urine is cloudy and smells abnormal. Her urine is cultured, and she is given a prescription for antibiotics.
A. What is the most likely cause of the woman’s symptoms?
B. What microorganism is most likely responsible for the infection?
C. What factors may have predisposed her to this disorder?
D. What could this woman do to prevent future infection?

REVIEW EXERCISES
1. A 36-year-old man is admitted to the emergency department with a sudden onset of severe, intermittent, cramping pain that makes him feel nauseated. He describes the pain as originating in the left groin and radiating toward the flank. Microscopic examination of his urine reveals the presence of RBCs. His temperature is normal, and he does not exhibit signs of sepsis.
A. What is the probable cause of this man’s pain?
B. What diagnostic measure could be used to confirm the cause of his pain?
C. A plain-film radiograph reveals a 4- to 5-mm kidney stone in the left ureter. What are the chances that this man will pass the stone spontaneously?
D. What type of medications and other treatments should this man receive?
E. Once the stone has been passed, what type of measures can he use to prevent stone recurrence?
2. A 6-year-old boy is diagnosed with acute glomerulonephritis that developed after a streptococcal throat infection. At this time, the following manifestations are noted: a decrease in urine output, increasing lethargy, hyperventilation, and generalized edema. Trace amounts of protein are detected in his urine. Blood analysis reveals the following: pH = 7.35, HCO₃⁻ = 18 mEq/L, hematocrit = 29%, Na = 132 mEq/L, K = 5.6 mEq/L, BUN = 62 mg/dL, creatinine = 4.1 mg/dL, and albumin = 2 g/dL.
A. What is the probable cause of this boy’s glomerular disease?
B. Use the laboratory values in the Appendix to interpret his laboratory test results. Which values are significant and why?
C. Is he progressing to uremia? How can you tell?

Renal failure is a condition in which the kidneys fail to remove metabolic end products from the blood and regulate the fluid, electrolyte, and pH balance of the extracellular fluids. The underlying cause may be renal disease, systemic disease, or urologic defects of nonrenal origin. Renal failure can occur as an acute or a chronic disorder. Acute renal injury is abrupt in onset and often is reversible if recognized early and treated appropriately. In contrast, chronic kidney disease is the end result of irreparable damage to the kidneys. It develops slowly, usually over the course of a number of years. In fact, 80% of the nephrons need to be nonfunctioning before the symptoms of chronic kidney disease are manifested. Approximately 26 million American adults, or 1 in 9 adults, have some form of renal disease.¹

Acute renal injury or also termed acute kidney injury (AKI) represents a rapid decline in kidney function sufficient to increase blood levels of nitrogenous wastes and impair fluid and electrolyte balance.¹ Unlike chronic kidney disease (CKD) and failure, acute renal injury is potentially reversible if the precipitating factors can be corrected or removed before permanent kidney damage has occurred.
Acute renal injury is a common threat to seriously ill people in intensive care units, with a mortality rate ranging from 40% to 90%. Although treatment methods such as dialysis and renal replacement therapies are effective in correcting life-threatening fluid and electrolyte disorders, the mortality rate from acute renal failure has not improved substantially over the last few decades. This is probably because acute renal injury is seen more often in older adults than before, and because it frequently is superimposed on other life-threatening conditions, such as trauma, shock, and sepsis and comorbidities such as cardiovascular disease, diabetes, and respiratory disease.

The most common indicator of AKI is azotemia, an accumulation of nitrogenous wastes (urea nitrogen, uric acid, and creatinine) in the blood and a decrease in the glomerular filtration rate (GFR). New biomarkers for more accurate diagnosing of acute renal kidney injury are discussed. As a result, excretion of nitrogenous wastes is reduced, and fluid and electrolyte balance cannot be maintained.

**Types of Acute Renal Injury**

Acute renal injury can be caused by several types of conditions, including a decrease in blood flow without ischemic injury; ischemic, toxic, or obstructive tubular injury; and obstruction of urinary tract outflow. The causes of acute renal failure commonly are categorized as prerenal, intrarenal, and postrenal (Fig. 42.1). Collectively, prerenal and intrarenal causes account for 80% to 95% of acute renal failure cases. Causes of renal failure within these categories are summarized in Chart 42.1.

**Prerenal Failure**

Prerenal failure, the most common form of acute renal failure, is characterized by a marked decrease in renal blood flow. It is reversible if the cause of the decreased renal blood flow can be identified and corrected before kidney damage occurs. Causes of prerenal failure include profound depletion of vascular volume (e.g., hemorrhage, loss of extracellular fluid volume), impaired perfusion due to heart failure and cardiogenic shock, and decreased vascular filling because of increased vascular capacity (e.g., anaphylaxis or sepsis). Older adults are particularly at risk because of their...
predisposition to hypovolemia and their high prevalence of renal vascular disorders.

Some vasoactive mediators, drugs, and diagnostic agents stimulate intense intrarenal vasoconstriction and can induce glomerular hypoperfusion and prerenal failure. Examples include endotoxins, radiocontrast agents such as those used for cardiac catheterization, cyclosporine (an immunosuppressant drug that is used to prevent transplant rejection), and nonsteroidal anti-inflammatory drugs (NSAIDs). Many of these drugs also cause acute tubular necrosis (ATN; discussed later). In addition, several commonly used classes of drugs can impair renal adaptive mechanisms and can convert compensated renal hypoperfusion into prerenal failure. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) reduce the effects of renin on renal blood flow; when combined with diuretics, they may cause prerenal failure in persons with decreased blood flow due to large-vessel or small-vessel kidney disease. Prostaglandins have a vasodilatory effect on renal blood vessels. NSAIDs can reduce renal blood flow through inhibition of prostaglandin synthesis. In some persons with diminished renal perfusion, NSAIDs can precipitate prerenal failure.

Normally, the kidneys receive 20% to 25% of the cardiac output. This large blood supply is required for the glomeruli to remove metabolic wastes and regulate body fluids and electrolytes. Fortunately, the normal kidney can tolerate relatively large reductions in blood flow before renal damage occurs. As renal blood flow is reduced, the GFR decreases, the amount of sodium and other substances that are filtered by the glomeruli is reduced, and the need for energy-dependent mechanisms to reabsorb these substances is reduced. As the GFR and urine output approach zero, oxygen consumption by the kidney approaches that required to keep renal tubular cells alive. When blood flow falls below this level, which is about 20% to 25% of normal, ischemic changes occur. Because of their high metabolic rate, the tubular epithelial cells are most vulnerable to ischemic injury. Improperly treated, prolonged renal hypoperfusion can lead to ischemic tubular necrosis with significant morbidity and mortality. However, the majority of people who experience the prolonged renal hypoperfusion do not have tubular epithelial necrosis, so the term ATN is being used less frequently and AKI refers to this intrarenal pathology.

Prerenal failure is manifested by a sharp decrease in urine output and a disproportionate elevation of blood urea nitrogen (BUN) in relation to serum creatinine levels. The kidney normally responds to a decrease in the GFR with a decrease in urine output. Thus, an early sign of prerenal failure is a sharp decrease in urine output. A low fractional excretion of sodium (<1%) suggests that oliguria is due to decreased renal perfusion and that the nephrons are responding appropriately by decreasing the excretion of filtered sodium in an attempt to preserve vascular volume. BUN levels also depend on the GFR. A low GFR allows more time for small particles such as urea to be reabsorbed into the blood. Creatinine, which is larger and nondiffusible, remains in the tubular fluid, and the total amount of creatinine that is filtered, although small, is excreted in the urine. Consequently, there also is a disproportionate elevation in the ratio of BUN to serum creatinine, from a normal value of 10:1 to a ratio greater than 15:1 to 20:1.

**Postrenal Failure**

Postrenal failure results from obstruction of urine outflow from the kidneys. The obstruction can occur in the ureter (i.e., calculi and strictures), bladder (i.e., tumors or neurogenic bladder), or urethra (i.e., prostatic hyperplasia). Due to the increased urine not being able to be excreted due to the obstruction, retrograde pressure occurs throughout the tubules and nephrons, which ultimately damages the nephrons. Prostatic hyperplasia is the most common underlying problem. Because both ureters must be occluded to produce renal failure, obstruction of the bladder rarely causes acute renal failure unless one of the kidneys already is damaged or a person has only one kidney. The treatment of acute postrenal failure consists of treating the underlying cause of obstruction so that urine flow can be reestablished before permanent nephron damage occurs.

**Intrarenal Renal Failure or Acute Kidney Injury**

Intrarenal renal failure or acute kidney injury, as it is now more commonly known, results from conditions that cause damage to structures within the kidney. The most frequent etiology of intrarenal acute renal failure causes damage to the parenchyma in the glomeruli, vessels, tubules, or interstitium. The major causes of intrarenal failure are ischemia associated with prerenal failure, toxic insult to the tubular structures of the nephron, and intratubular obstruction. Acute glomerulonephritis and acute pyelonephritis also are intrarenal causes of acute renal failure. The decreased glomerular filtration and epithelial injury are due to many causes such as intrarenal vasoconstriction, decreased hydrostatic pressure in the glomeruli, changes in arterial tone by tubuloglomerular feedback, decreased capillary permeability in the glomeruli, increased tubular hydrostatic pressure secondary to obstruction, and backflow of glomerular filtrate into the interstitium. Injury to the tubular structures of the nephron is the most common cause and often is ischemic or toxic in origin.

**Acute Tubular Injury or Necrosis.** Acute tubular injury or necrosis is characterized by the destruction of tubular epithelial cells with acute suppression of renal function (Fig. 42.2). This acute injury can be caused by a variety of conditions, including acute tubular damage due to ischemia, sepsis, nephrotoxic effects of drugs, tubular obstruction, and toxins from a massive infection. Tubular epithelial cells are particularly sensitive to ischemia and also are vulnerable to toxins. The tubular injury that occurs frequently is reversible.

Ischemic ATN or acute tubular injury occurs most frequently in persons who have extensive surgery, severe
hypovolemia, or overwhelming sepsis, trauma, or burns. Sepsis produces ischemia by provoking a combination of systemic vasodilation and intrarenal hypoperfusion. In addition, sepsis results in the generation of toxins that sensitize renal tubular cells to the damaging effects of ischemia. ATN complicating trauma and burns frequently is multifactorial in origin, resulting from the combined effects of hypovolemia, myoglobinuria, and other toxins released from damaged tissue. Another etiology of acute tubular injury is experienced by people with hemolysis due to cardiac valvular disease and having a valve prosthesis. This etiology is becoming more common. In contrast to prerenal failure, the GFR does not improve with the restoration of renal blood flow in acute renal failure caused by ischemic ATN or acute tubular injury.

Nephrotic ATN or acute tubular injury complicates the administration of or exposure to many structurally diverse drugs and other nephrotoxic agents. These agents cause tubular injury by inducing varying combinations of renal vasoconstriction, direct tubular damage, or intratubular obstruction. The kidney is particularly vulnerable to nephrotic injury because of its rich blood supply and ability to concentrate toxins to high levels in the medullary portion of the kidney. The toxic effects, which cause some minor necrosis, are generally limited to the proximal tubule. In addition, the kidney is an important site for metabolic processes that transform relatively harmless agents into toxic metabolites. Pharmacologic agents that are directly toxic to the renal tubule include antimicrobials such as aminoglycosides (e.g., vancomycin, gentamicin), cancer chemotherapeutic agents such as cisplatin and radiocontrast agents. Several factors contribute to aminoglycoside nephrotoxicity, including a decrease in the GFR, preexisting renal disease, hypovolemia, and concurrent administration of other drugs that have a nephrotoxic effect. Cisplatin, which causes one third of patients who take even one dose to develop renal disease, accumulates in proximal tubule cells, inducing mitochondrial injury and inhibition of adenosine triphosphatase (ATP) activity and solute transport. Radiocontrast media-induced nephrotoxicity is thought to result from direct tubular toxicity and renal ischemia. The risk for renal damage caused by radiocontrast media is greatest in older adults and those with preexisting kidney disease, volume depletion, diabetes mellitus, and recent exposure to other nephrotoxic agents. The presence of myoglobin, hemoglobin, uric acid, myeloma light chains, or excess uric acid in the urine is the most frequent cause of ATN due to intratubular obstruction. Hemoglobinuria results from blood transfusion reactions and other hemolytic crises. Skeletal and cardiac muscles contain myoglobin, which corresponds to hemoglobin in function, serving as an oxygen reservoir in the muscle fibers. Myoglobin normally is not found in the serum or urine. Myoglobinuria most commonly results from muscle trauma, but may result from extreme exertion, hyperthermia, sepsis, prolonged seizures, potassium or phosphate depletion, and alcoholism or drug abuse. Both myoglobin and hemoglobin discolor the urine, which may range from the color of tea to red, brown, or black. “Dirty brown” granular casts and epithelial cells in the urine are correlated with acute tubular injury, red blood cell casts and protein in the urine is reflected by glomerulonephritis, and white blood cell casts and pyuria relate to acute tubulointerstitial nephritis. The course of ATN or acute tubular injury can be divided into three phases:

1. Onset or initiating phase
2. Maintenance phase
3. Recovery or convalescent phase

The onset or initiating phase, which lasts hours or days, is the time from the onset of the precipitating event (e.g., ischemic phase of prerenal failure or toxin exposure) until tubular injury occurs. The maintenance phase of ATN is characterized by a marked decrease in the GFR, causing sudden retention of endogenous metabolites, such as urea, potassium, sulfate, and creatinine, that normally are cleared by the kidneys. The urine output usually is lowest at this point. Fluid retention gives rise to edema, water intoxication, and pulmonary congestion. If the period of oliguria is prolonged, hypertension frequently develops and with it signs of uremia. When untreated, the neurologic manifestations of uremia progress from
neuromuscular irritability to seizures, somnolence, coma, and death. Hyperkalemia usually is asymptomatic until the serum potassium level rises above 6 to 6.5 mEq/L, at which point characteristic electrocardiographic changes and symptoms of muscle weakness are seen.

Formerly, most people with ATN were oliguric. During the past several decades, a nonoliguric form of ATN has become increasingly prevalent.2,6 People with nonoliguric failure have higher levels of glomerular filtration and excrete more nitrogenous waste, water, and electrolytes in their urine than persons with acute oliguric renal failure. Abnormalities in blood chemistry levels usually are milder and cause fewer complications. The decrease in oliguric ATN probably reflects new approaches to the treatment of poor cardiac performance and circulatory failure that focus on vigorous plasma volume expansion.

The recovery phase is the period during which repair of renal tissue takes place. Its onset usually is heralded by a gradual increase in urine output and a fall in serum creatinine, indicating that the nephrons have recovered to the point at which urine excretion is possible. Diuresis often occurs before renal function has fully returned to normal. Consequently, BUN and serum creatinine, potassium, and phosphate levels may remain elevated or continue to rise even though urine output is increased. In some cases, the diuresis may result from impaired nephron function and may cause excessive loss of water and electrolytes. Eventually, renal tubular function is restored with improvement in concentrating ability. At about the same time, the BUN and creatinine begin to return to normal. In some cases, mild to moderate kidney damage persists.

### Diagnosis and Treatment

Given the high morbidity and mortality rates associated with acute renal failure, attention should be focused on prevention and early diagnosis. This includes assessment measures to identify persons at risk for development of acute renal failure, including those with preexisting renal insufficiency and diabetes. These persons are particularly at risk for development of acute renal failure due to nephrotoxic drugs (e.g., aminoglycosides and radiocontrast agents), or drugs such as the NSAIDs that alter intrarenal hemodynamics. Older adults are susceptible to all forms of acute renal failure because of the effects of aging on renal reserve.

Careful observation of urine output is essential for people at risk for development of acute renal failure. Urine tests that measure urine osmolality, urinary sodium concentration, and fractional excretion of sodium help differentiate prerenal azotemia, in which the reabsorptive capacity of the tubular cells is maintained, from tubular necrosis, in which these functions are lost. One of the earliest manifestations of tubular damage is the inability to concentrate the urine.

Further diagnostic information that can be obtained from the urinalysis includes evidence of proteinuria, hemoglobinuria, and casts or crystals in the urine. Blood tests for BUN and creatinine provide information regarding the ability to remove nitrogenous wastes from the blood. It also is important to exclude urinary obstruction. However, these conventional markers of serum creatinine and urea nitrogen, fractional secretion of sodium to assess GFR, and urine output do not manifest for 1 to 2 days after the acute renal failure has begun. For example, when assessing serum creatinine in critically ill people, one cannot assume the person is in a steady hemodynamic state. Therefore, an increase in the creatinine level lags behind the renal injury. Also the person’s age, gender, muscle mass, and medications influence the creatinine levels. Urea is also not produced consistently and the amount of urea is increased by diet, medications, and infection and also affected by liver disease. With liver disease, the person’s urea will be decreased and not reflective of renal dysfunction. Lastly, fractional excretion of sodium is impacted by diuretics, specific diseases, and infection and is not an accurate predictor of decreased GFR.

Some new biomarkers for assessing AKI earlier than the conventional parameters are being trialed. Interleukin (IL)-18 is produced in the proximal tubule after AKI and is an inflammatory cytokine. This marker increases with ischemic AKI and is easily measured in the urine. Neutrophil gelatin–associated lipocalin (NGAL) is normally present in several organs including the kidneys. NGAL is measured in the blood and urine, and increased levels have been found to be predictive of graft dysfunction in renal transplants. Kidney injury molecule-1 is increased with acute renal injury in the proximal tubular cells.

A major concern in the treatment of acute renal failure is identifying and correcting the cause (e.g., improving renal perfusion, discontinuing nephrotoxic drugs). Fluids are carefully regulated in an effort to maintain normal fluid volume and electrolyte concentrations. Because secondary infections are a major cause of death in people with acute renal failure, constant effort is needed to prevent and treat such infections.

Hemodialysis or continuous renal replacement therapy (CRRT) may be indicated when nitrogenous wastes and the water and electrolyte balance cannot be kept under control by other means. CRRT has emerged as a method for treating acute renal failure in people too hemodynamically unstable to tolerate hemodialysis. An associated advantage of the CRRTs is the ability to administer nutritional support. The disadvantages are the need for prolonged anticoagulation and continuous sophisticated monitoring.

### IN SUMMARY

AKI is an acute, potentially reversible suppression of kidney function. It is a common threat to seriously ill people in intensive care units, with a high mortality rate. AKI is characterized by a decrease in GFR, accumulation...
of nitrogenous wastes in the blood (i.e., azotemia), and alterations in body fluids and electrolytes. Acute renal failure is classified as prerenal, intrinsic or intrarenal, or postrenal in origin. Prerenal failure is caused by decreased blood flow to the kidneys, postrenal failure by obstruction to urine output, and intrarenal failure by disorders in the kidney itself. ATN or AKI, due to ischemia, sepsis, or nephrotoxic agents, is a common cause of acute intrarenal failure. ATN typically progresses through three phases: the initiation phase, during which tubular injury is induced; the maintenance phase, during which the GFR falls, nitrogenous wastes accumulate, and urine output decreases; and the recovery or reparative phase, during which the GFR, urine output, and blood levels of nitrogenous wastes return to normal.

Because of the high morbidity and mortality rates associated with acute renal failure, identification of people at risk is important to clinical decision making. New biomarkers such as IL-18, NGAL, and kidney injury molecule-1 are in various trial stages, which should be helpful in earlier assessment of AKI in the future. Acute renal failure often is reversible, making early identification and correction of the underlying cause (e.g., improving renal perfusion, discontinuing nephrotoxic drugs) important. Treatment includes the judicious administration of fluids and hemodialysis or CRRT.

**Definition and Classification**

In 2002, the Kidney Disease Outcome Quality Initiative (K/DOQI) of the National Kidney Foundation (NKF) published clinical practice guidelines for CKD.\(^1\) The goals of the Work Group that developed the guidelines were to define CKD and classify its stages, to evaluate laboratory measures used for assessment of kidney disease, and to associate the level of kidney function with the complications of CKD. The guidelines use the GFR to classify CKD into five stages, beginning with kidney damage with normal or elevated GFR, progressing to CKD and, potentially, to kidney failure. It is anticipated that early detection of kidney damage along with implementation of aggressive measures to decrease its progression can delay or prevent the onset of kidney failure.\(^2\)

According to the NKF guidelines, individuals with a GFR of 60 to 89 mL/min/1.73 m² (corrected for body surface area) without kidney damage are classified as “decreased GFR.”\(^3\) Decreased GFR without recognized markers of kidney damage can occur in infants and older adults and is usually considered to be “normal for age.” Other causes of chronically decreased GFR without kidney damage in adults include removal of one kidney, extracellular fluid volume depletion, and systemic illnesses associated with reduced kidney perfusion, such as heart failure and cirrhosis.\(^4\) Even at this stage, there is often a characteristic loss of renal reserve.

CKD is defined as either kidney damage or a GFR less than 60 mL/min/1.73 m² for 3 months or longer.\(^4\) CKD can result from a number of conditions that cause permanent loss of nephrons, including diabetes, hypertension, glomerulonephritis, systemic lupus erythematosus, and polycystic kidney disease.

Hypertension and diabetic kidney disease are the two main causes of CKD in the United States.\(^2\)

The NKF Practice Guidelines define kidney failure “as either

1. A GFR of less than 15 mL/min/1.73 m², usually accompanied by most of the signs and symptoms of uremia, or
2. A need to start renal replacement therapy (dialysis or transplantation)”\(^14\)

CKD is a worldwide problem that affects people of all ages, races, and economic groups. The prevalence and incidence of the disease, which mirror those of conditions such as diabetes, hypertension, and obesity, are rising. In the United States alone, more than 20 million people, or 1 in 9 adults have CKD. Another 20 million people are at increased risk for development of the disorder.\(^1\)
These guidelines point out that kidney failure is not synonymous with end-stage renal disease (ESRD).

Regardless of cause, CKD represents a loss of functioning kidney nephrons with progressive deterioration of glomerular filtration, tubular reabsorptive capacity, and endocrine functions of the kidneys (Fig. 42.3). All forms of CKD are characterized by a reduction in the GFR, reflecting a corresponding reduction in the number of functional nephrons. The rate of nephron destruction differs from case to case, ranging from several months to many years. Typically, the signs and symptoms of CKD occur gradually and do not become evident until the disease is far advanced. This is because of the amazing compensatory ability of the kidneys. As kidney structures are destroyed, the remaining nephrons undergo structural and functional hypertrophy, each increasing its function as a means of compensating for those that have been lost. In the process, each of the remaining nephrons must filter more solute particles from the blood. It is only when the few remaining nephrons are destroyed that the manifestations of kidney failure become evident.\(^2\)

**KEY POINTS**

**CHRONIC KIDNEY DISEASE**

- CKD represents the progressive decline in kidney function due to the permanent loss of nephrons.
- CKD can result from a number of conditions, including diabetes, hypertension, glomerulonephritis, and other kidney diseases.
- The GFR is considered the best measure of kidney function.

**Assessment of Glomerular Filtration Rate and Other Indicators of Renal Function**

The GFR is considered the best measure of overall function of the kidney. The normal GFR, which varies with age, sex, and body size, is approximately 120 to 130 mL/min/1.73 mL/m\(^2\) for normal young healthy adults.\(^14\) In clinical practice, GFR is usually estimated using the serum creatinine concentration. Although the GFR can be obtained from measurements of creatinine clearance using timed (e.g., 24-hour) urine collection methods, the levels gathered are reportedly no more reliable than the estimated levels obtained by using serum creatinine levels.\(^14\) Because GFR varies with age, sex, ethnicity, and body size, the Cockcroft and Gault or Modification of Diet in Renal Diseases (MDRD) equations that take these factors into account are used for estimating the GFR based on serum creatinine levels\(^14\)–\(^16\) (Box 42.1).

Albuminuria serves as a key parameter for measuring nephron injury and repair.\(^17\) Urine normally contains small amounts of protein. However, a persistent increase in protein excretion usually is a sign of kidney damage. The

**FIGURE 42.3**  
Relation of renal function and nephron mass. Each kidney contains about 1 million tiny nephrons. A proportional relation exists between the number of nephrons affected by a disease process and the resulting GFR.

**BOX 42.1**  
PREDICTION OF CREATININE CLEARANCE USING SERUM CREATININE

- The Modification of Diet in Renal Diseases (MDRD) equation can be used to calculate adult creatinine clearance. Use the following Web site: http://nkdep.nih.gov/professionals/gfr_calculators/idms_con.htm
- The Cockcroft and Gault Equation can be used to calculate older adults’ creatinine clearance. Use the following Web site: http://www.mdcalc.com/creatinine-clearance-cockcroft-gault-equation. The equation result should be multiplied by a factor of 0.85 for women.
type of protein (e.g., low molecular weight globulins or albumin) depends on the type of kidney disease. Increased excretion of low molecular weight globulins is a marker of tubulointerstitial disease, and excretion of albumin a marker of CKD, resulting from hypertension or diabetes mellitus. For the diagnosis of CKD in adults and postpuberal children with diabetes, measurement of urinary albumin is preferred. In most cases, urine dipstick tests are acceptable for detecting albuminuria. If the urine dipstick test is positive (1+ or greater), albuminuria is usually confirmed by quantitative measurement of the albumin-to-creatinine ratio in a spot (untimed) urine specimen. Microalbuminuria, which is an early sign of diabetic kidney disease, refers to albumin excretion that is above the normal range, but below the range normally detected by tests of total protein excretion in the urine. Populations at risk for CKD (i.e., those with diabetes mellitus, hypertension, or family history of kidney disease) should be screened for microalbuminuria, at least annually, as part of their health examination.

Other markers of kidney damage include abnormalities in urine sediment (red and white blood cells) and abnormal findings on imaging studies. Also, the biomarker amino acid, cystatin C also known as cystatin 3, which has been used for predicting new onset cardiovascular disease has also been found to predict kidney disease. Ultrasonography is particularly useful for detecting a number of kidney disorders, including urinary tract obstructions, infections, stones, and polycystic kidney disease.

Mr. Reterez has a + urine dipstick for albumin/protein and blood. If he had been screened a few years ago, his microalbumin would most likely have tested positive. It would have been very helpful if his family members had told him more information regarding the family’s genetic disorder, which has seemingly been passed down through the generations. It is essential to know whether or not one carries the polycystic kidney gene for two reasons. First, a person can be screened carefully for any signs of renal disease and second, a person can be put on a list for a renal transplant early before the systemic symptoms and multisystem disease manifests. Both of Mr. Reterez’s kidneys are involved with polycystic kidney disease. Therefore, he is in urgent need of dialysis or a bilateral renal transplant.

Clinical Manifestations

The manifestations of CKD include an accumulation of nitrogenous wastes; alterations in water, electrolyte, and acid–base balance; mineral and skeletal disorders; anemia and coagulation disorders; hypertension and alterations in cardiovascular function; gastrointestinal disorders; neurologic complications; disorders of skin integrity; and disorders of immunologic function (Fig. 42.4). The point at which these disorders make their appearance and the severity of the manifestations are determined largely by the extent of renal function that is
present and the coexisting disease conditions. Many of them make their appearance before the GFR has reached the kidney failure stage.

Accumulation of Nitrogenous Wastes
The accumulation of nitrogenous wastes in the blood, or azotemia, is an early sign of kidney failure, usually occurring before other symptoms become evident. Urea is one of the first nitrogenous wastes to accumulate in the blood, and the BUN level becomes increasingly elevated as CKD progresses. The normal concentration of urea in the plasma is approximately 20 mg/dL. In kidney failure, this level may rise to as high as 800 mg/dL. Creatinine, a byproduct of muscle metabolism, is freely filtered in the glomerulus and is not reabsorbed in the renal tubules. It is produced at a relatively constant rate, and essentially all the creatinine that is filtered in the glomerulus is lost in the urine rather than being reabsorbed into the blood. Thus, serum creatinine can be used as an indirect method for assessing the GFR and the extent of kidney damage that has occurred in CKD.

Uremia, which literally means “urine in the blood,” is the term used to describe the clinical manifestations of kidney failure. Few symptoms of uremia appear until at least two thirds of the kidney’s nephrons have been destroyed. Uremia differs from azotemia, which merely indicates the accumulation of nitrogenous wastes in the blood and can occur without symptoms. The uremic state includes signs and symptoms of altered fluid, electrolyte, and acid–base balance; alterations in regulatory functions (e.g., blood pressure control, production of red blood cells, and impaired vitamin D synthesis); and the effects of uremia on body function (e.g., uremic encephalopathy, peripheral neuropathy, pruritus). At this stage, virtually every organ and structure in the body is affected. The symptoms at the onset of uremia (e.g., weakness, fatigue, nausea, apathy) are usually milder. More severe symptoms include extreme weakness, frequent vomiting, lethargy, and confusion. Without treatment of dialysis or a renal transplant, coma and death can follow.

Fluid, Electrolyte, and Acid–Base Disorders
The kidneys function in the regulation of extracellular fluid volume. They do this by either eliminating or conserving sodium and water. Chronic renal failure can produce dehydration or fluid overload, depending on the pathologic process of the kidney disease. In addition to volume regulation, the ability of the kidneys to concentrate the urine is diminished. One of the earliest symptoms of kidney damage is polyuria with urine that is almost isotonic with plasma (i.e., specific gravity of 1.008 to 1.012) and varies little from voiding to voiding.

As renal function declines further, the ability to regulate sodium excretion is reduced. The kidneys normally tolerate large variations in sodium intake while maintaining normal serum sodium levels. In chronic renal failure, they lose the ability to regulate sodium excretion. There is impaired ability to adjust to a sudden reduction in sodium intake and poor tolerance of an acute sodium overload. Volume depletion with an accompanying decrease in the GFR can occur with a restricted sodium intake or excess sodium loss caused by diarrhea or vomiting. Salt wasting is a common problem in advanced kidney failure because of impaired tubular reabsorption of sodium. Increasing sodium intake in persons with kidney failure often improves the GFR and whatever renal function remains. In patients with associated hypertension, the possibility of increasing blood pressure or producing congestive heart failure often excludes supplemental sodium intake.

Approximately, 90% of potassium excretion is through the kidneys. In kidney failure, potassium excretion by each nephron increases as the kidneys adapt to a decrease in the GFR. In addition, excretion in the gastrointestinal tract is increased. As a result, hyperkalemia usually does not develop until kidney function is severely compromised. Because of this adaptive mechanism, it usually is not necessary to restrict potassium intake in patients with CKD until the GFR has dropped below 5 to 10 mL/min/1.73 m². In people with kidney failure, hyperkalemia often results from failure to follow dietary potassium restrictions; constipation; acute acidosis that causes the release of intracellular potassium into the extracellular fluid; trauma or infection that causes release of potassium from body tissues; or exposure to medications that contain potassium, prevent its entry into cells, or block its secretion in distal nephrons.

The kidneys normally regulate blood pH by eliminating hydrogen ions produced in metabolic processes and regenerating bicarbonate. This is achieved through hydrogen ion secretion, sodium and bicarbonate reabsorption, and the production of ammonia, which acts as a buffer for titratable acids. With a decline in kidney function, these mechanisms become impaired and metabolic acidosis may occur when the person is challenged with an excessive acid load or loses excessive alkali, as in diarrhea. The acidosis that occurs in people with kidney failure seems to stabilize as the disease progresses, probably as a result of the tremendous buffering capacity of bone. However, this buffering action is thought to increase bone resorption and contribute to the skeletal disorders that occur in persons with CKD.

Disorders of Calcium and Phosphorus Metabolism and Bone Disease
Abnormalities of calcium and phosphorus metabolism occur early in the course of CKD. The regulation of serum phosphate levels requires a daily urinary excretion of an amount equal to that ingested in the diet. With deteriorating renal function, phosphate excretion is impaired, and as a result serum phosphate levels rise. At the same time, serum calcium levels, which are inversely regulated in relation to serum phosphate levels, fall. The drop in serum calcium, in turn, stimulates parathyroid hormone (PTH) release, with a resultant increase in calcium resorption from bone. Although serum calcium levels are maintained through increased PTH function, this adjustment is accomplished at the expense of the skeletal system and other body organs.

Vitamin D synthesis also is impaired in CKD. The kidneys regulate vitamin D activity by converting the inactive form of vitamin D (25(OH) vitamin D₃) to calcitriol (1,25(OH)
vitamin D₃), the active form of vitamin D. Calcitriol is known to have a direct suppressive effect on PTH production; therefore, reduced levels of calcitriol cause elevated levels of PTH. In addition, reduced calcitriol levels lead to impaired calcium absorption from the gastrointestinal tract. Vitamin D also regulates osteoblast differentiation, thereby affecting bone replacement.

Most people with CKD develop a secondary hyperparathyroidism, the result of chronic stimulation of the parathyroid glands. Over the past two to three decades, the principal biochemical marker for diagnosis of CKD has been the measurement of PTH function using an immunoreactive technique called intact PTH.

**Skeletal Disorders.** The term renal osteodystrophy or CKD-Mineral Bone Disorder is used to describe the skeletal complications of CKD. The skeletal changes that occur with CKD have been divided into two major types of disorders: high–bone-turnover and low–bone-turnover osteodystrophy. Some people may have predominantly one type of bone disorder, whereas others may have a mixed type of bone disease. Inherent to both of these conditions are abnormal reabsorption and defective remodeling of bone. Mild forms of defective bone metabolism may be observed in early stages of CKD (stage 2), and they become more severe as kidney function deteriorates as in stage 5.

High–bone-turnover osteodystrophy, sometimes referred to as osteitis fibrosa, is characterized by increased bone resorption and formation, with bone resorption predominating. The disorder is associated with secondary hyperparathyroidism; altered vitamin D metabolism, along with resistance to the action of vitamin D; and impaired regulation of locally produced growth factors and inhibitors. There is an increase in both osteoblast and osteoclast numbers and activity. Although the osteoblasts produce excessive amounts of bone matrix, mineralization fails to keep pace, and there is a decrease in bone density and formation of porous and coarse-fibered bone. Cortical bone is affected more severely than cancellous bone. Bone marrow fibrosis is another component of osteitis fibrosa; it occurs in areas of increased bone cell activity. In advanced stages of the disorder, cysts may develop in the bone, a condition called osteitis fibrosa cystica.

Low–bone-turnover osteodystrophy is characterized by decreased numbers of osteoblasts and low or reduced numbers of osteoclasts, a low rate of bone turnover, and an accumulation of unmineralized bone matrix. There are two forms of low–bone-turnover osteodystrophy: osteomalacia and adynamic osteodystrophy. Osteomalacia is characterized by a slow rate of bone formation and defects in bone mineralization, which may be caused by vitamin D deficiency, excess aluminum deposition, or metabolic acidosis. Metabolic acidosis is thought to have a direct effect on both osteoblastic and osteoclastic activity, as well as on the mineralization process, by decreasing the availability of trivalent phosphate. Until the 1980s, the osteomalacia seen in CKD resulted mainly from aluminum intoxication. Aluminum intoxication causes decreased and defective mineralization of bone by existing osteoblasts and more long-term inhibition of osteoblast differentiation. During the 1970s and 1980s, it was discovered that accumulation of aluminum from water used in dialysis and aluminum salts used as phosphate binders caused osteomalacia and adynamic bone disease. This discovery led to a change in the composition of dialysis solutions and the substitution of calcium carbonate for aluminum salts as phosphate binders. As a result, the prevalence of osteomalacia in persons with CKD has declined.

The second type of low–bone-turnover osteodystrophy, adynamic osteodystrophy, is characterized by a low number of osteoblasts, with the osteoclast number being normal or reduced. It is now recognized as being as common as high–bone-turnover osteodystrophy and is especially common among persons with diabetes. Adynamic bone disease is characterized by reduced bone volume and mineralization that may result, in part, from excessive suppression of PTH production with calcitriol.

Regardless of the cause of skeletal abnormalities in CKD, bone disease can lead to bone tenderness and muscle weakness. Bone fractures complicate both high- and low-turnover types of bone disease. However, it is now recognized that people with adynamic bone disease may be more predisposed to fractures than those with osteitis fibrosa cystica. In the latter disorder, however, PTH-associated proximal muscle weakness in the lower extremities often coexists, giving rise to gait abnormalities and making it difficult to get out of a chair or climb stairs.

Early treatment of hyperphosphatemia and hypocalcemia is important to prevent or slow the development of skeletal complications. Milk products and other foods high in phosphorus content are restricted in the diet. Phosphate-binding antacids (aluminum salts, calcium carbonate, or calcium acetate) may be prescribed to decrease absorption of phosphate from the gastrointestinal tract. Calcium-containing phosphate binders can lead to hypercalcemia, thus worsening soft tissue calcification, especially in persons receiving vitamin D therapy. Aluminum-containing antacids can contribute to the development of osteodystrophy or CKD–mineral and bone disorder.

Activated pharmacologic forms of vitamin D (e.g., calcitriol) often are used to increase serum calcium levels and, at least partially, reverse the secondary hyperparathyroidism and osteitis fibrosis that occur with CKD. Although calcitriol is effective in controlling PTH overproduction, its stimulatory effects on intestinal absorption of calcium and phosphorus, along with its suppressive effects on bone turnover, predispose to hypercalcemia and hyperphosphatemia and to an increase in the calcium–phosphate (Ca × P) product. Hypercalcemia and an elevated Ca × P product increase the risk for metastatic calcification, a complication associated with cardiac dysfunction and death. There is more to osteodystrophy and chronic renal disease than skeletal bone dysfunction, since people with this condition also have a higher cardiovascular risk and have been found to have left ventricular hypertrophy and arterial stiffness secondary to vascular calcification.

Secondary hyperparathyroidism in CKD may also be treated by activating the calcium sensing receptor on the
parathyroid gland with medication such as the calcimimetic agent cinacalcet. However, because adynamic bone disease is often a consequence of overzealous treatment of secondary hyperparathyroidism, these agents require careful use.

**Hematologic Disorders**

**Anemia.** Chronic anemia (hemoglobin levels <13.5 g/dL in adult men and <12 g/dL in adult women) is the most profound hematologic alteration that accompanies CKD. African Americans and people with diabetes have even higher rates of anemia for each advanced stage of CKD. The NKF guidelines recommend that those people with a GFR less than 60 mL/min/1.73 m² should be evaluated for anemia. Assessment for anemia and its causes includes measures of hemoglobin, hematocrit, and iron stores.

The anemia of CKD is due to several factors, including chronic blood loss, hemolysis, bone marrow suppression due to retained uremic factors, and decreased red cell production due to impaired production of erythropoietin and iron deficiency. The kidneys are the primary site for the production of the hormone erythropoietin, which controls red blood cell production.

In renal failure, erythropoietin production usually is insufficient to stimulate adequate red blood cell production by the bone marrow. Among the causes of iron deficiency in people with CKD are anorexia and dietary restrictions that limit intake, and the blood loss that occurs during dialysis.

When untreated, anemia causes or contributes to weakness, fatigue, depression, insomnia, and decreased cognitive function. There also is an increasing concern regarding the physiologic effects of anemia on cardiovascular function. The anemia of renal failure produces a decrease in blood viscosity and a compensatory increase in heart rate. The decreased blood viscosity also exacerbates peripheral vasodilation and contributes to decreased vascular resistance. Cardiac output increases in a compensatory fashion to maintain tissue perfusion. Anemia also limits myocardial oxygen supply, particularly in people with coronary heart disease, leading to angina pectoris and other ischemic events.

**Mr. Reterez** has severe fatigue probably due to a low hematocrit and hemoglobin secondary to his CKD, which occurred due to his polycystic kidney disease. This is anemia of chronic disease. Most likely, Mr. Reterez will be put on an erythropoietin supplement to assist in triggering his bone marrow to reproduce more red blood cells. He will also be carefully checked by his primary care provider for signs of cardiovascular disease and also managed for hypertension since his blood pressure is 145/92 and his pulse is 92.

A significant advance in medical management of CKD was realized when recombinant human erythropoietin (rhEPO) became available in 1989 to help maintain hematocrit levels in people with kidney failure. One erythropoiesis-stimulating protein with a prolonged half-life was introduced for treatment of anemia in CKD about 3 years ago. It is darbepoetin alfa, a hyperglycosylated analog of rhEPO. However, evidence suggests it is no more effective, but is more expensive for people with CKD on dialysis than epoetin alfa. Secondary benefits of treating anemia with rhEPO, previously attributed to the correction of uremia, include improvement in appetite, energy level, sexual function, skin color, and hair and nail growth, and reduced cold intolerance. Because worsening of hypertension and seizures have occurred when the hematocrit was raised too suddenly, frequent measurements of hematocrit are necessary. Additionally, currently researchers are questioning if erythropoietin-stimulating agents are as effective as once thought or if they are actually toxic. More evidence is needed to validate whether the erythropoietin-stimulating agents should be used or not.

**Coagulopathies.** Bleeding disorders are manifested by epistaxis, menorrhagia, gastrointestinal bleeding, and bruising of the skin and subcutaneous tissues. Although platelet production often is normal in CKD, platelet function is impaired. Coagulative function improves with dialysis but does not completely normalize, suggesting that uremia contributes to the problem. People with CKD also have greater susceptibility to thrombotic disorders.

**Cardiovascular Disorders**

The overall mortality rate from cardiovascular disease in people with CKD is many times that of the general population. Even after stratification for age, the incidence of cardiovascular disease remains 10 to 20 times higher in people with CKD than in the general population.

**Hypertension.** Hypertension commonly is an early manifestation of CKD. The mechanisms that produce hypertension in CKD are multifactorial. They include an increased vascular resistance, increased renin–angiotensin system activity, increased sodium and water retention, increased aldosterone levels, and increased vasomotor tone. Treatment of hypertension in people with CKD is many times that of the general population.

Early identification and aggressive treatment of hypertension has been shown to slow the progression of renal impairment in many types of kidney disease. Treatment involves salt and water restriction and the use of antihypertensive medications to control blood pressure. Many people with CKD need to take several antihypertensive medications to control blood pressure. There is a new class of hypertension drugs called endothelin blockers. These drugs are being trialed in people with difficult-to-manage hypertension.

**Heart Disease.** The spectrum of cardiovascular disease due to CKD includes left ventricular hypertrophy and ischemic heart disease. People with CKD tend to have an increased prevalence of left ventricular dysfunction, with both depressed left ventricular ejection fraction, as in systolic dysfunction, and impaired ventricular filling, as in diastolic failure. Multiple factors lead to development of left ventricular dysfunction, including extracellular fluid overload, shunting of blood...
through an arteriovenous fistula for dialysis, and anemia. Anemia, in particular, has been correlated with the presence of left ventricular hypertrophy.21 These abnormalities, coupled with the hypertension that often is present, cause increased myocardial work and oxygen demand, with eventual development of heart failure.

Congestive heart failure and pulmonary edema tend to occur in the late stages of kidney failure. Coexisting conditions that have been identified as contributing to the burden of cardiovascular disease include hypertension, anemia, diabetes mellitus, dyslipidemia, and coagulopathies. PTH also may play a role in the pathogenesis of cardiomyopathy in renal failure.27

**Pericarditis.** Pericarditis occurs in many people with stage 5 CKD due to the uremia and prolonged dialysis.2 The manifestations of uremic pericarditis resemble those of viral pericarditis, with all its potential complications, including cardiac tamponade. The presenting signs include mild to severe chest pain with respiratory accentuation and a pericardial friction rub. Fever is variable in the absence of infection and is more common in dialysis than uremic pericarditis.2

**Gastrointestinal Disorders**

Anorexia, nausea, and vomiting are common in people with uremia, along with a metallic taste in the mouth that further depresses the appetite. Early morning nausea is common. Ulceration and bleeding of the gastrointestinal mucosa may develop, and hiccups are common. A possible cause of nausea and vomiting is the decomposition of urea by intestinal flora, resulting in a high concentration of ammonia. PTH increases gastric acid secretion and contributes to gastrointestinal problems. Nausea and vomiting often improve with restriction of dietary protein and after initiation of dialysis, and disappear after kidney transplantation.

**Neuromuscular Disorders**

Many people with CKD have alterations in peripheral and central nervous system function.2 Peripheral neuropathy, or involvement of the peripheral nerves, affects the lower limbs more frequently than the upper limbs. It is symmetric and affects both sensory and motor function. Neuropathy is caused by atrophy and demyelination of nerve fibers, possibly caused by uremic toxins. Restless legs syndrome is a manifestation of peripheral nerve involvement and can be seen in as many as two thirds of patients on dialysis. This syndrome is characterized by creeping, pricking, and itching sensations that typically are more intense at rest. Temporary relief is obtained by moving the legs. A burning sensation of the feet, which may be followed by muscle weakness and atrophy, is a manifestation of uremia.

The central nervous system disturbances in uremia are similar to those caused by other metabolic and toxic disorders. Sometimes referred to as **uremic encephalopathy**, the condition is poorly understood and may result, at least in part, from an excess of toxic organic acids that alter neural function. Electrolyte abnormalities, such as sodium shifts, also may contribute. The manifestations are more closely related to the progress of the uremic disorder than to the level of the metabolic end products. Reductions in alertness and awareness are the earliest and most significant indications of uremic encephalopathy. These often are followed by an inability to fix attention, loss of recent memory, and perceptual errors in identifying people and objects. Delirium and coma occur late in the disease course. Seizures are the preterminal event.

Disorders of motor function commonly accompany the neurologic manifestations of uremic encephalopathy. During the early stages, there often is difficulty in performing fine movements of the extremities. The person’s gait becomes unsteady and clumsy with tremulousness of movement. Asterixis (dorsiflexion movements of the hands and feet) typically occurs as the disease progresses. It can be elicited by having the person hyperextend his or her arms at the elbow and wrist with the fingers spread apart. If asterixis is present, this position causes side-to-side flapping movements of the fingers.

**Altered Immune Function**

Infection is a common complication and cause of hospitalization and death for people with kidney failure.2 Immunologic abnormalities decrease the efficiency of the immune response to infection.2 All aspects of inflammation and immune function may be affected adversely by the high levels of urea and metabolic wastes, including a decreased granulocyte count, impaired humoral and cell-mediated immunity, and defective phagocyte function. The acute inflammatory response and delayed-type hypersensitivity response are impaired. Although people with CKD have normal humoral responses to vaccines, a more aggressive immunization program may be needed. Skin and mucosal barriers to infection also may be defective. In people who are maintained on dialysis, vascular access devices are common portals of entry for pathogens. Many people with CKD fail to mount a fever with infection, making the diagnosis more difficult.

**Disorders of Skin Integrity**

Skin manifestations are common in people with CKD.2 The skin often is pale owing to anemia and may have a sallow, yellow-brown hue. The skin and mucous membranes often are dry, and subcutaneous bruising is common. Skin dryness or xerosis is caused by a reduction in perspiration owing to the decreased size of sweat glands and the diminished activity of oil glands. Pruritus is common; it results from the high serum phosphate levels and the development of phosphate crystals that occur with hyperparathyroidism. Severe scratching and repeated needle sticks, especially with hemodialysis, break the skin integrity and increase the risk for infection. In the advanced stages of untreated kidney failure, urea crystals may precipitate on the skin as a result of the high urea concentration in body fluids. The fingernails may also become thin and brittle.

**Sexual Dysfunction**

The cause of sexual dysfunction in men and women with CKD is unclear. The cause probably is multifactorial and may
result from high levels of uremic toxins, neuropathy, altered endocrine function, psychological factors, and medications (e.g., antihypertensive drugs). Alterations in physiologic sexual responses, reproductive ability, and libido are common.

Impotence occurs in many men on dialysis. De-rangements of the pituitary and gonadal hormones, such as decreases in testosterone levels and increases in prolactin and luteinizing hormone levels, are common and cause erectile difficulties and decreased spermocyte counts. Loss of libido may result from chronic anemia and decreased testosterone levels. Several drugs, such as exogenous testosterone and bromocriptine, have been used in an attempt to return hormone levels to normal. Sildenafil citrate has been shown in small trials of people on long-term hemodialysis to be effective and safe.

Impaired sexual function in women is manifested by abnormal levels of progesterone, luteinizing hormone, and prolactin. Hypofertility, menstrual abnormalities, decreased vaginal lubrication, and various orgasmic problems have been described.

**Elimination of Drugs**

The kidneys are responsible for the elimination of many drugs and their metabolites. CKD and its treatment can interfere with the absorption, distribution, and elimination of drugs. The administration of large quantities of phosphate-binding antacids to control hyperphosphatemia and hypocalcemia in patients with advanced renal failure interferes with the absorption of some drugs. Many drugs are bound to plasma proteins, such as albumin, for transport in the body; the unbound portion of the drug is available to act at the various receptor sites and is free to be metabolized. A decrease in plasma proteins, particularly albumin, that occurs in many people with CKD results in less protein-bound drug and greater amounts of free drug.

In the process of metabolism, some drugs form intermediate metabolites that are toxic if not eliminated. Some pathways of drug metabolism, such as hydrolysis, are slowed with uremia. In people with diabetes, for example, insulin requirements may be reduced as renal function deteriorates. Decreased elimination by the kidneys allows drugs or their metabolites to accumulate in the body and requires that drug dosages be adjusted accordingly. Some drugs contain unwanted nitrogen, sodium, potassium, and magnesium and must be avoided in patients with CKD. Penicillin, for example, contains potassium. Nitrofurantoin and ammonium chloride add to the body’s nitrogen pool. Many antacids contain magnesium. Because of problems with drug dosing and elimination, people with CKD should be cautioned against the use of over-the-counter remedies.

**Treatment**

CKD is treated by conservative management to prevent or slow the rate of nephron destruction and, when necessary, by renal replacement therapy with dialysis or transplantation.

**Measures to Slow Progression of the Disorder**

Conservative treatment can often delay the progression of CKD. It includes measures to retard deterioration of renal function and assist the body in managing the effects of impaired function. Urinary tract infections should be treated promptly and medication with renal damaging potential should be avoided. It should be noted that these strategies are complementary to the treatment of the original cause of the renal disorder, which is of the utmost importance and needs to be continually addressed.

Blood pressure control is important, as is control of blood sugar in people with diabetes mellitus. Intensive glycemic control in people with diabetes helps to prevent the development of microalbuminuria and retards the progression of diabetic nephropathy. In addition to reduction in cardiovascular risk, antihypertensive therapy in people with CKD aims to slow the progression of nephron loss by lowering intraglomerular hypertension and hypertrophy. Elevated blood pressure also increases proteinuria due to transmission of the elevated pressure to the glomeruli. The ACE inhibitors and ARBs, which have a unique effect on the glomerular microcirculation (i.e., dilation of the efferent arteriole), are increasingly being used in the treatment of hypertension and proteinuria, particularly in people with diabetes.

It has become apparent that smoking has a negative impact on kidney function, and it is one of the most remedial risk factors for CKD. The mechanisms of smoking-induced renal damage appear to include both acute hemodynamic effects (i.e., increase in blood pressure, intraglomerular pressure, and urinary albumin excretion) and chronic effects (endothelial cell dysfunction). Smoking is particularly nephrotoxic in older adults with hypertension, and those with diabetes. Importantly, the adverse effects of smoking appear to be independent of the underlying kidney disease.

**Dialysis and Transplantation**

Dialysis or renal replacement therapy is indicated when advanced uremia or serious electrolyte imbalances are present. Just 50 years ago, many people with CKD progressed to the final stages of kidney failure and then died. The high mortality rate was associated with limitations in the treatment of kidney disease and with the tremendous cost of ongoing treatment. In 1972, federal support began for dialysis and transplantation through a Medicare entitlement program in the United States. During the past several decades, an increasing number of people have required renal replacement therapy with dialysis or transplantation. The number of people beginning hemodialysis has grown substantially. In 2008, greater than half a million people in the United States started on dialysis or received a renal transplant. In 2008, there were 16,520 renal transplants in the United States, but 4573 people died due to a lack of transplant. In 2009, there were approximately 82,364 people awaiting a renal transplant.

The choice between dialysis and transplantation is dictated by age, related health problems, donor availability, and
personal preference. Although transplantation often is the preferred treatment, dialysis plays a critical role as a treatment method for kidney failure. It is life sustaining for people who are not candidates for transplantation or who are awaiting transplantation. There are two broad categories of dialysis: hemodialysis and peritoneal dialysis.

**Hemodialysis.** The basic principles of hemodialysis have remained unchanged over the years, although new technology has improved the efficiency and speed of dialysis. A hemodialysis system, or artificial kidney, consists of three parts: a blood delivery system, a dialyzer, and a dialysis fluid delivery system. The dialyzer is usually a hollow cylinder composed of bundles of capillary tubes through which blood circulates, while the dialysate travels on the outside of the tubes. The walls of the capillary tubes in the dialysis chamber are made up of a semipermeable membrane material that allows all molecules except blood cells and plasma proteins to move freely in both directions—from the blood into the dialyzing solution and from the dialyzing solution into the blood. The direction of flow is determined by the concentration of the substances contained in the two solutions. The waste products and excess electrolytes in the blood normally diffuse into the dialyzing solution. If there is a need to replace or add substances, such as bicarbonate, to the blood, these can be added to the dialyzing solution (Fig. 42.5).

During dialysis, blood moves from an artery through the tubing and blood chamber in the dialysis machine and then back into the body through a vein. Access to the vascular system is accomplished through an external arteriovenous shunt (i.e., tubing implanted into an artery and a vein) or, more commonly, through an internal arteriovenous fistula (i.e., anastomosis of a vein to an artery, usually in the forearm). Heparin is used to prevent clotting during the dialysis treatment; it can be administered continuously or intermittently. Problems that may occur during dialysis, depending on the rates of blood flow and solute removal, include hypotension, nausea, vomiting, muscle cramps, headache, chest pain, and disequilibrium syndrome.

Most people undergo dialysis three times each week for 3 to 4 hours. Treatment is determined by kinetic profiles, referred to as $Kt/V$ values, which consider dialyzer size, dialysate, flow rate, time of dialysis, and body size. Many dialysis centers provide the option for patients to learn how to perform hemodialysis at home.

**Peritoneal Dialysis.** Peritoneal dialysis was introduced in the mid 1970s. Improvements in technology and the ability to deliver adequate dialysis resulted in improved outcomes and the acceptance of peritoneal dialysis as a renal replacement therapy.

The same principles of diffusion, osmosis, and ultrafiltration that apply to hemodialysis apply to peritoneal dialysis. The thin serous membrane of the peritoneal cavity serves as the dialyzing membrane. A Silastic catheter is surgically implanted in the peritoneal cavity below the umbilicus to provide access. The catheter is tunneled through subcutaneous

---

**FIGURE 42.5** Schematic diagram of a hemodialysis system. The blood compartment and dialysis solution compartment are separated by a semipermeable membrane. This membrane is porous enough to allow all the constituents, except the plasma proteins and blood cells, to diffuse between the two compartments.
Peritoneal dialysis can be performed at home or in a dialysis center and can be carried out by continuous ambulatory peritoneal dialysis (CAPD), continuous cyclic peritoneal dialysis (CCPD), or nocturnal intermittent peritoneal dialysis (NIPD)—all with variations in the number of exchanges and dwell times. Individual preference, manual ability, lifestyle, knowledge of the procedure, and physiologic response to treatment are used to determine the type of dialysis that is used. The most common method is CAPD, a self-care procedure in which the person manages the dialysis procedure at home. CAPD involves instilling the dialysate into the peritoneal cavity and rolling up the bag and tubing and securing them under clothing during the dwell. After the dwell time is completed (usually 4 to 6 hours during the day), the bag is unrolled and lowered, allowing the waste-containing dialysis solution to drain from the peritoneal cavity into the bag. Each exchange, which involves draining the solution and infusing a new solution, requires approximately 30 to 45 minutes. Four exchanges usually are performed each day. In CCPD, exchanges are performed in an automated manner, usually at night, with the person connected to an automatic cycler, which then performs four or five cycles, while the person sleeps. In the morning, the person, with the last exchange remaining in the abdomen, is disconnected from the cycler and goes about his or her usual activities. In NIPD, the person is given approximately 10 hours of automatic cycling each night, with the abdomen left dry during the day.

Potential problems with peritoneal dialysis include infection, catheter malfunction, dehydration caused by excessive fluid removal, hyperglycemia, and hernia. The most serious complication is infection, which can occur at the catheter exit site, in the subcutaneous tunnel, or in the peritoneal cavity (i.e., peritonitis).

**Transplantation.** Greatly improved success rates have made kidney transplantation the treatment of choice for many patients with CKD. The availability of donor organs continues to limit the number of transplantations performed each year. Donor organs are obtained from cadavers and living related donors (e.g., parent, sibling). Transplants from living unrelated donors (e.g., spouse) have been used in cases of suitable ABO blood type and tissue compatibility.

The success of transplantation depends on multiple variables such as the general health of the person, the degree of histocompatibility with the donor, the degree of end-organ disease the person may have, and how well the immunologic response is managed. Maintenance immunosuppressive therapy typically consists of prednisone, azathioprine, and cyclosporine (or tacrolimus). IL-2, a cytokine, plays an essential role in T- and B-cell activation. Cyclosporine and tacrolimus, calcineurin inhibitors, inhibit IL-2 synthesis. IL-2 receptor antagonists such as basiliximab and daclizumab are more frequently being used. Monoclonal antibodies such as alemtuzumab is starting to be used. OKT-3 (directed against the CD3 T-cell receptor), and ATGAM, which is a polyclonal antibody, are used rarely such as when the person is experiencing steroid resistance and allograft rejection. The Janus kinase (JAK) 3 inhibitors are a new classification of immunosuppressive therapy that are also starting to be in use and have effective results. Two examples of this drug category include AEB-071, which inhibits protein kinase, and LEA29Y or Belatacept, which have both improved transplant patients’ rate of rejection. However, most of these immunosuppressive drugs have serious side effects such as cardiovascular problems, metabolic dysfunction, and cancer.

Rejection, which is categorized as acute and chronic, can occur at any time. Acute rejection most commonly occurs during the first several months after transplantation and involves a cellular response with the proliferation of T lymphocytes. Chronic rejection can occur months to years after transplantation. Because chronic rejection is caused by both cellular and humoral immunity, it does not respond well to increased immunosuppressive therapy.

Maintenance immunosuppressive therapy and increased use of immunosuppression to treat rejection predispose
the person to a spectrum of infectious complications. Prophylactic antimicrobials may be prescribed to decrease the incidence of common infections, such as candidiasis, herpesvirus infections, and Pneumocystis jiroveci (formerly P. carinii) pneumonia. Other infections, such as cytomegalovirus infection and aspergillosis, are seen with chronic immunosuppression.

**Dietary Management**

A major component in the treatment of CKD is nutritional management. The goal of dietary treatment is to provide optimum nutrition while maintaining tolerable levels of metabolic wastes. The specific diet prescription depends on the type and severity of renal disease and on the dialysis modality. Because of the severe restrictions placed on food and fluid intake, these diets may be complicated and unappetizing. After kidney transplantation, some dietary restrictions still may be necessary, even when renal function is normal, to control the adverse effects from immunosuppressive medication.

**Protein.** Restriction of dietary proteins may decrease the progress of renal impairment in people with advanced renal disease. Proteins are broken down to form nitrogenous wastes, and reducing the amount of protein in the diet lowers the BUN and reduces symptoms.

Considerable controversy exists over the degree of protein restriction needed. If the diet is too low in protein, protein malnutrition can occur, with a loss of strength, muscle mass, and body weight. People on hemodialysis usually require a higher dietary protein intake to prevent protein and energy malnutrition due to anorexia from uremia itself, the dialysis procedure, intercurrent illness, and acidemia. People on peritoneal dialysis also have significant protein losses and require a higher dietary protein intake. At least 50% of the protein intake should consist of proteins of high biologic value, such as those in eggs, lean meat, and milk, which are rich in essential amino acids. Proteins with a high biologic value are believed to promote the reuse of endogenous nitrogen, decreasing the amount of nitrogenous wastes that are produced and ameliorating the symptoms of uremia. In reusing nitrogen, the proteins ingested in the diet are broken down into their constituent amino acids and recycled in the synthesis of protein required by the body. In contrast to proteins with a high biologic value, fewer than half of the amino acids in cereal proteins are reused. Amino acids that are not reused to build body proteins are broken down and form the end products of protein metabolism, such as urea.

**Carbohydrates, Fat, and Calories.** With CKD, adequate calories in the form of carbohydrates and fat are required to meet energy needs. This is particularly important when the protein content of the diet is severely restricted. If sufficient calories are not available, the limited protein in the diet goes into energy production, or body tissue itself is used for energy purposes. Caloric intake for people on CAPD includes food intake and calories absorbed from the dialysis solution.

**Fluid and Electrolytes.** The sodium and fluid restrictions depend on the kidneys’ ability to excrete sodium and water and must be individually determined. Renal disease of glomerular origin is more likely to contribute to sodium retention, whereas tubular dysfunction causes salt wasting. Fluid intake in excess of what the kidneys can excrete causes circulatory overload, edema, and water intoxication. Thirst is a common problem among patients on hemodialysis, often resulting in large weight gains between treatments. Inadequate intake, on the other hand, causes volume depletion and hypotension and can cause further decreases in the already compromised GFR. It is common practice to allow a daily fluid intake of 500 to 800 mL, which is equal to insensible water loss plus a quantity equal to the 24-hour urine output.

When the GFR falls to extremely low levels in kidney failure or during hemodialysis therapy, dietary restriction of potassium becomes mandatory. Using salt substitutes that contain potassium, or ingesting fruits, fruit juice, chocolate, potatoes, or other high-potassium foods can cause hyperkalemia. Most people on CAPD do not need to limit potassium intake and often may even need to increase intake.

People with CKD are usually encouraged to limit their dietary phosphorus as a means of preventing secondary hyperparathyroidism, renal osteodystrophy, and metastatic calcification. Unfortunately, many processed and convenience foods contain considerable amounts of phosphorus additives.

**IN SUMMARY**

CKD results from the destructive effects of many forms of renal disease. Regardless of the cause, the consequences of nephron destruction in CKD are alterations in the filtration, reabsorption, and endocrine functions of the kidneys. Chronic disease is defined as either diagnosed kidney damage or GFR of less than 60 mL/min/1.73 m² for 3 months or more, and kidney failure as a GFR of less than 15 mL/min/1.73 m², usually accompanied by most of the signs and symptoms of uremia, or a need to start renal replacement therapy.

CKD affects almost every body system. It causes an accumulation of nitrogenous wastes (i.e., azotemia), alters sodium and water excretion, and alters regulation of body levels of potassium, phosphate, calcium, and magnesium. It also causes skeletal disorders, anemia, cardiovascular disorders, neurologic disturbances, gastrointestinal dysfunction, and discomfotting skin changes.

The treatment measures for CKD can be divided into two types: conservative treatment measures and renal replacement therapy. Conservative treatment consists of measures to prevent or retard deterioration in remaining renal function and assist the body in compensating for the existing impairment. Interventions that have been shown to retard the progression of CKD include blood pressure normalization and control of blood glucose in persons with diabetes. Activated vitamin D can be used
to increase calcium absorption and control secondary hyperparathyroidism. Recombinant human erythropoietin is being assessed as to whether it should be used to treat the profound anemia that occurs in persons with CKD. Renal replacement therapy (dialysis or kidney transplantation) is indicated when advanced uremia and serious electrolyte problems are present.

### Chronic Kidney Disease in Children and Older Adults

After completing this section of the chapter, you should be able to meet the following objectives:

- List the causes of CKD in children and describe the special problems of children with kidney failure.
- State why CKD is more common in older adults and describe measures to prevent or delay the onset of kidney failure in this population.

Although the spectrum of CKD among children and older adults is similar to that of adults, several unique issues affecting these groups warrant further discussion.

### Chronic Kidney Disease in Children

The true incidence of CKD in infants and children is unknown. There are 1 or 2 new pediatric cases with renal disease out of 100,000 children under 19 years of age. Adults are 20 times more likely to acquire kidney disease than children.

#### Etiology

The causes of CKD in children include congenital malformations, inherited disorders, acquired diseases, and metabolic syndromes. In children younger than 5 years of age, CKD is commonly the result of congenital malformations such as renal dysplasia or obstructive uropathy. After 5 years of age, acquired diseases (e.g., glomerulonephritis) and inherited disorders (e.g., familial juvenile nephronophthisis) predominate. CKD related to metabolic disorders, such as hyperoxaluria and inherited disorders, such as polycystic kidney disease may present throughout childhood.

The stages for progression of CKD in children are similar to those for adults, but apply only to children who are older than 2 years of age. This is because of the extremely small body size of infants and toddlers in addition to their very low GFR. Critical growth periods occur during the first 2 years of life and during adolescence. Physical growth and cognitive development are slowed in children with CKD. Puberty usually occurs at a later age in children with CKD, partly because of endocrine abnormalities. Renal osteodystrophies are more common and extensive in children than in adults. The most common condition seen in children is high–bone-turnover bone disease caused by secondary hyperparathyroidism. Some hereditary renal diseases, such as medullary cystic disease, have patterns of skeletal involvement that further complicate the problems of renal osteodystrophy. Clinical manifestations of renal osteodystrophy include muscle weakness, bone pain, and fractures with minor trauma. In growing children, rachitic changes, varus and valgus deformities of long bones, and slipped capital femoral epiphysis may be seen. Additionally, any child with CKD will have the potential to develop ectopic vascular calcification, which begins in the early stages of CKD before dialysis is initiated. Once the child reaches ESRD and is on dialysis three times a week, cardiovascular dysfunction progresses very quickly. Factors related to impaired growth include deficient nutrition, anemia, renal osteodystrophy, chronic acidosis, and cases of nephrotic syndrome that require high-dose corticosteroid therapy. Nutrition is believed to be one of the most important determinants during infancy. For many children, catch-up growth is important because a growth deficit frequently is established during the first months of life.

#### Clinical Manifestations

The manifestations of CKD in children are quite varied and depend on the underlying disease condition. Features of CKD that are marked during childhood include severe growth impairment, developmental delay, delay in sexual maturation, bone abnormalities, and development of psychosocial problems.

### Chronic Kidney Disease in Older Adults

Since the mid 1980s, there have been increasing numbers of older adults accepted to renal replacement/supportive therapy programs. As one ages, there is more chance of acquiring CKD. However, the true prevalence or outcomes of CKD in older adults have not been systematically studied. The presentation and course of CKD may be altered because of age-related changes in the kidneys and concurrent medical
conditions. More research needs to be conducted that includes older adults with CKD who may have the problem secondary to aging versus diabetes mellitus. It seems most older adults (>65 years) do not have CKD due to proteinuria or diabetes.

**Etiology and Diagnosis**

Aging is associated with a steady decline in kidney function, a decreasing GFR and subsequently with reduced homeostatic regulation under stressful conditions. This reduction in GFR makes older adults more susceptible to the detrimental effects of nephrotoxic drugs, such as radiographic contrast compounds. The reduction in GFR related to aging is not accompanied by a parallel rise in the serum creatinine level because the serum creatinine level, which results from muscle metabolism, is significantly reduced in older adults because of diminished muscle mass and other age-related changes. The NKF guidelines suggest that the same criteria for establishing the presence of CKD in younger adults (i.e., GFR < 60 mL/min/1.73 m²) should be used for the older adults. Evaluation of older adults with a GFR of 60 to 89 mL/min/1.73 m² should include age-adjusted measurements of creatinine clearance, along with assessment of CKD risks, and a blood pressure reading.

**Clinical Manifestations**

The prevalence of cerebrovascular, cardiovascular, and skeletal system chronic disease is frequently seen with older adults. Because of concurrent disease, the presenting symptoms of kidney disease in older adults may be less typical than those observed in younger adults. For example, congestive heart failure and hypertension may be the dominant clinical features with the onset of acute glomerulonephritis, whereas oliguria and discolored urine more often are the first signs in younger adults. The course of CKD may be more complicated in older patients with numerous chronic diseases.

**Treatment**

The NKF guidelines indicate that clinical interventions for older adults with CKD should be based on diagnosis, severity of kidney function impairment, and stratification of risk for progression to renal failure and cardiovascular disease. People with low risk may require only modification of dosages of medications excreted by the kidney, monitoring of blood pressure, avoidance of drugs and procedures that increase the risk of acute renal failure, and lifestyle modification to reduce the risk of cardiovascular disease.

Older adults with more severe impairment of kidney function may require renal replacement therapy. The NKF cite that from 1999 to 2008 there has been a 300% increase in kidney transplants among older adults. Treatment options for CKD in older adults include hemodialysis, peritoneal dialysis, transplantation, and acceptance of death from uremia. Neither hemodialysis nor peritoneal dialysis has proved to be superior in older adults. The mode of renal replacement therapy should be individualized, taking into account underlying medical and psychosocial factors. Age alone should not determine renal transplantation. With increasing experience, many transplantation centers have increased the age for acceptance on transplant waiting lists. Reluctance to provide transplantation as an alternative may have been due, at least in part, to the scarcity of available organs and the view that younger persons are more likely to benefit for a longer time. The general reduction in T-lymphocyte function that occurs with aging has been suggested as a beneficial effect that increases transplant graft survival.

---

**IN SUMMARY**

Available data suggest that approximately 1% of people with CKD are in the pediatric age range. The causes of CKD include congenital malformations (e.g., renal dysplasia and obstructive uropathy), inherited disorders (e.g., polycystic kidney disease), acquired diseases (e.g., glomerulonephritis), and metabolic syndromes (e.g., hyperoxaluria). Problems associated with CKD in children include growth impairment, delay in sexual maturation, and more extensive bone abnormalities than in adults. Although all forms of renal replacement therapy can be safely and reliably used in children, CCPD, nocturnal intermittent peritoneal dialysis (NIPD), or transplantation optimizes growth and development.

Currently, it is common practice to accept older adults for renal replacement therapy programs if it is assessed that this will increase their quality of life. Normal aging is associated with a decline in the GFR, which makes elderly persons more susceptible to the detrimental effects of nephrotoxic drugs and other conditions that compromise renal function. Current guidelines for diagnosis of CKD and stratification of risk for progression to kidney failure are the same as for younger adults. Treatment options for failure in older adults are similar to those for younger adults.

---

**REVIEW EXERCISES**

1. A 55-year-old man with diabetes and coronary heart disease, who had undergone cardiac catheterization with the use of a radiocontrast agent 2 days ago, is admitted to the emergency department with a flulike syndrome including chills, nausea, vomiting, abdominal pain, fatigue, and pulmonary congestion. His serum creatinine is elevated, and he has protein in his urine. He is admitted to the intensive care unit with a tentative diagnosis of AKI due to radiocontrast nephropathy.
   
   **A.** Radiocontrast agents are thought to exert their effects through decreased renal perfusion and through direct toxic effects on renal tubular structures. Explain how each of these phenomena contributes to the development of AKI.

   **B.** Explain the elevated serum creatinine, proteinuria, and presence of pulmonary congestion.
2. A 35-year-old, 70-kg white man with diabetes mellitus is seen in the diabetic clinic for his 6-month check-up. His serum creatinine, which was slightly elevated at his last visit, is now 1.6 mg/dL. Use the following Web site to estimate his GFR: http://www.mdcalc.com/creatinine-clearance-cockcroft-gault-equation

   A. Would he be classified as having CKD? If so, what stage? What might be done to delay or prevent further deterioration of his kidney function?

3. CKD is accompanied by hyperphosphatemia, hypocalcemia, impaired activation of vitamin D, hyperparathyroidism, and skeletal complications.

   A. Explain the impaired activation of vitamin D and its consequences on calcium and phosphate homeostasis, parathyroid function, and mineralization of bone in persons with CKD.

   B. Explain the possible complications of the administration of activated forms of vitamin D on parathyroid function and calcium and phosphate homeostasis (e.g., calcium × phosphate product).

CANCER OF THE BLADDER

Etiology and Pathophysiology
Clinical Manifestations
Diagnosis and Treatment

While the kidneys control the formation of urine and regulate the composition of body fluids, the bladder stores urine and controls its elimination from the body. Alterations in the storage and expulsion functions of the bladder can result in incontinence, with its accompanying social and hygienic problems, or obstruction of urinary flow, which has deleterious effects on ureteral and, ultimately, renal function. The discussion in this chapter focuses on the normal control of urine elimination, urinary obstruction and stasis, neurogenic bladder, incontinence, and bladder cancer.

Bladder Structure

The bladder, also known as the urinary vesicle, is a freely movable organ located retroperitoneally on the pelvic floor, just posterior to the pubic symphysis. It consists of two main components: the body in which urine collects, and the neck, which is a funnel-shaped extension of the body that connects with the urethra. In the male, the urethra continues anteriorly through the penis, with the prostate gland surrounding the neck of the bladder where it empties into the urethra. In the female, the bladder is located anterior to the vagina and uterus.
detrusor muscle contracts, the sphincter is pulled open as the shape of the bladder changes. In the female, the urethra (4 cm) is shorter than in the male (17 cm), and usually affords less resistance to urine outflow.2

Another muscle important to bladder function is the external sphincter, a circular muscle composed of striated muscle fibers that surrounds the urethra distal to the base of the bladder.1 The external sphincter operates as a reserve mechanism to stop micturition when it is occurring and to maintain continence in the face of unusually high bladder pressure. The skeletal muscle of the pelvic floor also contributes to the support of the bladder and the maintenance of continence.

Neural Control of Bladder Function

Normal bladder function requires the coordinated interaction between the sensory and motor components of the involuntary autonomic and voluntary somatic nervous systems.1 The motor component of the neural reflex that causes bladder emptying is controlled by the parasympathetic nervous system, whereas the relaxation and storage function of the bladder is controlled by the sympathetic nervous system.1 The somatic nervous system provides for the voluntary control of the external sphincter and pelvic floor muscles. These functions are controlled by three neurologic centers: the spinal cord reflex centers, the micturition center in the pons, and cortical and subcortical centers.1

Spinal Cord Centers

The centers for reflex control of bladder function are located in the sacral (S1 through S4) and thoracolumbar (T11 through L2) segments of the spinal cord (Fig. 43.2).

Urine passes from the kidneys to the bladder through the ureters. The interior of the bladder has openings for both the ureters and the urethra. The smooth triangular area that is bounded by these three openings is called the trigone (Fig. 43.1). There are no valves at the ureteral openings, but as the pressure of the urine in the bladder rises, the ends of the ureters are compressed against the bladder wall to prevent the backflow of urine.1

The bladder is composed of four layers. The first is an outer serosal layer, which covers the upper surface and is continuous with the peritoneum. The second is a network of smooth muscle fibers called the detrusor muscle. The third is a submucosal layer of loose connective tissue, and the fourth is an inner mucosal lining of transitional epithelium (urothelium).1 This stratified epithelium is essentially impermeable to salts and water. The tonicity and composition of the urine often is quite different from that of the blood, and the epithelial lining of the bladder acts as an effective barrier to prevent the passage of water and other urine elements between the bladder and the blood. The epithelial lining of the bladder is several layers thick in the empty bladder. However, when the bladder is distended, as few as two or three layers are seen. This change reflects the ability of these cells to flatten and unfold to accommodate the increased surface area of a distended bladder (see Fig. 43.1).2

The detrusor muscle is the muscle of micturition (passage of urine). When it contracts, urine is expelled from the bladder. Muscles in the bladder neck, sometimes referred to as the internal urethral sphincter, are a continuation of the detrusor muscle.2 They run down obliquely behind the proximal urethra, forming the posterior urethra in males and the entire urethra in females.1 When the bladder is relaxed, these circular muscle fibers are closed and act as a sphincter.2 When the detrusor muscle contracts, the sphincter is pulled open as the shape of the bladder changes. In the female, the urethra (4 cm) is shorter than in the male (17 cm), and usually affords less resistance to urine outflow.2
The parasympathetic lower motor neurons (LMNs) for the detrusor muscle of the bladder are located in the sacral segments of the spinal cord; their axons travel to the bladder by way of the pelvic nerve. LMNs for the external sphincter also are located in the sacral segments of the spinal cord. These LMNs receive their control from the motor cortex through the corticospinal tract and send impulses to the external sphincter through the pudendal nerve. The bladder neck and trigone area of the bladder, because of their different embryonic origins, receive sympathetic outflow from the thoracolumbar (T11 to L2) segments of the spinal cord. In the male, the seminal vesicles, ampulla, and vas deferens also receive sympathetic innervation from the thoracolumbar segments of the cord.

The afferent input from the bladder and urethra is carried to the central nervous system (CNS) by fibers that travel with the parasympathetic (pelvic), somatic (pudendal), and sympathetic (hypogastric) nerves. The pelvic nerve carries sensory fibers from the stretch receptors in the bladder wall, the pudendal nerve carries sensory fibers from the external sphincter and pelvic muscles, and the hypogastric nerve carries sensory fibers from the trigone area.

**Pontine Micturition Center**

The immediate coordination of the normal micturition reflex occurs in the micturition center in the pons, facilitated by descending input from the forebrain and ascending input from the reflex centers in the spinal cord (Fig. 43.3). This center is thought to coordinate the activity of the detrusor muscle and the external sphincter. As bladder filling occurs, ascending spinal afferents relay this information to the micturition center, which also receives important descending information from the forebrain concerning behavioral cues for bladder emptying and urine storage. Descending pathways from the pontine micturition center produce coordinated inhibition or relaxation of the external sphincter. Disruption of pontine control of micturition, as in spinal cord injury, results in uninhibited spinal reflex–controlled contraction of the bladder without relaxation of the external sphincter, a condition known as detrusor–sphincter dyssynergia.
Cortical and Subcortical Centers

Cortical brain centers enable inhibition of the micturition center in the pons and conscious control of urination. Neural influences from the subcortical centers in the basal ganglia modulate the contractile response. They modify and delay the detrusor contractile response during filling and then modulate the expulsive activity of the bladder to facilitate complete emptying.

Micturition and Maintenance of Continence

To maintain continence, or retention of urine, the bladder must function as a low-pressure storage system, with the pressure in the bladder being lower than that in the urethra. To ensure that this condition is met, the increase in intravesical pressure (internal bladder pressure) that accompanies bladder filling is almost imperceptible. Abnormal sustained elevations in intravesical pressures (>40 to 50 cm H₂O) often are associated with vesicoureteral reflux (i.e., backflow of urine from the bladder into the ureter) and the development of ureteral dilation. Although the pressure in the bladder is maintained at low levels, sphincter pressure remains high (45 to 65 cm H₂O) as a means of preventing loss of urine as the bladder fills.

Micturition, or the act of bladder emptying, involves both sensory and motor functions associated with bladder emptying. When the bladder is distended to 150 to 250 mL in the adult, the sensation of fullness is transmitted to the spinal cord and then to the cerebral cortex. At approximately 400 to 500 mL the person will sense fullness of the bladder. During the act of micturition, the detrusor muscle of the bladder fundus and bladder neck contract down on the urine; the ureteral orifices are forced shut; the bladder neck is widened and shortened as it is pulled up by the globular muscles in the bladder fundus; the resistance of the internal sphincter in the bladder neck is decreased; and the external sphincter relaxes as urine moves out of the bladder.

Pharmacology of Micturition

The autonomic nervous system (ANS) and its neuromediators play a central role in micturition. Parasympathetic innervation of the bladder is mediated by the neurotransmitter acetylcholine. Two types of cholinergic receptors, nicotinic and muscarinic, affect various aspects of micturition. **Nicotinic** (N) receptors are found in the synapses between the preganglionic and postganglionic neurons of the sympathetic and the parasympathetic system, as well as in the neuromuscular endplates of the striated muscle fibers of the external sphincter and pelvic muscles. **Muscarinic** (M) receptors are found in the postganglionic parasympathetic endings of the detrusor muscle. Several subtypes of M receptors have been identified. Both M₁ and M₃ receptors appear to mediate detrusor muscle activity, with the M₃ subtype mediating direct activation of detrusor muscle contraction. The M₂ subtype appears to act indirectly by inhibiting sympathetically mediated detrusor muscle relaxation.

The identification of muscarinic receptor subtypes has facilitated the development of medications, muscarinic agonists, that selectively target only the bladder structures while minimizing undesired side effects. However, many people still experience side effects from some of the nonselective muscarinic agonists, including confusion, loss of memory, and somnolence.

Although sympathetic innervation is not essential to the act of micturition, it allows the bladder to store a large volume without the involuntary escape of urine—a mechanism that is consistent with the fight-or-flight function subserved by the sympathetic nervous system. The bladder is supplied with α₁- and β₂-adrenergic receptors. The β₂-adrenergic receptors are found in the detrusor muscle. They produce relaxation of the detrusor muscle, increasing the bladder volume at which the micturition reflex is triggered. The α₁-adrenergic receptors are found in the trigone area, including the intramural ureteral musculature, bladder neck, and internal sphincter. The activation of α₁-adrenergic receptors produces contraction of these muscles. Sympathetic activity ceases when the micturition reflex is activated. During male ejaculation, which is mediated by the sympathetic nervous system, the musculature of the trigone area and that of the bladder neck and prostatic urethra contract and prevent the backflow of seminal fluid into the bladder.

Because of their effects on bladder function, drugs that selectively activate or block ANS outflow or receptor activity can alter urine elimination. Table 43.1 describes the action of drug groups that can impair bladder function or can be used in the treatment of micturition disorders. Many of the nonprescription cold preparations contain α-adrenergic agonists and many antihistamine agents have anticholinergic properties. These drugs can cause urinary retention. In addition, many antidepressant and antipsychotic drugs also have anticholinergic actions that frequently cause urine retention, which puts people at risk for urinary infections.

Continence in Children

In infants and young children, micturition is an involuntary act that is triggered by a spinal cord reflex; when the bladder fills to a given capacity, the detrusor muscle contracts, and the external sphincter relaxes. As the child grows, the bladder gradually enlarges, with an increase in capacity, in ounces, that approximates the age of the child plus 2. This formula applies up to age 12 to 14 years. As the bladder grows and increases in capacity, the tone of the external sphincter muscle increases. Toilet training begins at about 2 to 3 years of age when the child becomes conscious of the need to urinate. Conscious control of bladder function depends on (1) normal bladder growth, (2) myelination of the ascending afferents that signal awareness of bladder filling, (3) development of cortical control and descending communication with the sacral micturition center, (4) ability to consciously tighten the external sphincter to prevent incontinence, and (5) motivation of the child to stay dry. Girls typically achieve continence before boys, and bowel control is typically achieved before bladder control.
examination (i.e., pelvic and abdominal palpation) can be used to assess PVR volume. Rectal examination is used to test for perineal sensation, sphincter tone, fecal impaction, and rectal mass. It is also used to assess the contour of the prostate in men.

**Laboratory and Radiologic Studies**

Urine tests provide information about kidney function and urinary tract infections. The presence of bacteriuria or pyuria suggests urinary tract infection and the possibility of urinary tract obstruction. Blood tests (i.e., blood urea nitrogen and creatinine) provide information about renal function.

Bladder structures can be visualized indirectly by taking x-ray films of the abdomen and by using excretory urography, which involves the use of a radiopaque dye, computed tomographic (CT) scanning, magnetic resonance imaging (MRI), or ultrasonography. Cystoscopy enables direct visualization of the urethra, bladder, and ureteral orifices.

**Diagnostic Methods of Evaluating Bladder Structure and Function**

Bladder structure and function can be assessed by a number of methods. Reports or observations of frequency, hesitancy, straining to urinate or void, and a weak or interrupted stream are suggestive of outflow obstruction. Palpation and percussion provide information about bladder distention.

**Physical Examination**

Postvoid residual (PVR) urine volume provides information about bladder emptying. It can be estimated by abdominal palpation and percussion. Catherization and ultrasonography can be used to obtain specific measurements of PVR. A PVR value of less than 50 mL is considered adequate bladder emptying, and more than 200 mL indicates inadequate bladder emptying.

Pelvic examination is used in women to assess perineal skin condition, perivaginal muscle tone, genital atrophy, pelvic prolapse (e.g., cystocele, rectocele, uterine prolapse), pelvic mass, or other conditions that may impair bladder function. Bimanual examination (i.e., pelvic and abdominal palpation) can be used to assess PVR volume. Rectal examination is used to test for perineal sensation, sphincter tone, fecal impaction, and rectal mass. It is also used to assess the contour of the prostate in men.

**KEY POINTS**

**BLADDER FUNCTION**

- The control of the storage and emptying functions of the bladder involves both involuntary (ANS) and voluntary (somatic nervous system) control.
- The striated muscles in the external sphincter and pelvic floor, which are innervated by the somatic nervous system, provide for the voluntary control of urination and maintenance of continence.

**Urodynamic Studies**

Urodynamic studies are used to study bladder function and voiding problems. Three aspects of bladder function can be assessed by urodynamic studies: bladder, urethral, and intra-abdominal pressure changes; characteristics of urine
flow; and the activity of the striated muscles of the external sphincter and pelvic floor.\(^{11}\) Specific urodynamic tests include uroflowmetry, cystometry, urethral pressure profile, and sphincter electromyography (EMG). It often is advantageous to evaluate several components of bladder function simultaneously.

**Uroflowmetry.** Uroflowmetry measures the flow rate (milliliters per minute) during urination.\(^{11}\) It commonly is done using a weight-recording device located at the bottom of a commode receptacle unit. As the person being tested voids, the weight of the commode receptacle unit increases. This weight change is electronically recorded and then analyzed as volume (weight converted to milliliters) versus time.

**Cystometry.** Cystometry is used to measure bladder pressure during filling and voiding. It provides valuable information about total bladder capacity, intravesical pressures during bladder filling, the ability to perceive bladder fullness and the desire to urinate, the ability of the bladder to contract and sustain a contraction, uninhibited bladder contractions, and the ability to inhibit urination.\(^{11}\) The test can be done by allowing physiologic filling of the bladder with urine and recording intravesical pressure throughout a voiding cycle, or by using a catheter to fill the bladder with water and measuring intravesical pressure against the volume of water instilled into the bladder.\(^{11}\)

In a normally functioning bladder, the sensation of bladder fullness is first perceived when the bladder contains 100 to 200 mL of urine while bladder pressure remains constant at approximately 8 to 15 cm H\(_2\)O. The desire to void occurs when the bladder is full (normal capacity is approximately 400 to 500 mL). At this point, a definite sensation of fullness occurs, the pressure rises sharply to 40 to 100 cm H\(_2\)O, and voiding occurs around the catheter.\(^{16}\) Urinary incontinence requires that urethral pressure exceed bladder pressure. If the urethral resistance is high because of obstruction, greater pressure is required, a condition that can be detected by cystometry.

**Urethral Pressure Profile.** The urethral pressure profile is used to evaluate the intraluminal pressure changes along the length of the urethra with the bladder at rest.\(^{11}\) It provides information about smooth muscle activity along the length of the urethra. This test can be done using the infusion method, the membrane catheter method, or the microtip transducer. The infusion method involves the insertion of a small double-lumen urethral catheter, followed by the infusion of water into the bladder and measurement of the changes in urethral pressure as the catheter is slowly withdrawn.

**Sphincter Electromyography.** Sphincter EMG allows the activity of the striated (voluntary) muscles of the perineal area to be studied.\(^{11}\) Activity is recorded using an anal plug electrode, a catheter electrode, adhesive skin electrodes, or needle electrodes.\(^{10}\) Electrode placement is based on the muscle groups that need to be tested. The test usually is done along with urodynamic tests such as cystometry and uroflowmetry.

**IN SUMMARY**

Although the kidneys function in the formation of urine and the regulation of body fluids, it is the bladder that stores and controls the elimination of urine. Micturition is a function of the peripheral ANS, subject to facilitation or inhibition from higher neurologic centers. The parasympathetic nervous system controls the function of the detrusor muscle and internal sphincter; its cell bodies are located in S1 through S3 of the spinal cord and communicate with the bladder through the pelvic nerve. Efferent sympathetic control originates at the thoracolumbar level (T11 through L2) of the spinal cord and produces relaxation of the detrusor muscle and contraction of the internal sphincter. Skeletal muscle found in the external sphincter and the pelvic muscles that support the bladder are supplied by the pudendal nerve, which exits the spinal cord at the sacral level (S2 through S4) of the spinal cord. The pontine micturition center coordinates the action of the detrusor muscle and the external sphincter, whereas cortical centers permit conscious control of micturition.

Bladder structure and function can be evaluated using physical examination, laboratory and radiologic studies, urodynamic studies that measure bladder, urethral, and abdominal pressures; urine flow characteristics; and skeletal muscle activity of the external sphincter.

**ALTERATIONS IN BLADDER FUNCTION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the causes of, and compensatory changes that occur with, urinary tract obstruction.
- Differentiate lesions that produce storage dysfunction associated with spastic bladder from those that produce emptying dysfunction associated with flaccid bladder in terms of the level of the lesions and their effects on bladder function.
- Define incontinence and differentiate between stress incontinence, overactive bladder/urge incontinence, and overflow incontinence.

Alterations in bladder function include urinary obstruction with retention or stasis of urine and urinary incontinence with involuntary loss of urine. Although the two conditions have almost opposite effects on urination, they can have similar causes. Both can result from structural changes in the bladder, urethra, or surrounding organs or from impairment of neurologic control of bladder function.
Lower Urinary Tract Obstruction and Stasis

Urinary tract obstructions are classified according to cause (congenital or acquired), degree (partial or complete), duration (acute or chronic), and level (upper or lower urinary tract). In lower urinary tract obstruction and stasis, urine is produced normally by the kidneys but is retained in the bladder. Because it has the potential to produce vesicoureteral reflux and cause kidney damage, lower urinary tract obstruction and stasis is a serious disorder.

The common sites of congenital obstructions are the external meatus (i.e., meatal stenosis) in boys and just inside the external urinary meatus in girls. Another congenital cause of urinary stasis is the damage to sacral nerves that is seen in spina bifida and meningomyelocele.

The acquired causes of lower urinary tract obstruction and stasis are numerous. In males, the most important acquired cause of urinary obstruction is external compression of the urethra caused by the enlargement of the prostate gland. In males and females, gonorrhea and other sexually transmitted infections contribute to the incidence of infection-produced urethral strictures. Bladder tumors and secondary invasion of the bladder by tumors arising in structures that surround the bladder and urethra can compress the bladder neck or urethra and cause obstruction. Because of the proximity of the involved structures, constipation and fecal impaction can compress the urethra and produce urethral obstruction.

Compensatory and Decompensatory Changes

The body compensates for the obstruction of urine outflow with mechanisms designed to prevent urine retention. These mechanisms can be divided into two stages: a compensatory stage and a decompensatory stage. The degree to which these changes occur and their effect on bladder structure and urinary function depend on the extent of the obstruction, the rapidity with which it occurs, and the presence of other contributing factors, such as neurologic impairment and infection.

During the early stage of obstruction, the bladder begins to hypertrophy and becomes hypersensitive to afferent stimuli arising from stretch receptors in the bladder wall. The ability to suppress urination is diminished, and bladder contraction can become so strong that it virtually produces bladder spasm. There is urgency, sometimes to the point of incontinence, and frequency during the day and at night.

With continuation and progression of the obstruction, compensatory changes begin to occur. There is further hypertrophy of the bladder muscle, the thickness of the bladder wall may double, and the pressure generated by detrusor contraction can increase from a normal 20 to 40 cm H₂O to 50 to 100 cm H₂O to overcome the resistance from the obstruction. As the force needed to expel urine from the bladder increases, compensatory mechanisms may become ineffective, causing muscle fatigue before complete emptying can be accomplished. After a few minutes, voiding can again be initiated and completed, accounting for the frequency of urination.

The inner bladder surface forms smooth folds. With continued outflow obstruction, this smooth surface is replaced with coarsely woven structures (i.e., hypertrophied smooth muscle fibers) called trabeculae. Small pockets of mucosal tissue, called cellules, commonly develop between the trabecular ridges. These pockets form diverticula when they extend between the actual fibers of the bladder muscle (Fig. 43.4). Because the diverticula have no muscle, they are unable to contract and expel their urine into the bladder, and secondary infections caused by stasis are common.

Along with hypertrophy of the bladder wall, there is hypertrophy of the trigone area and the interureteric ridge, which is located between the two ureters. This causes back-pressure on the ureters, the development of hydroureters (i.e., dilated, urine-filled ureters), and, eventually, kidney damage. Stasis of urine predisposes to urinary tract infections.

When compensatory mechanisms no longer are effective, signs of decompensation begin to appear. The period of detrusor muscle contraction becomes too short to expel the urine completely, and residual urine remains in the bladder. At this point, the symptoms of obstruction—frequency of urination, hesitancy, need to strain to initiate urination, a weak and small stream, and termination of the stream before the bladder is completely emptied—become pronounced. With progressive decompensation, the bladder may become severely overstretched, with a residual urine volume of 1000 to 3000 mL.
nerves that connect the bladder to the reflex micturition center in the sacral cord, the ascending and descending tracts in the spinal cord, the pontine micturition center, or the cortical centers that are involved in voluntary control of micturition (see Fig. 43.3).

Neurogenic disorders of bladder function commonly are manifested in one of two ways: failure to store urine (spastic bladder dysfunction) or failure to empty urine (flaccid bladder dysfunction). Spastic bladder dysfunction usually results from neurologic lesions located above the level of the sacral micturition reflexes, whereas flaccid bladder dysfunction results from lesions at the level of the sacral micturition reflexes or the peripheral nerves that innervate the bladder. In addition to disorders of detrusor muscle function, disruption of micturition occurs when the neurologic control of external sphincter function is disrupted. Some disorders, such as stroke and Parkinson disease, may affect both the storage and emptying functions of the bladder. Table 43.2 describes the characteristics of neurogenic bladder according to the level of the lesion.

At this point, it loses its power of contraction and overflow incontinence occurs. The signs of outflow obstruction and urine retention are summarized in Chart 43.1.

**Treatment of Lower Urinary Tract Obstruction**

The immediate treatment of lower urinary tract obstruction and stasis is directed toward relief of bladder distention. This usually is accomplished through urinary catheterization. Constipation or fecal impaction should be corrected. Long-term treatment is directed toward correcting the problem causing the obstruction.

**Neurogenic Bladder Disorders**

The urinary bladder is unique in that it is probably the only autonomically innervated visceral organ that is under CNS control. The neural control of bladder function can be interrupted at any level. It can be interrupted at the level of the peripheral nerves that connect the bladder to the reflex micturition center in the sacral cord, the ascending and descending tracts in the spinal cord, the pontine micturition center, or the cortical centers that are involved in voluntary control of micturition (see Fig. 43.3). Neurogenic disorders of bladder function commonly are manifested in one of two ways: failure to store urine (spastic bladder dysfunction) or failure to empty urine (flaccid bladder dysfunction). Spastic bladder dysfunction usually results from neurologic lesions located above the level of the sacral micturition reflexes, whereas flaccid bladder dysfunction results from lesions at the level of the sacral micturition reflexes or the peripheral nerves that innervate the bladder. In addition to disorders of detrusor muscle function, disruption of micturition occurs when the neurologic control of external sphincter function is disrupted. Some disorders, such as stroke and Parkinson disease, may affect both the storage and emptying functions of the bladder. Table 43.2 describes the characteristics of neurogenic bladder according to the level of the lesion.

**Spastic Bladder: Failure to Store Urine**

Failure to store urine results from conditions that cause reflex bladder spasm and a decrease in bladder volume. It commonly is caused by conditions that produce partial or extensive neural damage above the micturition reflex center in the sacral cord (see Fig. 43.3). As a result, segmental reflexes regulate bladder function, without control from higher brain centers. The degree of bladder spasticity and dysfunction depends on the level and extent of neurologic dysfunction. Usually, both the ANS neurons controlling bladder function and the somatic neurons controlling the function of the striated muscles in the external sphincter are affected. In some cases, there is a detrusor–sphincter dyssynergia with uncoordinated...
contraction and relaxation of the detrusor and external sphincter muscles. The most common causes of spastic bladder dysfunction are spinal cord lesions such as spinal cord injury, herniated intervertebral disk, vascular lesions, tumors, and myelitis. Other neurologic conditions that affect voiding are stroke, multiple sclerosis, and brain tumors.

**Bladder Dysfunction Caused by Spinal Cord Injury.** The immediate and early effects of spinal cord injury on bladder function are quite different from those that follow recovery from the initial injury. During the period immediately after spinal cord injury, a state of spinal shock develops, during which all the reflexes, including the micturition reflex, are depressed. During this stage, the bladder becomes atonic and cannot contract. Catheterization is necessary to prevent injury to urinary structures associated with overdistention of the bladder. Intermittent catheterization is the preferred method of catheterization.

After the acute stage of spinal cord injury, the micturition response changes from a long-tract reflex to a segmental reflex. Because the sacral reflex arc remains intact, stimuli generated by bladder stretch receptors during filling produce frequent spontaneous contractions of the detrusor muscle. This creates a small, hyperactive bladder subject to high-pressure and short-duration uninhibited bladder contractions. Voiding is interrupted, involuntary, or incomplete. Dilation of the internal sphincter and spasticity of the external sphincter and perineal muscles innervated by upper motor neurons occur, producing resistance to bladder emptying. Hypertrophy of the trigone develops, often leading to vesicoureteral reflux and risk for renal damage.

Spastic bladder due to spinal cord injuries at the cervical level is often accompanied by a condition known as autonomic hyperreflexia. Because the injury interrupts CNS control of sympathetic reflexes in the spinal cord, severe hypertension, bradycardia, and sweating can be triggered by insertion of a catheter or mild overdistention of the bladder.

**Uninhibited Neurogenic Bladder.** A mild form of reflex neurogenic bladder, sometimes called uninhibited bladder, can develop after a stroke, during the early stages of multiple sclerosis, or as a result of lesions located in the inhibitory centers of the cortex or the pyramidal tract. With this type of disorder, the sacral reflex arc and sensation are retained, the urine stream is normal, and there is no residual urine. Bladder capacity is diminished, however, because of increased detrusor muscle tone and spasticity.

**Detrusor–Sphincter Dyssynergia.** Depending on the level of the lesion, the coordinated activity of the detrusor muscle and the external sphincter may be affected. Lesions that affect the micturition center in the pons or impair communication between the micturition center and spinal cord centers interrupt the coordinated activity of the detrusor muscle and the external sphincter. This is called detrusor–sphincter dyssynergia. Instead of relaxing during micturition, the external sphincter becomes more constricted. This condition can lead to elevated intravesical pressures, vesicoureteral reflux, and kidney damage.

**Treatment of Spastic Bladder.** Among the methods used to treat spastic bladder and detrusor–sphincter dyssynergia are the administration of anticholinergic medications to decrease bladder hyperactivity and urinary catheterization to produce bladder emptying. A sphincterotomy (surgical resection of the external sphincter) or implantable urethral stent may be used to decrease outflow resistance in a person who cannot be managed with medications and catheterization procedures. An alternative to surgical resection of the external sphincter is the injection of botulinum toxin type A (BTX-A) to produce paralysis of the striated muscles in the external sphincter.

---

**KEY POINTS**

**NEUROGENIC BLADDER DISORDERS**

- Spastic bladder dysfunction results from neurologic lesions above the level of the sacral cord that allow neurons in the micturition center to function reflexively without control from higher CNS centers.
- Flaccid bladder dysfunction results from neurologic disorders affecting the motor neurons in the sacral cord or peripheral nerves that control detrusor muscle contraction and bladder emptying.

**Flaccid Bladder: Failure to Empty Urine**

Failure to empty the bladder can be due to flaccid bladder dysfunction, peripheral neuropathies that interrupt afferent or efferent communication between the bladder and the spinal cord, or conditions that prevent relaxation of the external sphincter (see Fig. 43.3).

**Flaccid Bladder Dysfunction.** Detrusor muscle areflexia, or flaccid neurogenic bladder, occurs when there is injury to the micturition center of the sacral cord, the cauda equina, or the sacral nerves that supply the bladder. Atony of the detrusor muscle and loss of the perception of bladder fullness permit the overstretching of the detrusor muscle that contributes to weakness and ineffective bladder contractions. External sphincter tone and perineal muscle tone are diminished. Voluntary urination does not occur, but increasing the intra-abdominal pressure or applying manual suprapubic pressure can achieve fairly efficient emptying. Among the causes of flaccid neurogenic bladder are trauma, tumors, and congenital anomalies (e.g., spina bifida, meningomyelocele).

**Bladder Dysfunction Caused by Peripheral Neuropathies.** In addition to CNS lesions and conditions that disrupt bladder function, disorders of the peripheral (pelvic, pudendal, and hypogastric) nerves that supply the muscles of micturition can
Bladder atony with dysfunction is a frequent complication of diabetes mellitus. The disorder initially affects the sensory axons of the urinary bladder without involvement of the pudendal nerve. This leads to large residual volumes after micturition, sometimes complicated by infection. There frequently is a need for training, accompanied by hesitation, weakness of the stream, dribbling, and a sensation of incomplete bladder emptying. The chief complications are vesicoureteral reflux and ascending urinary tract infection. Because people with diabetes are already at risk for development of kidney disease, urinary stasis and reflux can have serious effects on renal function. Treatment consists of client education, including the need for frequent voiding (e.g., every 3 to 4 hours while awake), use of abdominal compression to achieve more complete bladder emptying, and intermittent catheterization when necessary.

**Nonrelaxing External Sphincter**

Another condition that affects micturition and bladder function is the nonrelaxing external sphincter. This condition usually is related to a delay in maturation, developmental regression, psychomotor disorders, or locally irritative lesions. Inadequate relaxation of the external sphincter can be the result of anxiety or depression. Any local irritation can produce spasms of the sphincter through afferent sensory input from the pudendal nerve, including vaginitis, perineal inflammation, and inflammation or irritation of the urethra. In men, chronic prostatitis contributes to impaired relaxation of the external sphincter.

**Treatment of Neurogenic Bladder Disorders**

The goals of treatment for neurogenic bladder disorders focus on preventing bladder overdistention, urinary tract infections, and potentially life-threatening kidney damage and reducing the undesirable social and psychological effects of the disorder. The methods used in treatment of neurogenic bladder disorders are individualized based on the type of neurologic lesion that is involved; information obtained through the health history, including fluid intake; report or observation of voiding patterns; presence of other health problems; urodynamic studies when indicated; and the ability of the person to participate in the treatment. Treatment methods include catheterization, bladder training, pharmacologic manipulation of bladder function, and surgery.

**Catheterization.** Catheterization involves the insertion of a small-diameter latex or silicone tube into the bladder through the urethra. The catheter may be inserted on a one-time basis to relieve temporary bladder distention, left indwelling (i.e., retention catheter), or inserted intermittently. With acute overdistention of the bladder, usually no more than 1000 mL of urine is removed from the bladder at one time. The theory behind this limitation is that removing more than this amount at one time releases pressure on the pelvic blood vessels and predisposes to alterations in circulatory function.

Permanent indwelling catheters sometimes are used when there is urine retention or incontinence in people who are ill or debilitated or when conservative or surgical methods for the correction of incontinence are not feasible. The use of permanent indwelling bladder catheters in patients with spinal cord injury has been shown to produce a number of complications, including urinary tract infections, pyelonephritis, and kidney stones. Because urethral catheters often produce urethral irritation and injury, a suprapubic catheter may be inserted in people requiring long-term catheter drainage.

Intermittent catheterization is used to treat urine retention or incomplete emptying secondary to various neurologic or obstructive disorders. Properly used, it prevents bladder overdistention and urethral irritation, allows more freedom of activity, and provides periodic distention of the bladder to prevent muscle atony. It often is used with pharmacologic manipulation to achieve continence. When possible, it is learned and managed as a self-care procedure (i.e., intermittent self-catheterization).

The clean procedure typically is used for self-catheterization. It is performed at 3- to 4-hour intervals to prevent overdistention of the bladder. The best results are obtained if only 300 to 400 mL is allowed to collect in the bladder between catheterizations. Following this plan, it would be less likely for autonomic dysreflexia to occur.

**Bladder Retraining.** Bladder retraining differs with the type of disorder. Methods used to supplement bladder retraining include monitoring fluid intake to prevent urinary tract infections and control urine volume and osmolality, developing scheduled times for urination, and using body positions that facilitate micturition. Adequate fluid intake also is needed to prevent urinary tract infections, the irritating effects of which increase bladder irritability and the risk for urinary incontinence and renal damage. Fluid intake must be balanced to prevent bladder overdistention from occurring during the night. Developing scheduled times for urinating prevents overdistention of the bladder.

The methods used for bladder retraining depend on the type of lesion causing the disorder. In spastic neurogenic bladder, methods designed to trigger the sacral micturition reflex are used; in flaccid neurogenic bladder, manual methods that increase intravesical pressure are used. Credé maneuvers, which are used with the person in a sitting position, consists of applying pressure with four fingers of one hand or both hands to the suprapubic area as a means of increasing intravesical pressure. The Valsalva maneuver (i.e., bearing down by exhaling against a closed glottis) increases intra-abdominal pressure and aids in bladder emptying. This maneuver is repeated until the bladder is empty. For the best results, the person must cooperate fully with the procedures and, if possible, learn to perform them independently.

Biofeedback methods have been useful for teaching some aspects of bladder control. They involve the use of EMG or cystometry as a feedback signal for training a person to control the function of the external sphincter or raise intravesical pressure enough to overcome outflow resistance.
Pharmacologic Manipulation. Pharmacologic manipulation includes the use of drugs to alter the contractile properties of the bladder, decrease the outflow resistance of the internal sphincter, and relax the external sphincter. The usefulness of drug therapy often is evaluated during cystometric studies. Antimuscarinic drugs, such as oxybutynin, tolterodine, and propantheline, decrease detrusor muscle tone and increase bladder capacity in people with spastic bladder dysfunction.16 Cholinergic drugs that stimulate parasympathetic receptors, such as bethanechol, provide increased bladder tonus and may prove helpful in the symptomatic treatment of milder forms of flaccid neurogenic bladder.8 Muscle relaxants, such as diazepam and baclofen, may be used to decrease the tone of the external sphincter.

Surgical Procedures. Among the surgical procedures used in the management of neurogenic bladder are sphincterectomy, reconstruction of the sphincter, nerve resection of the sacral reflex nerves that cause spasticity or the pudendal nerve that controls the external sphincter, and urinary diversion.11 Urinary diversion can be done by creating an ileal or a colon loop into which the ureters are anastomosed; the distal end of the loop is brought out and attached to the abdominal wall. Extensive research is being conducted on methods of restoring voluntary control of the storage and evacuation functions of the bladder through the use of implanted electrodes.

Urinary Incontinence

The Agency for Health Care Policy and Research Urinary Incontinence Guideline Panel have defined urinary incontinence as the involuntary loss or leakage of urine.22 Urinary incontinence is a common problem, particularly in older adults, with women being affected twice as often as men.16

Incontinence can be caused by a number of conditions. It can occur without the person’s knowledge or the person may be aware of the condition but be unable to prevent it. The Urinary Incontinence Guideline Panel has identified four main types of incontinence: stress incontinence, urge incontinence, overflow incontinence, and mixed incontinence, which is a combination of stress and urge incontinence.16 Recently, the term urge incontinence has been expanded to include overactive bladder (i.e., overactive bladder/urge incontinence). One other category, functional incontinence, must also be considered. This type of incontinence includes those people who cognitively are not capable of knowing they need to urinate and so just urinate whenever the bladder is full. Table 43.3 summarizes the characteristics of stress incontinence, overactive bladder/urge incontinence, overflow incontinence, and functional incontinence.

**Stress Incontinence**

Stress incontinence is the involuntary loss of urine during coughing, laughing, sneezing, or lifting that increases intra-abdominal pressure commonly due to pelvic floor muscle dysfunction.11,17,18 With severe urinary stress incontinence, any strain or increase in bladder pressure leads to urinary leakage.

![PUV angle](image-url)

**FIGURE 43.5** Normal 90- to 100-degree posterior urethrovesical (PUV) angle. In the presence of a normal PUV angle, sudden changes in intra-abdominal pressure are transmitted optimally to all sides of the proximal urethra, ensuring that intraurethral pressure remains higher than intravesical pressure. Loss of the PUV angle results in displacement of the vesicle neck to the most dependent portion of the bladder, preventing the equal transmission of sudden increases in intra-abdominal pressure.

In women, the angle between the bladder and the posterior proximal urethra (i.e., urethrovesical junction) is important to continence (Fig. 43.5). During the first stage of voiding, this angle is lost as the bladder descends. In women, diminution of muscle tone associated with normal aging, childbirth, or surgical procedures can cause weakness of the pelvic floor muscles and result in stress incontinence by obliterating the critical posterior urethrovesical angle. In these women, loss of the posterior urethrovesical angle, descent and funneling of the bladder neck, and backward and downward rotation of the bladder occur, so that the bladder and urethra are already in an anatomic position for the first stage of voiding. Any activity...
that causes downward pressure on the bladder is sufficient to allow the urine to escape involuntarily.

Another cause of stress incontinence is intrinsic urethral deficiency, which may result from congenital sphincter weakness, as occurs with meningomyelocele. It also may be acquired as a result of trauma, irradiation, or sacral cord lesions. Stress incontinence in men may result from a congenital defect or from trauma or surgery to the bladder outlet, as occurs with prostatectomy. Neurologic dysfunction, as occurs with impaired sympathetic innervation of the bladder neck, impaired pelvic nerve innervation to the intrinsic sphincter, or impaired pudendal nerve innervation to the external sphincter, may also be contributing factors.

Severe stress incontinence is prevalent in women, especially those over age 60 years. In fact, approximately 86% of women over 60 years of age experience some degree of stress incontinence. However, only 47% of these women actually go to a provider for assistance for their incontinence. Due to the high number of women experiencing stress incontinence, Muller proposes that providers and staff do massive health teaching initiatives to assist women and men in preventing or correcting stress incontinence.

**Overactive Bladder/Urge Incontinence**

The Urinary Incontinence Guideline Panel has defined urge incontinence as the involuntary loss of urine associated with a strong desire to void (urgency). To expand the number and types of patients eligible for clinical trials, the U.S. Food and Drug Administration adopted the term overactive bladder to describe the clinical syndrome that describes not only urge incontinence but frequency, dysuria, and nocturia. The International Continence Society defines overactive bladder as the presence of involuntary bladder contractions during filling and while the person is trying to inhibit micturition. Although overactive bladder often is associated with urge incontinence, it can occur without incontinence. Approximately 16% of women and 17% of men over 40 years of age in the United States have OAB. Despite media coverage of overactive bladder and advances in treatment, many people continue to suffer in silence, probably because they are embarrassed or think it is an inevitable consequence of aging.

The symptoms of overactive bladder, which are caused by involuntary bladder contractions during filling, may occur alone or in any combination, and they constitute overactive bladder when they occur in the absence of other pathologic processes. Regardless of the primary cause of overactive bladder, two types of mechanisms are thought to contribute to its symptomatology: those involving CNS and neural control of bladder sensation and emptying (neurogenic) and those involving the smooth muscle of the bladder itself (myogenic).

The neurogenic theory for overactive bladder postulates that the CNS functions as an on–off switching circuit for voluntary control of bladder function. Therefore, damage to the CNS inhibitory pathways may trigger bladder overactivity owing to uncontrolled voiding reflexes. Neurogenic causes of overactive bladder include stroke, Parkinson disease, and multiple sclerosis. Other neurogenic causes of overactive bladder include increased sensitization of the afferent nerves that sense bladder filling or increased sensitivity to efferent nerves that produce bladder emptying.

The myogenic causes of overactive bladder are thought to result from changes in the properties of the smooth muscle of the bladder itself. One example is overactive bladder associated with bladder outlet obstruction. It is hypothesized that the sustained increase in intravesical pressure that occurs with the outlet obstruction causes a partial destruction of the nerve endings that control bladder excitability. This partial denervation results in increased excitability of the individual muscle cells. The result is urgency and frequency of urination due to spontaneous bladder contractions resulting from detrusor muscle hyperexcitability. Disorders of detrusor muscle structure and excitability also can occur as the result of the aging process or disease conditions such as diabetes mellitus. Overactive bladder symptoms usually are exaggerated by incomplete bladder emptying, a common accompaniment of overactive bladder.

**Overflow Incontinence**

Overflow incontinence is an involuntary loss of urine that occurs when intravesical pressure exceeds the maximal urethral pressure because of bladder distention in the absence of detrusor activity. It can occur with retention of urine owing to nervous system lesions or obstruction of the bladder neck. With this type of incontinence, the bladder is distended, and small amounts of urine are passed, particularly at night. In men, one of the most common causes of obstructive incontinence is enlargement of the prostate gland. Another cause that commonly is overlooked is fecal impaction (i.e., dry, hard feces in the rectum). When a large bolus of stool forms in the rectum, it can push against the urethra and block the flow of urine.

**Functional Incontinence**

Functional incontinence is often the term given to the type of incontinence that causes problems for a person attempting to use the toilet when they feel they need to urinate.

This type of incontinence may be caused by factors outside the lower urinary tract, such as the inability to locate, reach, or receive assistance in reaching an appropriate place to void. This may be a particular problem for older adults, who may have problems with mobility and manual dexterity or find themselves in unfamiliar surroundings. It occurs when a person cannot find or reach the bathroom or manipulate clothing quickly enough. Failing vision may contribute to the problem. Embarrassment in front of other people at having to use the bathroom, particularly if the timing seems inappropriate, may cause a person to delay emptying the bladder and may lead to incontinence. Treatment with drugs such as diuretics may cause the bladder to fill more rapidly than usual, making it difficult to reach the bathroom in time if there are problems with mobility or if a bathroom is not readily available. Night sedation may cause a person to sleep through the signal that normally would waken a person so that he or she could get up and empty the bladder and avoid wetting the bed.
Other Causes of Incontinence

Other causes of incontinence include decreased bladder compliance or distensibility. This abnormal bladder condition may result from radiation therapy, radical pelvic surgery, or interstitial cystitis. Many people with this disorder have severe urgency related to bladder hypersensitivity that results in loss of bladder elasticity, such that any small increase in bladder volume or detrusor function causes a sharp rise in bladder pressure and severe urgency.

Incontinence may occur as a transient and correctable phenomenon, or it may not be totally correctable and occur with various degrees of frequency. Among the transient causes of urinary incontinence are recurrent urinary tract infections, medications that alter bladder function or perception of bladder filling and the need to urinate, diuretics and conditions that increase bladder filling, stool impaction, restricted mobility, and confusional and cognitive dysfunction states.

Diagnosis

Urinary incontinence is not a single disease but a symptom with many possible causes. As a symptom, it requires full investigation to establish its cause. This usually is accomplished through a careful history, physical examination, blood tests, and urinalysis. A voiding record (i.e., diary) may be used to determine the frequency, timing, and amount of voiding, as well as other factors associated with the incontinence. Because many drugs affect bladder function, a full drug history is essential. Estimation of PVR volume is recommended for all people with incontinence. Provocative stress testing is done when stress incontinence is suspected. This test is done by having the person relax and then cough vigorously while the examiner observes for urine loss. The test usually is done in the lithotomy position; if no leakage is observed, it is repeated in the supine position. If leakage occurs, another position is selected, and the test is repeated. Urodynamic studies may be needed to provide information about urinary pressures and urine flow rates.

Treatment

Treatment or management depends on the type of incontinence, accompanying health problems, and the person’s age. It includes behavioral (e.g., pelvic floor exercises) measures; pharmacologic measures; surgical correction of pelvic relaxation disorders associated with stress incontinence; and, when urine flow cannot be controlled, noncatheter devices to obstruct urine flow or collect urine as it is passed. Indwelling catheters, although a solution to the problem of urinary incontinence, usually are considered only after all other treatment methods have failed. In some types of incontinence, such as that associated with spinal cord injury or meningo(myelo)cele, self-catheterization may provide the best means for controlling urine elimination.

Behavioral Measures. Behavioral methods include fluid management, timed/prompted voiding, pelvic floor exercises, bladder retraining, and toileting assistance. Bladder retraining and biofeedback techniques seek to reestablish cortical control over bladder function by having the person ignore urgency and respond only to cortical signals during waking hours. Toileting assistance techniques are caregiver-dependent techniques used to treat people with cognitive and motor dysfunction.

Muscle-tensing exercises of the pelvic muscles may prove effective in treatment of stress incontinence. These pelvic floor muscle exercises were first advocated by Kegel, and they commonly are called Kegel exercises. Two groups of muscles are strengthened: those of the back part of the pelvic floor (i.e., muscles used to contract the anus and control the passing of stool) and the front muscles of the pelvic floor (i.e., muscles used to stop the flow of urine during voiding). In learning the exercises, a woman concentrates on identifying the muscle groups and learning how to control contraction. After this has been accomplished, she can start an exercise program that consists of slowly contracting the muscles, beginning at the front and working to the back while counting to four and then releasing. The exercises can be done while sitting or standing and usually are performed in repetitions of 10, three times each day. A vaginal cone, a tampon-like device, may be used to enhance the benefits of the exercise. The cone is placed in the vagina, and the woman is instructed to hold it in place by contracting the proper inner muscles.

Pharmacologic Treatment. Pharmacologic treatment is aimed at using drugs to alter the physiologic mechanisms that contribute to the neurogenic or myogenic causes of incontinence. They include the use of drugs that increase sphincter tone in stress incontinence, decrease hyperreactivity of the detrusor muscle in overactive bladder/urate incontinence, or relieve outflow obstruction in overflow incontinence.

The α-adrenergic agonist drugs, such as pseudoephedrine, increase sympathetic relaxation of the detrusor muscle and internal sphincter tone and may be used in treating stress incontinence. The tricyclic antidepressants (particularly imipramine hydrochloride) are useful in facilitating urine storage because they decrease bladder contractility and increase outlet resistance. Although these drugs have a weak anticholinergic effect on smooth muscle, it has recently been postulated that their beneficial effects may be caused by increased serotonin activity (due to reuptake blockade) in the CNS. This may involve a direct inhibition of normal excitatory pathways or depression of afferent ascending neural activity. Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor, is thought to increase external sphincter tone by stimulation of the pudendal motor α-adrenergic receptors and serotonin-2 receptors. Because serious side effects (e.g., CNS effects, postural hypotension, cardiac arrhythmias) can occur with imipramine and other tricyclic antidepressants, these agents need to be used with caution.

Acetylcholine is the neurotransmitter that mediates detrusor contraction in overactive bladder. Therefore, anticholinergic medications are used to suppress these contractions. Some of the antimuscarinic drugs (e.g., oxybutynin, tolterodine, trospium, darifenacin, solifenacin) have greater selectivity for the M3 muscarinic receptors and produce fewer side effects than some of the older agents (e.g., hyoscyamine, propantheline). All anticholinergic drugs can have bothersome side effects. Although dry mouth is the most common,
incontinence and cognitive effects can occur. The use of controlled-release (e.g., oxybutynin, atolerodine) or transdermal drug delivery (e.g., oxybutynin) can reduce but not completely eliminate side effects. Botulinum toxin (BTX-A) injection into the bladder was recently introduced as an alternative treatment for people with overactive bladder who do not respond to anticholinergic agents or cannot tolerate their side effects.

The primary treatment of overflow incontinence that results from benign prostatic hypertrophy is relief of outflow obstruction. α-Adrenergic blocker therapy is based on the hypothesis that clinical manifestations of prostatic hyperplasia are caused partly by α₁-adrenergic–mediated contraction of prostatic smooth muscle, resulting in bladder outlet obstruction. Bladder outlet obstruction contributes to overfilling of the bladder and large-volume contraction, or frequency of urination resulting from incomplete bladder emptying. α-Adrenergic antagonists such as alfuzosin, doxazosin, tamsulosin, and terazosin are treatment options for men with symptomatic prostatic hyperplasia. The primary adverse effects of α-adrenergic blocker therapy are orthostatic hypotension, dizziness, fatigue, ejaculatory problems, and nasal congestion.

**Surgical Treatment of Stress Incontinence.** Surgical intervention may be considered when other treatment methods have proved ineffective. Three types of surgical procedures are used: procedures that increase outlet resistance, decrease detrusor muscle instability, or remove outflow obstruction to reduce overflow incontinence and detrusor muscle instability. A minimally invasive procedure for the treatment of stress incontinence is the periurethral injection of a bulking agent. Both of these agents typically require multiple treatment sessions to achieve a cure.

**Noncatheter Device Management Measures.** Two types of noncatheter devices commonly are used in the management of urinary incontinence: one obstructs flow, and the other collects urine as it is passed. Obstruction of urine flow is achieved by compressing the urethra or stimulating contraction of the pelvic floor muscles. Penile clamps are available that occlude the urethra without obstructing blood circulation to the penis. Clamps must be removed at 3-hour intervals to empty the bladder. Complications such as penile and urethral erosion can occur if clamps are used incorrectly. In women, compression of the urethra usually is accomplished by intravaginal devices. Surgically implanted artificial sphincters are available for use in men and women. These devices consist of an inflatable cuff that surrounds the proximal urethra. The cuff is connected by tubing to an implanted fluid reservoir and an inflation bulb. Pressing the bulb, which is placed in the scrotum in men, inflates the cuff. It is emptied in a similar manner.

When urinary incontinence cannot be prevented, various types of urine collection devices or protective pads are used. Men can be fitted with collection devices (i.e., condom or sheath urinals) that are worn over the penis and attached to a container at the bedside or fastened to the body. There are no effective external collection devices for women. Pants and pads usually are used. Dribbling bags (men) and pads (women) in which the urine changes to a nonpourable gel are available for occasional dribbling but are unsuitable for considerable wetting.

**KEY POINTS**

**INCONTINENCE**

- Incontinence represents the involuntary loss of urine due to increased bladder pressures (overflow bladder with urge incontinence or overflow incontinence) or decreased ability of the vesicourethral sphincter to prevent the escape of urine (stress incontinence).

**Special Needs of Older Adults**

Urinary incontinence is a common problem in older adults, both male and female. Incontinence increases social isolation, frequently leads to institutionalization of older adults, and predisposes to infections and skin breakdown. The economic and social costs of incontinence are staggering.

Many factors contribute to incontinence in older adults, a number of which can be altered. The overall capacity of the bladder is reduced, as is the urethral closing pressure. Detrusor muscle function also tends to decline with aging. Detrusor muscle function also tends to decline with aging, and there is a trend toward a reduction in the strength of bladder contraction and impairment in emptying that leads to larger PVR volumes. It has been proposed that many of these changes are due to degenerative detrusor muscle changes rather than neurologic changes, as was once thought. The combination of involuntary detrusor contraction (detrusor hyperactivity) leading to urge incontinence, along with impaired contractile function, leads to incomplete bladder emptying. Urge incontinence is the most frequent type of incontinence in older men. In about 50% of these men, detrusor overactivity is found. The urge to urinate comes on suddenly, without warning, accompanied by an uncontrolled detrusor contraction causing incontinence.

Furthermore, advancing age often results in restricted mobility, an increasing number of medications being taken, comorbid illness, infection, and stool impaction, all of which can precipitate urinary incontinence. Many older adults experience nocturia and also have difficulty getting to the toilet in time. This can be caused by arthritis that makes walking or removing clothing difficult or by failing vision that makes trips to the bathroom precarious, especially in new and unfamiliar surroundings.

Medication prescribed for other health problems may prevent a healthy bladder from functioning normally. Potent, fast-acting diuretics are known for their ability to cause urge incontinence. Impaired thirst or limited access to fluids predisposes to constipation with urethral obstruction and overflow incontinence and to concentrated and infected urine, which increases bladder excitability. Drugs such as hypnotics, tranquilizers, and sedatives can interfere with the conscious inhibition
of voiding, leading to urge incontinence. Diuretics, particularly in older adults, increase the flow of urine and may contribute to incontinence, particularly in people with diminished bladder capacity and in those who have difficulty reaching the toilet.

**Diagnosis and Treatment.** As with urinary incontinence in younger people, incontinence in older adults requires a thorough history and physical examination to determine the cause of the problem. A voiding history is important. A voiding diary provides a means for the person to provide objective information about the number of bathroom visits, the number of protective pads used, and even the volume of urine voided. A medication history is also important because medications can affect bladder function.\(^5\)

There are many neurologic conditions that predispose to urinary incontinence. The transient and often treatable causes of urinary incontinence in older adults may best be remembered with the acronym DIAPPERS, in which the D stands for dementia/dementias, I for infection (urinary or vaginal), A for atrophic vaginitis, P for pharmaceutical agents, P for psychological causes, E for endocrine conditions (diabetes), R for restricted mobility, and S for stool impaction.\(^29\) These eight transient causes of incontinence should be identified and treated before other treatment options are considered.

Treatment may involve changes in the physical environment so that the older adult can reach the bathroom more easily or remove clothing more quickly. Habit training with regularly scheduled toileting—usually every 2 to 4 hours—often is effective. Many older adults who void on a regular schedule can gradually increase the interval between toileting while improving their ability to suppress bladder instability. The treatment plan may require dietary changes to prevent constipation or a plan to promote adequate fluid intake to ensure adequate bladder filling and prevent urinary stasis and symptomatic urinary tract infections.

**IN SUMMARY**

Alterations in bladder function include urinary obstruction with retention of urine, neurogenic bladder, and urinary incontinence with involuntary loss of urine. Urine retention occurs when the outflow of urine from the bladder is obstructed because of urethral obstruction or impaired bladder innervation. Urethral obstruction causes bladder irritability, detrusor muscle hypertrophy, formation of trabeculae and diverticula, development of hydrourerets, and eventual renal failure.

Neurogenic bladder is caused by interruption in the innervation of the bladder. It can result in spastic bladder dysfunction caused by failure of the bladder to fill or flaccid bladder dysfunction caused by failure of the bladder to empty. Spastic bladder dysfunction usually results from neurologic lesions that are above the level of the sacral micturition reflex center; flaccid bladder dysfunction results from lesions at the level of the sacral micturition reflexes or peripheral innervation of the bladder. A third type of neurogenic disorder involves a nonrelaxing external sphincter.

Urinary incontinence is the involuntary loss of urine in amounts sufficient to be a problem. It may manifest as stress incontinence, in which the loss of urine occurs as a result of coughing, sneezing, laughing, or lifting; overactive bladder/urge incontinence, characterized by urgency, frequency, and nocturia associated with hyperactive bladder contractions; or overflow incontinence, which results when intravesical pressure exceeds the maximal urethral pressure because of bladder distention. Other causes of incontinence include a small, contracted bladder or external environmental conditions that make it difficult to access proper toileting facilities, which is called functional incontinence.

Diagnosis usually is accomplished through a careful history (including a voiding record and full drug history), physical examination, blood tests and urinalysis, and in some cases urodynamic studies. Treatment methods include correction of the underlying cause, such as the removal of obstruction due to prostatic hyperplasia; behavioral methods that focus on bladder and habit training and exercises to improve pelvic floor function; pharmacologic methods to improve bladder and external sphincter tone; surgical treatment; noncatheter device management measures; and the use of catheters and urine collection devices.

Urinary incontinence is a common problem in older adults. Many factors, including health problems, medications, and changes in bladder structure and function, contribute to incontinence in elderly persons. The acronym DIAPPERS—D (dementia), I (infection), A (atrophic vaginitis), P (pharmaceutical), P (psychological), E (endocrine), R (restricted mobility), and S (stool impaction)—emphasizes the transient and often treatable causes of incontinence in the elderly.

**CANCER OF THE BLADDER**

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Discuss the difference between superficial and invasive bladder cancer in terms of bladder involvement, extension of the disease, and prognosis.
- State the most common sign of bladder cancer.

Bladder cancer is the most frequent form of urinary tract cancer in the United States, accounting for more than 70,530 new cases and 14,680 deaths each year.\(^30\) African Americans have only half the risk of white European Americans of getting bladder cancer, and men are more commonly diagnosed than women. Approximately 90% of people with bladder cancer are older than 55 years of age.\(^30\)

The most common bladder cancer is derived from the transitional (urothelium) cells that line the bladder, so it is sometimes referred to as urothelial carcinoma.\(^30\) These tumors can range from low-grade noninvasive tumors to high-grade tumors that
The treatment of bladder cancer depends on the extent of the lesion and the health of the person. Endoscopic resection usually is done for diagnostic purposes and may be used as a treatment for superficial lesions. Diathermy (i.e., electrocautery) may be used to remove the tumors. Segmental surgical resection may be used for removing a large single lesion. When the tumor is invasive, cystectomy with resection of the pelvic lymph nodes frequently is the treatment of choice. In men, the prostate and seminal vesicles often are removed as well. Cystectomy requires urinary diversion, an alternative reservoir, usually created from the ileum (e.g., an ileal loop) that is designed to collect the urine. Traditionally, the ileostomy reservoir drains urine continuously into an external collecting device.

Although a number of chemotherapeutic drugs have been used in the treatment of bladder cancer, no chemotherapeutic regimens for the disease have been established. A primary protocol for early-diagnosed bladder cancer has been initially successful but there is no proven secondary protocol at this time. Perhaps of more importance is the increasing use of intra-vesical chemotherapy, in which the cytotoxic drug is instilled directly into the bladder, thereby avoiding the side effects of systemic therapy. These drugs can be instilled prophylactically, after surgical resection of all the demonstrable tumor tissue, or therapeutically, in the presence of residual disease. Among the chemotherapeutic drugs that have been used for this purpose are thiotepa, mitomycin C, and doxorubicin (Adriamycin). The intravesical administration of bacille Calmette-Guérin (BCG) vaccine, made from a strain of Mycobacterium bovis that formerly was used to protect against tuberculosis, causes a significant reduction in the rate of relapse and prolongs relapse-free intervals in people with cancer in situ. The vaccine is thought to act as a nonspecific stimulator of cell-mediated immunity. It is not known whether the effects of BCG are immunologic or include a component of direct toxicity. Several strains of this agent exist, and it is not known which strains are the most active and least toxic. There are also inhibitors of tumor angiogenesis and inhibitors of epidermal growth factor drugs that are proving effective with bladder cancer.

IN SUMMARY

Cancer of the bladder is the most common cause of urinary tract cancer in the United States. Bladder cancers fall into two major groups: low-grade noninvasive tumors, and high-grade invasive tumors that are associated with metastasis and a worse prognosis. Although the cause of cancer of the bladder is unknown, evidence suggests that carcinogens excreted in the urine may play a role. Microscopic and gross, painless hematuria are the most frequent presenting signs of bladder cancer. The methods used in treatment of bladder cancer depend on the cytologic grade of the tumor and the lesion’s degree of invasiveness. The methods include surgical removal of the tumor, radiation therapy, and chemotherapy. In many cases, chemotherapeutic or immunotherapeutic agents can be instilled directly into the bladder, thereby avoiding the side effects of systemic therapy.
UNIT X Disorders of Renal Function and Fluids and Electrolytes

### REVIEW EXERCISES

1. A 23-year-old man is recovering after the acute phase of a cervical (C6) spinal cord injury with complete loss of motor and sensory function below the level of injury. He is now experiencing spastic bladder contractions with involuntary and incomplete urination. Urodynamic studies reveal spastic contraction of the external sphincter with urine retention and high bladder pressures.

   - **A.** Explain the reason for the involuntary urination and incomplete emptying of the bladder despite high bladder pressures.
   - **B.** What are possible complications associated with overdistention and high pressure within the bladder?

2. A 66-year-old woman complains of leakage of urine during coughing, sneezing, laughing, or squatting down.

   - **A.** Explain the source of this woman’s problem.
   - **B.** One of the recommended treatments for stress incontinence is the use of Kegel exercises, which focus on strengthening the muscles of the pelvic floor. Explain how these exercises contribute to the control of urine leakage in women with stress incontinence.

Ms. Rytel, 26 years old, presents with a 36-hour history of vomiting and abdominal pain. She has never experienced these symptoms before. However, she has a history of multiple abdominal surgeries, including lysis of adhesions, due to a motor vehicle crash that occurred 12 months ago. On examination, Ms. Rytel’s abdomen is distended and slightly tender with hypoactive sounds. She cannot recall the last time she had a bowel movement and is presently not passing gas. She has pallor and is diaphoretic, and her vital signs are as follows: heart rate, 99/minute; blood pressure, 134/76 mm Hg; respiratory rate, 25/minute; SpO₂, 98% on room air; and temperature 99.0°F. Her WBC count is 18,000/μL (normal, 4.8 to 10.8 × 10³/μL), and an abdominal x-ray is pending. More discussion related to the pathophysiology of Ms. Rytel’s abdominal pain occurs in Chapter 44 and Chapter 45.
In the digestive system, food is broken down and its nutrients are absorbed, wastes are collected and eliminated, vitamins are synthesized, and enzymes are produced. The gastrointestinal (GI) tract is also becoming increasingly recognized as an endocrine organ that produces and augments hormones that contribute to the regulation of appetite and nutrient intake and function in the use and storage of nutrients. Three groups of hormones—gastrin, cholecystokinin (CCK), and secretins—can affect the GI tract in multiple ways consistent with endocrine, paracrine, and neurocrine substances. The GI tract has multiple collections of specialized cells interspersed throughout GI tissue that secrete these types of hormones. This differs from the thyroid, which is primarily composed of dense collections of specialized cells.

The GI tract also is referred to as the digestive tract, the alimentary canal, and, at times, the gut. The intestinal portion also may be called the bowel. For the purposes of this text, the liver and pancreas, which produce secretions that aid in digestion, are considered accessory organs.
The major physiologic functions of the GI system are to digest food and absorb nutrients into the bloodstream. It carries out these functions by motility, secretion, digestion, and absorption. In the digestive tract, food and other materials move slowly along its length as they are systematically broken down into ions and molecules that can be absorbed into the body. In the large intestine, unabsorbed nutrients and wastes are collected for later elimination.

Structurally, the GI tract is a long tube with a lumen (i.e., hollow center) beginning at the esophagus and ending at the rectum (Fig. 44.1). Nutrients do not become part of the internal environment until they have passed through the intestinal wall and have entered the blood or lymph channels. The GI tract can be divided into three parts:

1. The upper part—the mouth, esophagus, and stomach—acts as an intake source and receptacle through which food passes and in which initial digestive processes take place.

2. The middle portion—the duodenum, jejunum, and ileum—is where most digestive and absorptive processes occur.

3. The lower segment—the cecum, colon, and rectum—serves as a storage channel for the efficient elimination of waste.

The accessory organs, which include the salivary glands, liver, and pancreas, produce secretions that aid in digestion.

**Upper Gastrointestinal Tract**

The mouth forms the entryway for food to pass into the GI tract. It contains the teeth, used in the mastication of food, and the tongue and other structures needed to direct food toward the pharyngeal structures and the esophagus. The mouth also serves as a receptacle for saliva produced by the salivary glands. Saliva moistens and lubricates food, so it is easier to
swallow. It also contains enzymes involved in the initial digestion of lipids and starches.

**Esophagus**
The esophagus is a straight, collapsible tube, about 25 cm (10 inches) in length. It lies behind the trachea and connects the oropharynx with the stomach. The esophagus functions primarily as a conduit for the passage of food from the pharynx to the stomach. Its structure is uniquely designed for this purpose. The smooth muscle layers provide the peristaltic movements needed to move food along its length. In addition, the mucosal and submucosal glands secrete mucus, which protects its surface and aids in lubricating food.

There are sphincters at either end of the esophagus—an upper esophageal sphincter and a lower esophageal sphincter. The upper sphincter, the **pharyngoesophageal sphincter**, consists of a circular layer of striated muscle. It keeps air from entering the esophagus and stomach during breathing. The lower sphincter, the **gastroesophageal sphincter**, lies just above the area where the esophagus joins the stomach. The circular muscle in this area normally remains tonically contracted, creating a zone of high pressure that serves to prevent reflux of gastric contents into the esophagus. During swallowing, there is “receptive relaxation” of the lower esophageal sphincter, which allows easy propulsion of the esophageal contents into the stomach. The lower esophageal sphincter passes through an opening, or **hiatus**, in the diaphragm as it joins with the stomach, which is located in the abdomen. The portion of the diaphragm that surrounds the lower esophageal sphincter helps to maintain the zone of high pressure needed to prevent reflux of stomach contents into the esophagus.

**Stomach**
The stomach is a pouchlike structure that lies in the left side of the abdomen and serves as a food storage reservoir during the early stages of digestion. The esophagus opens into the stomach through an opening called the **cardiac orifice** (named because of its proximity to the heart). The small part of the stomach that surrounds the cardiac orifice is called the **cardiac region**. The dome-shaped region that bulges above the cardiac region is called the **fundus**, the middle portion is called the **body**, and the funnel-shaped portion that connects with the small intestine is called the **pyloric region** (Fig. 44.2). The wider and more superior part of the pyloric region, the **antrum**, narrows to form the pyloric channel as it approaches the small intestine. At the end of the pyloric channel, the circular layer smooth muscle thickens to form the **pyloric sphincter**. This muscle serves as a valve that controls the rate of stomach emptying and prevents the regurgitation of intestinal contents back into the stomach.

**Middle Gastrointestinal Tract**
The small intestine, which forms the middle portion of the digestive tract, consists of three subdivisions—the **duodenum**, **jejunum**, and **ileum** (see Fig. 44.1). The **duodenum**, which is approximately 25 cm (10 inches) long, connects the stomach to the jejunum and contains the opening for the common bile duct and the main pancreatic duct. Bile and pancreatic juices enter the intestine through these ducts. Food is digested and absorbed in the jejunum and ileum, which have a combined length of approximately 3 m (9 feet).

**Lower Gastrointestinal Tract**
The large intestine, which forms the lower GI tract, is approximately 1.5 m (4.5 to 5 feet) long and 6 to 7 cm (2.4 to 2.7 inches) in diameter. It is divided into the **cecum**, **colon**, **rectum**, and **anterior canal** (see Fig. 44.1). The **cecum** is a blind pouch that projects down at the junction of the ileum and the colon. The ileocecal valve lies at the upper border of the cecum and prevents the return of feces from the cecum into the small intestine. The appendix arises from the cecum approximately 2.5 cm (1 inch) from the ileocecal valve. The colon is further divided into ascending, transverse, descending, and sigmoid portions. The ascending colon extends from the cecum to the undersurface of the liver. From here, it turns abruptly to form the right colic (hepatic) flexure. The transverse colon crosses the upper half of the abdominal cavity from right to left and then curves sharply downward beneath the lower end of the spleen, forming the left colic (splenic) flexure. The descending colon extends from the colic flexure to the rectum. The rectum extends from the sigmoid colon to the anus. The anal canal passes between the two medial borders of the levator ani muscles. Powerful sphincter muscles guard against fecal incontinence.

**Gastrointestinal Wall Structure**
The digestive tract, below the upper third of the esophagus, is essentially a four-layered tube (Fig. 44.3).
First Layer

The inner **mucosal (first) layer** is made up of a lining epithelium, an underlying connective tissue called the *lamina propria*, and the muscularis mucosae, composed of smooth muscle cells that can contract and change the shape and surface area of the mucosal layer.\(^3\)

The mucosal layer performs numerous functions in its role as an interface between the body and environment, including

- Production of the mucus that lubricates and protects the inner surface of the alimentary canal
- Secretion of the digestive enzymes and substances that break down food
- Absorption of the breakdown products of digestion
- Maintenance of a barrier to prevent the entry of noxious substances and pathogenic organisms (This barrier includes lymphatics within the mucosa, which serve as the body’s first line of immune defense.)

The epithelial cells in the mucosal layer are constantly turning over and move from the outside of the wall structure to the luminal face every 5 days.\(^4\) Because of the regenerative capabilities of the mucosal layer, injury to this layer heals rapidly without leaving scar tissue.

Second Layer

The submucosal (second) layer consists of dense connective tissue and aggregates of adipose tissue. It contains the blood vessels, nerves, and structures responsible for secreting digestive enzymes. The submucosal glands deliver their secretions either directly to the lumen of the mucosal glands or via ducts that pass through the mucosa to the luminal surface.

Third Layer

The third layer, the **muscularis externa**, consists of an inner layer of circularly arranged smooth muscle cells and an outer layer of longitudinally arranged smooth muscle layers, which facilitate movement of contents of the GI tract.

Fourth Layer

The fourth or **serosal layer** is a serous membrane consisting of the mesothelium, which is comprised of a layer of simple squamous epithelium, and underlying connective tissue. This is the outermost layer (also known as the visceral peritoneum) of organs that are suspended in the peritoneal cavity. It is continuous with the parietal peritoneum and the mesenteries that make up the ventral and dorsal abdominal wall.\(^4\)

The peritoneum is the largest serous membrane in the body, having a surface area approximately equal to that of the skin. The peritoneum consists of two continuous layers—the *visceral peritoneum* and the *parietal peritoneum* (which lines the wall of the abdominopelvic cavity). Between the two layers is the *peritoneal cavity*, a potential space containing fluid secreted by the serous membranes. This serous fluid forms a moist and slippery surface that prevents friction between the continuously moving abdominal structures.

A *mesentery* is the double layer of peritoneum that encloses a portion or all of one of the abdominal viscera and attaches it to the abdominal wall (Fig. 44.4A). The mesentery contains the blood vessels, nerves, and lymphatic vessels that supply the intestinal wall (see Fig. 44.4B). It also holds the organs in place and stores fat. There are dorsal as well as ventral mesenteries. However, in most places, the mesentery is dorsal and attaches to the posterior abdominal wall. The mesentery that attaches to the jejunum and ileum is gathered...
in folds that attach to the dorsal abdominal wall along a short line of insertion. This gives the mesentery a fan-shaped appearance, with the intestines at the edge.

An omentum is a double-layered extension or fold of peritoneum that passes from the stomach or proximal part of the duodenum to adjacent organs in the abdominal cavity or abdominal wall. The greater omentum extends from the stomach to cover the transverse colon and the folds of the intestine. The lesser omentum extends between the transverse fissure of the liver and the lesser curvature of the stomach (see Fig. 44.4C). The greater omentum always contains some fat, which can be a considerable amount in some obese people. The greater omentum has considerable mobility and moves around in the peritoneal cavity with the peristaltic movements of the intestines. It often forms adhesions (i.e., bands of fibrous scar tissue) adjacent to inflamed organs such as the appendix, walling off the infection and thereby preventing its spread. The greater omentum also cushions the abdominal organs against injury and provides insulation against the loss of body heat.
IN SUMMARY

The GI tract is a long tube, with a lumen (i.e., hollow center) beginning at the esophagus and ending at the rectum. The functioning of the GI tract is dependent upon the release and regulation of hormones that occur in response to the consumption of food. The digestive tract can be divided into three parts—an upper part, consisting of the mouth, esophagus, and stomach; a middle part, consisting of the duodenum, jejunum, and ileum; and a lower part, consisting of the cecum, colon, and rectum. The accessory organs of the GI system consist of the salivary glands, the liver, and the pancreas. These organs produce secretions that aid in digestion.

Throughout its length, except for the mouth, throat, and upper esophagus, the GI tract is composed of four layers: an inner mucosal layer, a submucosal layer, a layer of circular and longitudinal smooth muscle fibers, and an outer serosal layer that forms the peritoneum and is continuous with the mesentery.

KEY POINTS

STRUCTURE AND FUNCTION OF THE GASTROINTESTINAL TRACT

- The GI tract is a long, hollow tube that extends from the mouth to the anus. Food and fluids that enter the GI tract do not become part of the internal environment until they have been broken down and absorbed into the blood or lymph channels.
- The nutrients contained in ingested foods and fluids must be broken down into molecules that can be absorbed across the wall of the intestine. Gastric acids and pepsin from the stomach begin the digestive process. Bile from the liver, digestive enzymes from the pancreas, and brush border enzymes break carbohydrates, fats, and proteins into molecules that can be absorbed from the intestine.

MOTILITY

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the properties of the interstitial smooth muscle cells that act as pacemakers for the GI tract.
- Compare the actions of the enteric and autonomic nervous systems (ANSs) as they relate to motility of the GI tract.
- Differentiate tonic and peristaltic movements in the GI tract.

Control of Gastrointestinal Motility

The motility of the GI tract propels food and fluids along its length, from mouth to anus, in a manner that facilitates digestion and absorption. The movements of the GI tract can be either rhythmic or tonic. The rhythmic movements consist of intermittent contractions that are responsible for mixing and moving food along the digestive tract. Rhythmic movements are found in the esophagus, antrum of the stomach, and small intestine. The tonic movements consist of a constant level of contraction or tone without regular periods of relaxation. They are found in the lower esophagus, the upper region of the stomach, the ileocecal valve, and the internal anal sphincter.

Pacemaker-Generated Slow-Wave Activity

All of the contractile tissue in the GI tract is smooth muscle, except for that in the pharynx, the upper third of the esophagus, and the external anal sphincter. Although the smooth muscle found in each region of the GI tract exhibits structural and functional differences, certain basic properties are common to all of the muscle cells. All of the smooth muscle of the GI tract is unitary smooth muscle. Low-resistance pathways, called gap junctions, electrically couple the cells. This allows the electrical signals initiating muscle contractions to move rapidly from one fiber to the next within each bundle.

Like the self-excitable cardiac muscle cells in the heart, some smooth muscle cells of the GI tract function as pacemaker cells. The interstitial cells of Cajal that are found in groups between the layers of smooth muscle tissue are hypothesized to function as the pacemakers. These cells display rhythmic, spontaneous oscillations in membrane potentials, called slow waves, ranging in frequency from about 3 per minute in the stomach to 12 per minute in the duodenum.

The amplitude and, to a lesser extent, the frequency of the slow waves can be modulated by the enteric nervous system, which lies entirely within the wall of the GI tract, and by the parasympathetic and sympathetic divisions of the ANS. In addition, a number of peptides, including neurotransmitters and GI hormones, assist in regulating GI motility. In general, the activity of the sympathetic nervous system decreases the amplitude of the slow waves or abolishes them altogether. In contrast, activation of the parasympathetic nervous system increases the amplitude of the slow waves.

Enteric Nervous System

The enteric nervous system consists of the myenteric and submucosal plexuses in the wall of the GI tract. These two plexuses are networks of nerve fibers and ganglion cell bodies. Interneurons in the plexuses connect afferent sensory fibers, effector motor neurons, and secretory cells to form reflex circuits that are located entirely in the GI tract wall.

The myenteric (Auerbach) plexus consists mainly of a linear chain of interconnected neurons that is located between the circular and longitudinal muscle layers. Because it lies between the two muscle layers and extends all the way down the intestinal wall, it is concerned mainly with motility along the
length of the gut. The submucosal (Meissner) plexus, which lies between the mucosal and muscle layers of the intestinal wall, is mainly concerned with controlling the secretions, absorption, and contraction of each segment of the intestinal tract. The activity of the neurons in the myenteric and submucosal plexuses is regulated by local influences, by input from the ANS, and by interconnecting fibers that transmit information between the two plexuses. Mechanoreceptors monitor the stretch and distention of the GI tract wall, and chemoreceptors monitor the chemical composition (i.e., osmolality, pH, and digestive products of protein and fat metabolism) of its contents. These receptors can communicate directly with ganglionic cells in the intramural plexuses or with visceral afferent fibers that influence ANS control of GI function.

**Autonomic Nervous System Innervation**

The autonomic innervation of the GI system is mediated by both the sympathetic and parasympathetic nervous systems (Fig. 44.5). Parasympathetic innervation to the stomach, small intestine, cecum, ascending colon, and transverse colon occurs through the vagus nerve. The remainder of the colon is innervated by the sympathetic innervation of the gastrointestinal tract mediated by activity in the intramural plexuses. For example, stimulation of sympathetic centers in the hypothalamus when GI motility is enhanced because of increased vagal activity, stimulation of sympathetic innervation is excitatory. Numerous vagovagal reflexes influence motility and secretions of the digestive tract.

Sympathetic innervation occurs through the thoracic chain of sympathetic ganglia and the celiac, superior mesenteric, and inferior mesenteric ganglia. The sympathetic nervous system exerts several effects on GI function. It controls the extent of mucus secretion by the mucosal glands, reduces motility by inhibiting the activity of intramural plexus neurons, enhances sphincter function, and increases the vascular smooth muscle tone of the blood vessels that supply the GI tract. The effect of sympathetic stimulation is to block the release of the excitatory neuromediators in the intramural plexuses, inhibiting GI motility. Sympathetic control of GI function is largely mediated by activity in the intramural plexuses. For example, when GI motility is enhanced because of increased vagal activity, stimulation of sympathetic centers in the hypothalamus promptly, and often completely, inhibits motility.

**Swallowing and Esophageal Motility**

Mastication begins the digestive process. Mastication (chewing) breaks food down into smaller pieces that can be easily swallowed. During this process, food is also lubricated with saliva and exposed to salivary amylase, which breaks down starch containing foods. Although chewing usually is considered a voluntary act, it can be carried out involuntarily by a person who has lost the function of the cerebral cortex.

The swallowing reflex is a rigidly ordered sequence of events that results in the propulsion of food from the mouth to the stomach through the esophagus. Although swallowing is initiated as a voluntary activity, it becomes involuntary as food or fluid reaches the pharynx. Sensory impulses for the reflex begin at tactile receptors in the pharynx and esophagus and are integrated with the motor components of the response in an area of the reticular formation of the medulla and lower pons called the swallowing center. The motor impulses for the oral and pharyngeal phases of swallowing are carried in the trigeminal (V), glossopharyngeal (IX), vagus (X), and hypoglossal (XII) cranial nerves, and impulses for the esophageal phase are carried by the vagus nerve. Diseases that disrupt these brain centers or their cranial nerves disrupt the coordination of swallowing and predispose a person to food and fluid lodging in the trachea and bronchi, which leads to risk of aspiration or aspiration pneumonia.

Swallowing consists of three phases—an oral or voluntary phase, a pharyngeal phase, and an esophageal phase (Fig 44.6). During the oral phase, the bolus is collected at the back of the mouth so the tongue can lift the food upward until it touches the posterior wall of the pharynx (Fig. 44.6A). At this point, the pharyngeal phase of swallowing is initiated. The soft palate is pulled upward, the palatopharyngeal folds are pulled together so that food does not enter the nasopharynx,
Motility of the small intestine is organized to optimize the digestion and absorption of nutrients and the propulsion of undigested material toward the colon. Peristaltic movements mix the ingested foodstuffs with digestive enzymes and secretions and circulate the intestinal contents to facilitate contact with the intestinal mucosa. The regulation of motility results from an interplay of input from the (1) enteric and (2) autonomic nervous systems and the intrinsic pacemaker activity of the (3) intestinal smooth muscle cells.

**Enteric Nervous System Innervation**

The GI system has its own nervous system, called the enteric nervous system. The enteric nervous system is composed mainly of two plexuses: (1) the outer myenteric (Auerbach) plexus that is located between the longitudinal and circular layers of smooth muscle cells and (2) an inner submucosal (Meissner) plexus that lies between the mucosal and circular muscle layers. The myenteric plexus controls mainly intestinal movements along the length of the gut, whereas the submucosal plexus is concerned mainly with controlling the function within each segment of the intestine. Fibers in the submucosal plexus also use signals originating from the intestinal epithelium to control intestinal secretion and local blood flow.

**ANS Innervation**

The intestine is also innervated by the parasympathetic and sympathetic branches of the ANS (see Fig. 44.5). Parasympathetic innervation is supplied mainly by the vagus nerve with postganglionic neurons located primarily in the myenteric and submucosal plexuses. Stimulation of these parasympathetic nerves causes a general increase in both intestinal motility and secretory activity. Sympathetic innervation is supplied by nerves that run between the spinal cord and the prevertebral ganglia and between these ganglia and the intestine. Stimulation of the sympathetic nervous system is largely inhibitory, producing a decrease in intestinal motility and secretory activity.
Intestinal smooth muscle has its own intrinsic slow-wave activity, which varies from about 12 per minute in the duodenum to 8 or 9 per minute in the ileum. This slow-wave activity is thought to reside in a network of specialized pacemaker cells, the interstitial cells of Cajal, that are interposed between the smooth muscle cells. Slow waves are not action potentials, and they do not directly induce muscle contraction; instead, they are rhythmic, wavelike fluctuations in the membrane potential that cyclically bring the membrane closer to threshold. If the peak voltage of the slow wave exceeds the cell's threshold potential, one or more action potentials may be triggered. Because action potentials occur at the peak of a smooth wave, slow-wave frequency determines the rate of smooth muscle contractions. Stretching the intestinal smooth muscle and parasympathetic nervous system stimulation increase excitability of the smooth muscle cells, whereas sympathetic stimulation decreases excitability.

The third phase of swallowing is the esophageal stage (Fig. 44.6C). As food enters the esophagus and stretches its walls, local and central nervous system (CNS) reflexes that initiate peristalsis are triggered. There are two types of peristalsis—primary and secondary. Primary peristalsis is controlled by the swallowing center in the brain stem and begins when food enters the esophagus. Secondary peristalsis is partially mediated by smooth muscle fibers in the esophagus and occurs when primary peristalsis is inadequate to move food through the esophagus. Peristalsis begins at the site of distention and moves downward. Before the peristaltic wave reaches the stomach, the lower esophageal sphincter relaxes to allow the bolus of food to enter the stomach. The pressure in the lower esophageal sphincter normally is greater than that in the stomach, an important factor in preventing the reflux of gastric contents. The lower esophageal sphincter is innervated by the vagus nerve. Increased levels of parasympathetic stimulation increase the constriction of the sphincter. The hormone gastrin also increases constriction of the sphincter. Gastrin provides the major stimulus for gastric acid production. Its action on the lower esophageal sphincter protects the esophageal mucosa when gastric acid levels are elevated.

Gastric Motility

The stomach serves as a food storage reservoir. The stomach has the ability to expand and contract in size in response to the amount of food or gas within it; in some cases, it may hold up to 1 to 1.5 L of volume. The chemical breakdown of protein begins in the stomach where food is converted to a creamy mixture called chyme.

Motility of the stomach results in the churning and mixing of solid foods and regulates the emptying of the gastric contents, or chyme, into the duodenum. Peristaltic mixing and churning contractions begin in a pacemaker area in the middle of the stomach and move toward the antrum. They occur at a frequency of three to five contractions per minute, each lasting 2 to 20 seconds. As the peristaltic wave approaches the antrum, it pushes the bolus of food toward the closed pyloris. Contraction of the antrum reverses the movement of the chyme, returning the larger particles to the body of the stomach for further churning and kneading. Because the pylorus is contracted during antral contraction, the gastric contents are emptied into the duodenum between contractions.

The pyloric sphincter prevents the backflow of gastric contents and allows them to flow into the duodenum at a rate commensurate with the ability of the duodenum to accept them. This is important because the regurgitation of bile salts and duodenal contents can damage the mucosal surface of the antrum and lead to gastric ulcers. Likewise, the duodenal mucosa can be damaged by the rapid influx of highly acid gastric contents.
or surgical incision of the muscular ring, may be done to relieve the obstruction. Gastric atony can occur as a complication of visceral neuropathies in diabetes mellitus. Surgical procedures that disrupt vagal activity also can result in gastric atony. Abnormally fast emptying occurs in the dumping syndrome, which is a consequence of certain types of gastric operations. This condition is characterized by the rapid dumping of hyperosmotic gastric secretions into the duodenum and jejunum.

Small Intestinal Motility

The small intestine is the major site for the digestion and absorption of food. Its movements are mixing and propulsive. There are two patterns of contractions in the small intestine—segmentation and peristaltic contractions. With segmentation waves, slow contractions of the circular muscle layer occlude the lumen and drive the contents forward and backward (Fig. 44.7A). Most of the contractions that produce segmentation waves are local events involving only 1 to 4 cm of intestine at a time. They function mainly to mix the chyme with the digestive enzymes from the pancreas and to ensure adequate exposure of all parts of the chyme to the mucosal surface of the intestine, where absorption takes place. The frequency of
segmenting activity increases after a meal. Presumably, it is stimulated by receptors in the stomach and intestine.

In contrast to the segmentation contractions, peristaltic movements are rhythmic propulsive movements designed to propel the chyme along the small intestine toward the large intestine. They occur when the smooth muscle layer constricts, forming a contractile band that forces the intraluminal contents forward. Normal peristalsis always moves in the direction from the mouth toward the anus. Regular peristaltic movements begin in the duodenum near the entry sites of the common duct and the main hepatic duct. They are accomplished by contraction of the proximal portion of the intestine with the sequential relaxation of its distal, or caudal, portion (see Fig. 44.7B). After material has been propelled to the ileocecal junction by peristaltic movement, stretching of the distal ileum produces a local reflex that relaxes the sphincter and allows fluid to squirt into the cecum. Motility disturbances of the small bowel are common, and auscultation of the abdomen can be used to assess bowel activity. Inflammatory changes often increase motility. In many instances, it is not certain whether changes in motility occur because of inflammation or are secondary to toxins and unabsorbed materials. Delayed passage of chyme in the small intestine also can be a problem. Transient interruption of intestinal motility often occurs after GI surgery. Intubation with suction often is required to remove the accumulating intestinal contents and gases until activity is resumed.

**Colonic Motility and Defecation**

The storage function of the colon dictates that movements in this section of the gut are different from those in the small intestine. Movements in the colon are of two types. The first types of movements are segmental mixing movements. These movements are called haustral churning because they occur within compartments called haustra. These movements involve filling and expelling the contents of the haustra, which ensures that all portions of the fecal mass are exposed to the intestinal surface. Second are the propulsive mass movements, in which a large segment of the colon (≥20 cm) contracts as a unit, moving the fecal contents forward as a unit. Mass movements last approximately 30 seconds, followed by a 2- to 3-minute period of relaxation, after which another contraction occurs. A series of mass movements lasts only for 10 to 30 minutes and may occur only several times a day. The mass movements normally initiate defecation. The normal colonic transit time is 24 to 48 hours, and normal stool is comprised of 75% water and 25% solid matter.

Defecation is controlled by the action of two sphincters—the internal and external anal sphincters (Fig. 44.8). The internal sphincter is a several-centimeters-long, circular thickening of smooth muscle that lies inside the anus. The external sphincter, which is composed of striated voluntary muscle, surrounds the internal sphincter. The external sphincter is controlled by nerve fibers in the pudendal nerve, which is part of the somatic nervous system.
system and therefore under voluntary control. Defecation reflexes control defecation. One of these reflexes is the intrinsic myenteric reflex mediated by the local enteric nervous system. It is initiated by distention of the rectal wall, with initiation of reflex peristaltic waves that spread through the descending colon, sigmoid colon, and rectum. A second defecation reflex, the parasympathetic reflex, is integrated at the level of the sacral cord. When the nerve endings in the rectum are stimulated, signals are transmitted first to the sacral cord and then reflexively back to the descending colon, sigmoid colon, rectum, and anus by the pelvic nerves. These impulses greatly increase peristaltic movements as well as relax the internal sphincter.

To prevent involuntary defecation from occurring, the external anal sphincter is under the conscious control of the cortex. As afferent impulses arrive at the sacral cord, signaling the presence of a distended rectum, messages are transmitted to the cortex. If defecation is inappropriate, the cortex initiates impulses that constrict the external sphincter and inhibit efferent parasympathetic activity. Normally, the afferent impulses in this reflex loop fatigue easily, and the urge to defecate soon ceases. At a more convenient time, contraction of the abdominal muscles compresses the contents in the large bowel, reinitiating afferent impulses to the cord.

**IN SUMMARY**

Motility of the GI tract propels food products and fluids along its length from the mouth to anus. The activity of GI smooth muscle is self-propagating and can continue without input from the nervous system. However, a network of intramural neurons that receive input from the ANS and local receptors that monitor wall stretch and the chemical composition of luminal contents regulate the rate and strength of contractions. Parasympathetic innervation occurs through the vagus nerve and nerve fibers from sacral segments of the spinal cord. This innervation increases GI motility. Sympathetic activity occurs through thoracolumbar output from the spinal cord; its paravertebral ganglia; and celiac, superior mesenteric, and inferior mesenteric ganglia. Sympathetic stimulation enhances sphincter function and reduces motility by inhibiting the activity of intramural plexus neurons.

**HORMONAL, SECRETORY, AND DIGESTIVE FUNCTIONS**

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Explain the protective function of saliva.
- Describe the function of the gastric mucosal barrier.
- Discuss the function of gut flora in terms of metabolic activities, trophic effects, and protection against invasion by pathogenic microorganisms.

**Gastrointestinal Hormones**

The GI tract is the largest endocrine organ in the body. It produces hormones that are involved in endocrine and paracrine regulation. Endocrine regulation involves an activated cell releasing a protein or hormone into the blood stream. This hormone then reaches a target cell, which responds by releasing another hormone or chemical (e.g., when stomach acid in chyme enters the intestine and stimulates the release of secretin). Paracrine regulation is a local event. For example, it occurs when a hormone reaches a target cell by simply crossing a cell membrane.

In addition, GI hormones can also interact with the CNS through the enteric and ANSs. Among the hormones produced by the GI tract are gastrin, ghrelin, secretin, CCK, and incretin hormones (glucagon-like peptide-1 [GLP-1] and GIP). These hormones influence appetite, GI motility, enzyme activity, electrolyte levels, and the secretion and actions of hormones such as growth hormone, insulin, and glucagon. A variety of factors stimulate them, including pH, quantity and type of macronutrient intake, nervous stimulation, and a deficit or excess of present hormone level. The actions of many of these hormones overlap. For example, two or more GI hormones may affect the same process in the same direction, or they may inhibit each other. The GI tract hormones and their functions are summarized in Table 44.1.

The stomach is the source of two important GI hormones—gastrin and ghrelin. G cells, located predominantly in the antrum of the stomach, produce gastrin. The primary function of gastrin is the stimulation of gastric acid secretion. Gastrin also has a trophic, or growth-producing, effect on the mucosa of the small intestine, colon, and acid-secreting area of the stomach. Ghrelin is another peptide hormone produced by endocrine cells in the mucosal layer of the fundus of the stomach. It displays potent growth hormone-releasing activity and has a stimulatory effect on food intake and digestive function, while balancing energy expenditure. The isolation of this hormone has led to new insights into its effects on other systems, such as blood sugar regulation and cardiovascular responses.

The intestine is the source of secretin, CCK, and incretin hormones. Secretin, which is secreted by S cells in the mucosa of the duodenum and jejunum, inhibits gastric acid secretion. The entry of an acid chyme into the intestine stimulates the release of secretin, which inhibits the release of gastrin. Secretin is released in response to duodenal pH, which stimulates the pancreas to secrete large quantities of fluid with a high bicarbonate concentration. The primary function of CCK, secreted by I cells in the intestinal mucosa, is the stimulation of pancreatic enzyme secretion. It potentiates the action of secretin, increasing the pancreatic bicarbonate response to low circulating levels of secretin, stimulates biliary secretion of fluid and bicarbonate, and regulates gallbladder contraction and gastric emptying. In a recent study, CCK has also been shown to inhibit food intake and to be an important mediator for appetite and the control of meal size.
Several gut-derived hormones have been identified as having what is termed an *incretin* effect. This means that they increase insulin release after an oral glucose load. This suggests that gut-derived factors can stimulate insulin secretion after a predominantly carbohydrate meal. The two hormones that account for about 90% of the incretin effect are GLP-1, which is released from L cells in the distal small bowel, and GIP, which is released by K cells in the upper gut (mainly the jejunum). Because increased levels of GLP-1 and GIP can lower blood glucose levels by augmenting insulin release in a glucose-dependent manner (i.e., at low blood glucose levels no further insulin is secreted, minimizing the risk of hypoglycemia), these hormones have been targeted as possible antidiabetic drugs. Moreover, GLP-1 can exert other metabolically beneficial effects, including suppression of glucagon release, slowing of gastric emptying, augmenting of net glucose clearance, and decreasing appetite and body weight.14,15

**Gastrointestinal Secretions**

Throughout the GI tract, secretory glands serve two basic functions:

1. Production of mucus to lubricate and protect the mucosal layer of the GI tract wall
2. Secretion of fluids and enzymes to aid in the digestion and absorption of nutrients

Each day, approximately 7000 mL of fluid is secreted into the GI tract (Table 44.2). Approximately 100 to 200 mL of this fluid leaves the body in the stool. The remainder is reabsorbed in the small and large intestines.8 These secretions are mainly water and have sodium and potassium concentrations similar to those of extracellular fluid. Because water and electrolytes for digestive tract secretions are derived from the extracellular fluid compartment, excessive secretion or impaired absorption can lead to extracellular fluid deficit.

The secretory and digestive functions of the gut are influenced by local, humoral, and neural influences. Neural control of GI secretory activity is mediated through the ANS. Secretory activity, like motility, is increased with parasympathetic stimulation and inhibited with sympathetic activity. Many of the local influences, including pH, osmolality, and chyme, consistently act as stimuli for neural and humoral mechanisms.

**Salivary Secretions**

Saliva is secreted by the salivary glands. The salivary glands consist of the parotid, submaxillary, sublingual, and buccal glands. Saliva has three functions. The first is protection and lubrication. Saliva is rich in mucus, which protects the oral mucosa and coats the food as it passes through the mouth.
Together, the epithelial, parietal, chief, and G cells within the stomach mucosa produce and secrete approximately 20 mEq of HCl in several hundred milliliters of gastric secretions (or gastric juices) each hour.

Gastric Acid Secretion. The cellular mechanism for HCl secretion by the parietal cells in the stomach involves the hydrogen (H\(^+\))/potassium (K\(^+\)) adenosine triphosphatase (ATPase) transporter and chloride (Cl\(^-\)) channels located on their luminal membrane (Fig. 44.10). During the process of HCl secretion, carbon dioxide (CO\(_2\)) produced by aerobic metabolism combines with water (H\(_2\)O), catalyzed by carbonic anhydrase, to form carbonic acid (H\(_2\)CO\(_3\)), which dissociates into H\(^+\) and bicarbonate (HCO\(_3^{-}\)). The H\(^+\) is secreted with Cl\(^-\) into the stomach, and the HCO\(_3^{-}\) moves out of the cell and into blood from the basolateral membrane. The absorbed HCO\(_3^{-}\) is responsible for the alkaline tide (increased pH) that occurs after a meal. At the luminal side of the membrane, H\(^+\) is secreted into the stomach by the H\(^+\)/K\(^+\)-ATPase transporter (also known as the proton pump). Chloride follows H\(^+\) into the stomach by diffusing through Cl\(^-\) channels in the luminal membrane. The proton pump inhibitors (e.g., omeprazole), which are used in the treatment of acid reflux and peptic ulcer, inhibit gastric acid secretion by binding irreversibly to the sulfhydryl groups of the H\(^+\)/K\(^+\)-ATPase transporter.\(^1\)

Three substances stimulate HCl secretion by the parietal cells: acetylcholine, gastrin, and histamine. Although each substance binds to different receptors on the parietal cell and has a different mechanism of action, they all serve to stimulate an increase in H\(^+\) secretion through the H\(^+\)/K\(^+\)-ATPase transporter. Acetylcholine is released from vagal nerves innervating the pharynx, and esophagus. The sublingual and buccal glands produce only mucus-type secretions. The second function of saliva is its protective antimicrobial action. The saliva cleans the mouth and contains the enzyme lysozyme, which has an antibacterial action. Third, saliva contains ptyalin and amylase, which initiate the digestion of dietary starches. The ANS primarily regulates secretions from the salivary glands. Parasympathetic stimulation increases flow and sympathetic stimulation decreases flow. The dry mouth that accompanies anxiety attests to the effects of sympathetic activity on salivary secretions.

Gastric Secretions

Mucus-secreting epithelial cells line the luminal surface and gastric pits of the stomach and serve as a protective barrier for the entire surface of the stomach (Fig. 44.9). In addition, the stomach mucosa has several other types of cells that secrete substances necessary for digestion. These include the parietal (or oxyntic) cells, chief cells, and G cells.

The parietal and chief cells are located in the proximal 80% (body and fundus) of the stomach and situated in the bases of the gastric pits (see Fig. 44.9). There are approximately 1 billion parietal cells in the stomach, which secrete hydrochloric acid (HCl) and intrinsic factor. The two major functions of gastric acid are to chemically breakdown and disinfect ingested food. Intrinsic factor is necessary for the absorption of vitamin B\(_{12}\). The chief cells secrete pepsinogen, which is converted rapidly to pepsin when exposed to the low pH of the gastric juices. Pepsin is an enzyme that initiates proteolysis or breakdown of proteins. The antrum is located in the distal 20% of the stomach. This area contains the G cells, which secrete gastrin.\(^1\)
the stomach and binds to acetylcholine receptors on the pari-
etal cells. Gastrin is secreted by G cells in the antrum of the
stomach and reaches the parietal cells through the circulation.
It binds to cholecystokinin type 2 (CCK2) receptors on the
parietal cells.3 Histamine is released from special endocrine
cells in the gastric mucosa and diffuses to nearby parietal
cells, where it binds to histamine-2 (H₂) receptors. H₁ recep-
tor blockers (e.g., cimetidine), used in the treatment of peptic
ulcer and gastroesophageal reflux, bind to H₁ receptors and
block the action of histamine on parietal cells.

**Mucosal Barrier.** One of the important characteristics of the
gastric mucosa is resistance to the highly acidic secretions
that it produces. In contrast to the acid-stimulatory factors
discussed previously, prostaglandin E₂ (after binding to its
receptor) inhibits acid secretion and stimulates mucus produc-
tion. Hence, it is an important factor in the maintenance of the
gastric mucosal barrier.13

However, when aspirin, nonsteroidal anti-inflammatory
drugs (NSAIDs), *Helicobacter pylori*, ethyl alcohol, or bile
salts damage the gastric mucosa, this barrier is disrupted and
hydrogen ions move into the tissue. As the hydrogen ions accu-
mulate in the mucosal cells, intracellular pH decreases, enzym-
ic reactions become impaired, and cellular structures are
disrupted. The result is local ischemia, vascular stasis, hypoxia,
and tissue necrosis. The mucosal surface is further protected
by prostaglandins. However, aspirin and NSAIDs inhibit pros-
taglandin synthesis by inhibition of cyclooxygenase (known as
COX, hence these agents are also known as COX inhibitors),
which also impairs the integrity of the mucosal surface.

**Intestinal Secretions**
The small intestine secretes digestive juices and receives secre-
tions from the liver and pancreas. An extensive array of mucus-
producing glands, called Brunner glands, is concentrated at
the site where the contents from the stomach and secretions
from the liver and pancreas enter the duodenum. These glands
secrete large amounts of alkaline mucus that protect the duo-
denum from the acid content in the gastric chyme and from
the action of the digestive enzymes. The activity of Brunner
glands is strongly influenced by ANS activity. For example,
sympathetic stimulation causes a marked decrease in mucus
production, leaving this area more susceptible to irritation. As
a result, ulcers are four times more likely to occur in the duo-
denum than in the stomach.16

In addition to mucus, the intestinal mucosa produces two
other types of secretions. The first is a serous fluid (pH 6.5
to 7.5) secreted by specialized cells (*i.e.*, crypts of Lieberkühn)
in the intestinal mucosal layer. This fluid, which is produced
at the rate of 2000 mL/day, acts as a vehicle for absorption.¹
The second type of secretion consists of surface enzymes that aid absorption. These enzymes are the peptidases, or enzymes that separate amino acids, and the disaccharidases, or enzymes that split sugars.

The large intestine usually secretes only mucus. ANS activity strongly influences mucus production in the bowel, as in other parts of the digestive tract. During intense parasympathetic stimulation, mucus secretion may increase to the point that the stool contains large amounts of obvious mucus. Although the bowel normally does not secrete water or electrolytes, these substances are lost in large quantities when the bowel becomes irritated or inflamed.

Intestinal Flora

The gut is the natural habitat of a large and diverse bacterial community. The major functions of the gut microflora include metabolic activities that salvage energy and absorbable nutrients, trophic effects on intestinal epithelial cells, and protection of the colonized host against invasion by pathogenic organisms.

The stomach and small intestine contain only a few species of bacteria. This is probably due to the composition of luminal contents (i.e., acids, bile, pancreatic secretions), which kills most ingested microorganisms, and the propulsive movements of this area, which impedes their colonization. The large intestine, on the other hand, contains a large and complex microbial ecosystem. It has been estimated that each individual has 300 to 500 different species of intestinal bacteria, with anaerobic bacteria outnumbering aerobic bacteria by a large percentage.

Colonization of the GI tract begins shortly after birth and is influenced by passage through the birth canal and the type of diet (breast milk vs. formula) the infant receives. Other environmental factors such as neonatal care, stress, pH, and immunologic status also can have an effect on the flora of infants.

The major metabolic function of colonic microflora is the fermentation of undigestible dietary residue and endogenous mucus produced by the epithelial cells. The genetic diversity of the microorganisms in the gut provides various enzymes and biochemical pathways that are distinct from those of the host. Fermentation of nondigestible carbohydrates, including resistant starches, cellulose, pectins, and unabsorbed sugars, is a major source of energy in the colon.

Colonic microorganisms also play a role in vitamin synthesis and in absorption of calcium, magnesium, and iron. The colonic flora, for example, synthesizes vitamin K. The newborn infant does not synthesize an adequate amount of vitamin K for the first week or so of life until the normal colonic bacterial flora becomes established.

The resident gut flora also provides a crucial line of resistance to colonization by exogenous microbes. Therefore, it is highly protective against invasion of tissues by pathogens. Colonization resistance also applies to opportunistic bacteria that are present in the gut but whose growth is restricted. The administration of broad-spectrum antibiotics can disrupt the microbial balance and allow overgrowth of species with potential pathogenicity, such as *Clostridium difficile*.

The role of probiotics as a supplement to the normal diet and as a treatment for several disease states has become increasingly recognized. Probiotics are live microorganisms that, when ingested, can modify the composition of enteric microflora. Commonly used probiotics are lactobacilli, bifidobacteria, and nonpathogenic *Escherichia coli*. Probiotics have shown value in several diseases, such as maintaining remission in ulcerative colitis.

IN SUMMARY

The secretions of the GI tract include saliva, gastric juices, bile, and pancreatic and intestinal secretions. Each day, more than 7000 mL of fluid is secreted into the digestive tract. All but 50 to 200 mL of this fluid is reabsorbed. Water, derived from the extracellular fluid compartment, is the major component of GI tract secretions. Neural, humoral, and local mechanisms contribute to the control of these secretions. The parasympathetic nervous system increases secretion, and sympathetic activity exerts an inhibitory effect. In addition to secreting fluids containing digestive enzymes, the GI tract produces and secretes hormones, such as gastrin, ghrelin, secretin, CCK, and the incretin hormones (GLP-1 and GIP), that influence appetite, GI motility, enzyme activity, and the secretions as actions of hormones such as growth hormone, insulin, and glucagon.

The gut is also the natural habitat of a large and diverse bacterial community. The major functions of the gut microflora include metabolic activities that salvage energy and absorbable nutrients, impart trophic effects on intestinal epithelial cells, and protect the colonized host against invasion by pathogenic organisms.

**DIGESTION AND ABSORPTION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Differentiate digestion from absorption.
- Relate the characteristics of the small intestine to its absorptive function.
- Compare the digestion and absorption of carbohydrates, fats, and proteins.

Digestion is the process of dismantling foods into their constituent parts. Digestion requires hydrolysis, enzyme cleavage, and fat emulsification. Hydrolysis is the breakdown of a compound that involves a chemical reaction with water. The importance of hydrolysis to digestion is evidenced by the amount of water (7 to 8 L) that is secreted into the GI tract daily. The intestinal
mucosa is impermeable to most large molecules. Therefore, most proteins, fats, and carbohydrates must be broken down into smaller particles before they can be absorbed. Although some digestion of carbohydrates and proteins begins in the stomach, digestion takes place mainly in the small intestine. The breakdown of fats to free fatty acids and monoglycerides takes place entirely in the small intestine. The liver, with its production of bile, and the pancreas, which supplies a number of digestive enzymes, play important roles in digestion.

Absorption is the process of moving nutrients and other materials from the external environment in the lumen of the GI tract into the internal environment. Absorption is accomplished by active transport and diffusion. The absorptive function of the large intestine focuses mainly on water reabsorption. A number of substances require a specific carrier or transport system. For example, vitamin B₁₂ is not absorbed in the absence of intrinsic factor, which is secreted by the parietal cells of the stomach. Transport of amino acids and glucose occurs mainly in the presence of sodium. Water is absorbed passively along an osmotic gradient.

The distinguishing characteristic of the small intestine is its large surface area, which in the adult is estimated to be approximately 250 m². Anatomic features that contribute to this enlarged surface area are the circular folds that extend into the lumen of the intestine and the villi. Villi are finger-like projections of mucous membrane, numbering as many as 25,000, which line the entire small intestine (Fig. 44.11). Each villus is equipped with an artery, vein, and lymph vessel (i.e., lacteal), which bring blood to the surface of the intestine and transport the nutrients and other materials that have passed into the blood from the lumen of the intestine (Fig. 44.12). Fats rely largely on the lymphatics for absorption.

Each villus is covered with cells called enterocytes that contribute to the absorptive and digestive functions of the small bowel and goblet cells that provide mucus. The crypts of Lieberkühn are glandular structures that open into the spaces between the villi. The enterocytes have a life span of approximately 3 to 5 days. It is believed that replacement cells differentiate from progenitor cells located in the area of the crypts. The maturing enterocytes migrate up the villus and eventually are extruded from the tip.

The enterocytes secrete enzymes that aid in the digestion of carbohydrates and proteins. These enzymes are called brush border enzymes because they adhere to the border of the villus structures. In this way, they have access to the carbohydrates and proteins as they come in contact with the absorptive surface of the intestine. This mechanism of secretion places the enzymes where they are needed and eliminates the need to produce enough enzymes to mix with the entire contents filling the lumen of the small bowel. The digested molecules diffuse through the membrane or are actively transported across the mucosal surface to enter the blood or, in the case of fatty acids, the lacteal. These molecules are then transported through the portal vein or lymphatics into the systemic circulation.

### Carbohydrate Absorption

Carbohydrates must be broken down into monosaccharides, or single sugars, before they can be absorbed from the small intestine. The average daily intake of carbohydrate in the American diet is approximately 350 to 400 g. Starch makes up approximately 60% of this total, sucrose (i.e., table sugar) approximately 30%, lactose (i.e., milk sugar) approximately 10%, and maltose less than 1%. Digestion of starch begins in the mouth with the action of amylase. Pancreatic secretions also contain an amylase. Amylase breaks down starch into several disaccharides, including maltose, isomaltose, and α-dextrins. The brush border...
enzymes convert the disaccharides into monosaccharides that can be absorbed (Table 44.3). Sucrose yields glucose and fructose, lactose is converted to glucose and galactose, and maltose is converted to two glucose molecules. When the disaccharides are not broken down to monosaccharides, they cannot be absorbed but remain as osmotically active particles in the contents of the digestive system, causing diarrhea. People with a deficiency of lactase, the enzyme that breaks down lactose, experience diarrhea when they drink milk or eat dairy products.7

Fructose is transported across the intestinal mucosa by facilitated diffusion, which does not require energy expenditure. Glucose and galactose move from the intestinal lumen into the intestinal cells by way of a sodium-glucose cotransporter (SGLT-1), against a chemical gradient. The energy for this step does not come directly from adenosine triphosphate (ATP), but from the sodium gradient created by the Na+/K+-ATPase pump located on the basolateral side of the membrane (Fig. 44.13). Glucose and galactose are transported from the cell into the blood across the basolateral membrane by facilitated diffusion using a glucose transporter-2 (GLUT-2) protein. Sodium is transported out of the cell by the Na+/K+-ATPase sodium pump. This creates the gradient needed to operate the transport system. Fructose is passively transported across the apical and basolateral membranes of the intestinal cell.

**Fat Absorption**

The average adult eating a Western diet consumes approximately 120 to 140 g of fat daily, principally as triglycerides. The first step in digestion of lipids is to break the large globules of dietary fat into smaller sizes so that water-soluble digestive enzymes can act on the surface molecules. This process, which is called emulsification, begins in the stomach with agitation of the globules and continues in the duodenum under the influence of bile from the liver (Fig. 44.14). Emulsification greatly increases the number of triglyceride molecules exposed to pancreatic lipase, which splits triglycerides into free fatty acids and monoglycerides. Bile salts play an additional role by forming micelles that transport these substances to the surface of the intestinal villi. Here they are taken into the epithelial cells and used to form new triglycerides. Water-soluble triglycerides, called chylomicrons, are formed and then released into the lymphatic system.3 Small quantities of short- and medium-chain fatty acids are absorbed directly into the portal blood rather than being converted into triglycerides and absorbed by way of the lymphatics.

Fat that is not absorbed in the intestine is excreted in the stool. Steatorrhea is the term used to describe fatty stools. Laboratory tests involve measuring the amount of fat contained in a 72-hour stool collection during which time the person is instructed to consume 50 to 150 g of fat per day. More than 6 g of fat per 24 hours is significant for poor absorption.21

Protein Absorption

Protein digestion begins in the stomach with the action of pepsin. In response to a meal and acid pH, the chief cells secrete pepsinogen, the enzyme precursor of pepsin. Pepsin is inactivated when it enters the intestine by the alkaline pH.

Proteins are broken down further by pancreatic enzymes, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. As with pepsin, the pancreatic enzymes are secreted as precursor molecules. An enzyme located on the brush border cells of the duodenal enterocytes activates trypsinogen, which lacks enzymatic activity. Activated trypsin activates additional trypsinogen molecules and other pancreatic precursor proteolytic enzymes. The amino acids are then liberated on the surface of the mucosal surface of the intestine by brush border enzymes that degrade proteins into peptides that are one, two, or three amino acids long. Similar to glucose, many amino acids are transported across the mucosal membrane in a sodium-linked process that uses ATP as an energy source. Facilitated diffusion processes that do not require sodium absorb some amino acids.

IN SUMMARY

The digestion and absorption of foods take place mainly in the small intestine. Digestion is the process of dismantling foods into their constituent parts. Digestion requires hydrolysis, enzyme cleavage, and fat emulsification. Proteins, fats, carbohydrates, and other components of the diet are broken down into molecules that can be transported from the intestinal lumen into the body fluids. Absorption is the process of moving nutrients...
and other materials from the external environment of the GI tract into the internal environment. Brush border enzymes break carbohydrates into monosaccharides that can be transported across the intestine into the bloodstream. The digestion of proteins begins in the stomach with the action of pepsin and is further facilitated in the GI tract by the pancreatic enzymes, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. Enzymes that break down proteins are released as proenzymes that are activated in the GI tract. The absorption of glucose and amino acids is facilitated by a sodium-dependent transport system. Fat in the diet is broken down by pancreatic lipase into triglycerides containing medium- and long-chain fatty acids. Bile salts form micelles that transport lipase into triglycerides containing medium- and long-chain fatty acids. Bile salts form micelles that transport lipase into triglycerides containing medium- and long-chain fatty acids.

- Alterations in Intestinal Motility

Gastrointestinal (GI) disorders do not receive the same publicity in the health-related media as heart disease, cancer, and cerebrovascular disease. In 2009, GI disease was not among the top 15 causes of disease in the United States. However, GI disease has a profound effect on those who suffer from it. According to government reports, digestive diseases rank third in the total economic burden of illness, resulting in considerable human suffering, personal expenditures for treatment, and lost working hours, as well as a drain on the nation’s economy. It has been estimated that 60 to 70 million people in the United States have a digestive disease at a cost of 100 billion dollars in medical services. Even more important is the fact that proper nutrition or a change in health practices could prevent or minimize many of these disorders.

Disruption in structure and function can occur at any level of the GI tract, from the esophagus to the colon and rectum. This chapter is divided into four sections:

1. Common manifestations of GI disorders
2. Disorders of the esophagus
3. Disorders of the stomach
4. Disorders of the small and large intestines

Disorders of the hepatobiliary system and exocrine pancreas are discussed in Chapter 46.
Chapter 45  Disorders of Gastrointestinal Function

Retching and Vomiting

Retching consists of the rhythmic spasmodic movements of the diaphragm, chest wall, and abdominal muscles. It usually precedes or alternates with periods of vomiting. Vomiting or emesis is the sudden and forceful oral expulsion of the contents of the stomach. It usually is preceded by nausea. The contents that are vomited are called vomitus. Vomiting, as a basic physiologic protective mechanism, limits the possibility of damage from ingested noxious agents by emptying the contents of the stomach and portions of the small intestine. Nausea and vomiting may represent a total-body response to drug therapy, including overdose, cumulative effects, toxicity, and side effects.

Vomiting involves two functionally distinct medullary centers—the vomiting center and the chemoreceptor trigger zone. The act of vomiting is thought to be a reflex that is integrated in the vomiting center, which is located in the dorsal portion of the reticular formation of the medulla near the sensory nuclei of the vagus (Fig. 45.1). The chemoreceptor trigger zone is located in a small area on the floor of the fourth ventricle, where it is exposed to both blood and cerebrospinal fluid. It is thought to mediate the emetic effects of bloodborne drugs and toxins.

The act of vomiting consists of taking a deep breath, closing the airways, and producing a strong, forceful contraction of the diaphragm and abdominal muscles along with relaxation of the gastroesophageal sphincter. Respiration ceases during the act of vomiting. Vomiting may be accompanied by dizziness, light-headedness, a decrease in blood pressure, and bradycardia.

After completing this section of the chapter, you should be able to meet the following objectives:

• Characterize the relationship among anorexia, nausea, retching, and vomiting.
• Describe the neural structures involved in vomiting and their mediators.

Anorexia, nausea, and vomiting are physiologic responses that are common to many GI disorders. These responses are protective to the extent that they signal the presence of disease and, in the case of vomiting, remove noxious agents from the GI tract. However, they also can contribute to impaired intake or loss of fluids and nutrients.

Anorexia

Anorexia represents a loss of appetite. Several factors influence appetite. One is hunger, which is stimulated by contractions of the empty stomach. The hypothalamus and other associated centers in the brain regulate appetite or the desire for food intake. Smell plays an important role, as evidenced by the fact that appetite can be stimulated or suppressed by the smell of food. Loss of appetite is associated with emotional factors, such as fear, depression, frustration, and anxiety. Many drugs and disease states cause anorexia. For example, in uremia, the accumulation of nitrogenous wastes in the blood contributes to the development of anorexia. Anorexia often is a forerunner of nausea, and most conditions that cause nausea and vomiting also produce anorexia.

Nausea

Nausea is an ill-defined and unpleasant subjective sensation. It is the conscious sensation resulting from stimulation of the medullary vomiting center that often precedes or accompanies vomiting. Nausea usually is preceded by anorexia, and stimuli such as foods and drugs that cause anorexia in small doses usually produce nausea when given in larger doses. A common cause of nausea is distention of the duodenum or upper small intestinal tract. Nausea frequently is accompanied by autonomic nervous system (ANS) manifestations such as watery salivation and vasocostriction with pallor, sweating, and tachycardia. Nausea also may function as an early warning signal of a pathologic process.

Remember Ms. Rytel who you met at the beginning of this unit? Ms. Rytel has a 36-hour history of vomiting. This is probably due to some adhesions from her multiple surgeries, which may be causing some obstruction. She has had nausea and experienced tachycardia and tachypnea and her color is very pale, which are all ANS manifestations.

COMMON MANIFESTATIONS OF GI DISORDERS ANOREXIA, NAUSEA, AND VOMITING

After completing this section of the chapter, you should be able to meet the following objectives:

• Characterize the relationship among anorexia, nausea, retching, and vomiting.
• Describe the neural structures involved in vomiting and their mediators.

Anorexia, nausea, and vomiting are physiologic responses that are common to many GI disorders. These responses are protective to the extent that they signal the presence of disease and, in the case of vomiting, remove noxious agents from the GI tract. However, they also can contribute to impaired intake or loss of fluids and nutrients.

Anorexia

Anorexia represents a loss of appetite. Several factors influence appetite. One is hunger, which is stimulated by contractions of the empty stomach. The hypothalamus and other associated centers in the brain regulate appetite or the desire for food intake. Smell plays an important role, as evidenced by the fact that appetite can be stimulated or suppressed by the smell of food. Loss of appetite is associated with emotional factors, such as fear, depression, frustration, and anxiety. Many drugs and disease states cause anorexia. For example, in uremia, the accumulation of nitrogenous wastes in the blood contributes to the development of anorexia. Anorexia often is a forerunner of nausea, and most conditions that cause nausea and vomiting also produce anorexia.

Nausea

Nausea is an ill-defined and unpleasant subjective sensation. It is the conscious sensation resulting from stimulation of the medullary vomiting center that often precedes or accompanies vomiting. Nausea usually is preceded by anorexia, and stimuli such as foods and drugs that cause anorexia in small doses usually produce nausea when given in larger doses. A common cause of nausea is distention of the duodenum or upper small intestinal tract. Nausea frequently is accompanied by autonomic nervous system (ANS) manifestations such as watery salivation and vasocostriction with pallor, sweating, and tachycardia. Nausea also may function as an early warning signal of a pathologic process.

Remember Ms. Rytel who you met at the beginning of this unit? Ms. Rytel has a 36-hour history of vomiting. This is probably due to some adhesions from her multiple surgeries, which may be causing some obstruction. She has had nausea and experienced tachycardia and tachypnea and her color is very pale, which are all ANS manifestations.
The vomiting center receives input from the GI tract and other organs; from the cerebral cortex; from the vestibular apparatus, which is responsible for motion sickness; and from the chemoreceptor trigger zone, which is activated by many drugs and endogenous and exogenous toxins (see Fig. 45.1). Hypoxia exerts a direct effect on the vomiting center, producing nausea and vomiting. This direct effect probably accounts for the vomiting that occurs during periods of decreased cardiac output, shock, environmental hypoxia, and brain ischemia caused by increased intracranial pressure. Inflammation of any of the intra-abdominal organs, including the liver, gallbladder, or urinary tract, can cause vomiting because of the stimulation of the visceral afferent pathways that communicate with the vomiting center. Distention or irritation of the GI tract also causes vomiting through the stimulation of visceral afferent neurons.

Several neurotransmitters and receptor subtypes are implicated as neuromediators in nausea and vomiting. Dopamine, serotonin, and opioid receptors are found in the GI tract and in the vomiting center and chemoreceptor trigger zone. Dopamine antagonists, such as prochlorperazine, depress vomiting caused by stimulation of the chemoreceptor trigger zone. Serotonin is believed to be involved in the nausea and emesis associated with cancer chemotherapy and radiation therapy. Serotonin antagonists (e.g., granisetron, ondansetron) are effective in treating the nausea and vomiting associated with these stimuli. Motion sickness appears to be a central nervous system (CNS) response to vestibular stimuli. Norepinephrine and acetylcholine receptors are located in the vestibular center. The acetylcholine receptors are thought to mediate the impulses responsible for exciting the vomiting center. Norepinephrine receptors may have a stabilizing influence that resists motion sickness. Many of the motion sickness drugs (e.g., dimenhydrinate) have a strong CNS anticholinergic effect and act on the receptors in the vomiting center and areas related to the vestibular system.

**IN SUMMARY**

The signs and symptoms of many GI tract disorders are manifested by anorexia, nausea, and vomiting. Anorexia, or loss of appetite, may occur alone or may accompany nausea and vomiting. Nausea, which is an ill-defined, unpleasant sensation, signals the stimulation of the medullary vomiting center. It often precedes vomiting and frequently is accompanied by autonomic responses, such as salivation and vasoconstriction with pallor, sweating, and tachycardia. The act of vomiting, which is integrated by the vomiting center, involves the forceful oral expulsion of the gastric contents. It is a basic physiologic mechanism that rids the GI tract of noxious agents.

**DISORDERS OF THE ESOPHAGUS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define and cite the causes of dysphagia, odynophagia, and achalasia.
- Relate the pathophysiology of gastroesophageal reflux to measures used in the diagnosis and treatment of the disorder in adults and children.
- State the reason for the poor prognosis associated with esophageal cancer.

The esophagus is a tube that connects the oropharynx with the stomach. It lies posterior to the trachea and larynx and extends through the mediastinum, intersecting the diaphragm at the level of the 11th thoracic vertebra.

The esophagus functions primarily as a conduit for passage of food and liquid from the pharynx to the stomach. The walls of the esophagus consist of a mucosal, submucosal, muscularis externa, and adventitial layer, reflecting the general structural organization of the GI tract. The inner mucosal layer contains nonkeratinized stratified epithelium. At the esophageal–stomach junction, the abrasion-resistant epithelium changes abruptly to the simple columnar epithelium of the stomach. The submucosal layer contains mucus-secreting glands that provide the mucin-containing fluids that lubricate the esophageal wall and aid in the passage of food. The muscularis externa layer consists of skeletal muscle in the superior third of the esophagus, a mixture of skeletal and smooth muscle in its middle third, and entirely smooth muscle in its lower third. The outer fibrous adventitial layer of the esophagus is composed entirely of connective tissue, which blends with surrounding structures along its route.

There are sphincters at either end of the esophagus: an upper esophageal sphincter and a lower esophageal sphincter. The upper esophageal, or pharyngoesophageal, sphincter consists of a circular layer of striated muscle, the cricopharyngeal muscle. The lower esophageal, or gastroesophageal, sphincter is an area approximately 3 cm above the junction with the stomach. The gastroesophageal sphincter is a physiologic rather than a true anatomic sphincter. That is, it acts as a valve, but the only structural evidence of a sphincter is a slight thickening of the circular smooth muscle. The smooth muscle in this portion of the esophagus normally remains tonically constricted, creating an intraluminal pressure of about 30 mm Hg, in contrast to the mid-portion of the esophagus, which normally remains relaxed.4 The lower esophageal sphincter...
passes through an opening, or \textit{hiatus}, in the diaphragm as it joins with the stomach, which is located in the abdomen. The portion of the diaphragm that surrounds the lower esophageal sphincter helps to maintain the zone of high pressure needed to prevent reflux of stomach contents.

**Congenital Anomalies**

Congenital anomalies of the esophagus require early detection and correction because they are incompatible with life. Esophageal atresia (EA) and tracheoesophageal fistula (TEF) are very common congenital anomalies of the esophagus, affecting approximately 1 in 45,000 neonates.\(^6\) In the most common form of EA, representing 85% of cases,\(^6\) the upper esophagus ends in a blind pouch and the TEF is connected to the trachea (Fig. 45.2). This defect now has a survival rate greater than 90% owing largely to early recognition and improved neonatal intensive care units. Infants weighing less than 1500 g have the greatest risk for mortality, especially when combined with a cardiac anomaly.\(^6\)

The newborn infant with EA/TEF typically has frothing and bubbling at the mouth and nose and episodes of coughing, vomiting, cyanosis, and respiratory distress. Feeding exacerbates these manifestations, causes regurgitation, and precipitates aspiration. The inability to pass a catheter into the stomach provides further evidence of the disorder. The infant with isolated TEF may develop respiratory symptoms at a later age.

Treatment of EA and TEF is surgical. Surgical ligation of the TEF and end-to-end anastomosis of the esophagus is performed when possible. Temporary ligation of the TEF and insertion of a gastrostomy tube may be used to delay the need for primary closure in preterm infants and those with more complicated lesions. The main goal of preoperative management is to maintain the airway and prevent lung damage from aspiration of gastric contents. Prone positioning minimizes movement of gastric secretions into a distal fistula, and esophageal suctioning minimizes the risk of aspiration from a blind pouch.

**Dysphagia**

The act of swallowing depends on the coordinated action of the tongue and pharynx. These structures are innervated by cranial nerves V, IX, X, and XII. \textit{Dysphagia} refers to difficulty in swallowing. If swallowing is painful, it is referred to as \textit{odynophagia}. Dysphagia can result from neuromuscular or structural causes. These disorders can produce narrowing of the esophagus, lack of salivary secretion, weakness of the muscular structures that propel the food bolus toward the stomach, or disruption of the neural networks coordinating the swallowing mechanism.\(^7\) An example of a neuromuscular cause involves lesions of the CNS, such as a stroke, which often involve the cranial nerves that control swallowing. Cancer of the esophagus and strictures resulting from scarring, a structural cause, can reduce the size of the esophageal lumen and make swallowing difficult. Scleroderma, an autoimmune disease that causes fibrous replacement of tissues throughout the body and in the GI tract, is another important cause of dysphagia.\(^8\)

People with dysphagia usually complain of choking, coughing, or an abnormal sensation of food sticking in the back of the throat or upper chest when they swallow.

In a condition called \textit{achalasia}, the lower esophageal sphincter fails to relax due to a disruption in the input from the enteric neural plexus and the vagus nerve.\(^9\) This results in difficulty passing food into the stomach, and the esophagus above the lower esophageal sphincter becomes enlarged. One or several meals may lodge in the esophagus and pass slowly into the stomach over time. There is danger of aspiration of esophageal contents into the lungs when the person lies down.

Endoscopy, barium esophagography, and videoradiography may be used to determine the site and extent of a swallowing disorder. Esophageal manometry, a procedure in which a small pressure-sensing catheter is inserted into the esophagus, may be done to measure pressures in different parts of the esophagus. Treatment of swallowing disorders depends on the cause and type of altered function that is present. Treatment of dysphagia often involves a multidisciplinary team of health professionals, including a speech pathologist. Mechanical dilation or surgical procedures may be done to enlarge the lower esophageal sphincter in persons with esophageal strictures.
Esophageal Diverticulum

A diverticulum of the esophagus is a herniation of the esophageal wall caused by a weakness of the muscularis layer. An esophageal diverticulum tends to retain food. Complaints that the food stops before it reaches the stomach are common, as are reports of gurgling, belching, coughing, and foul-smelling breath. The trapped food may cause esophagitis and ulceration. Because the condition usually is progressive, correction of the defect requires surgical intervention.

Tears (Mallory-Weiss Syndrome)

Longitudinal tears in the esophagus at the esophagogastric junction that often extend distally are termed Mallory-Weiss tears. They are most often encountered in persons with chronic alcoholism after a bout of severe retching or vomiting but may also occur during acute illness with severe vomiting. The presumed pathogenesis is inadequate relaxation of the esophageal sphincter during vomiting, with stretching and tearing of the esophageal junction at the moment of propulsive expulsion of gastric contents. Tears may involve only the mucosa or may penetrate the wall of the esophagus. Infection may lead to inflammatory ulcer or mediastinitis.

Most often bleeding is not severe and does not require surgical intervention. Severe bleeding usually responds to vasoconstrictive medications, transfusions, and balloon compression. Healing is usually prompt, with minimal or no residual effects.

Hiatal Hernia

Hiatal hernia is characterized by a protrusion or herniation of the stomach through the esophageal hiatus of the diaphragm. There are two anatomic patterns of hiatal herniation: axial, or sliding, and nonaxial, or paraesophageal. The sliding hiatal hernia is characterized by a bell-shaped protrusion of the stomach above the diaphragm (Fig. 45.3). Small sliding hiatal hernias are common and considered to be of no significance in asymptomatic people. However, in cases of severe erosive esophagitis where gastroesophageal reflux and a large hiatal hernia coexist, the hernia may retard esophageal acid clearance and contribute to the more severe esophagitis, especially Barrett esophagus (to be discussed). In paraesophageal hiatal hernias, a separate portion of the stomach, usually along the greater portion of the stomach, enters the thorax through a widened opening and then progressively enlarges. In extreme cases, most of the stomach herniates into the thorax. Large paraesophageal hiatal hernias may require surgical treatment.

Gastroesophageal Reflux

The term reflux refers to backward or return movement. In the context of gastroesophageal reflux, it refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn or pyrosis. It probably is the most common disorder originating in the GI tract. The associated symptoms usually occur soon after eating, are short lived, and seldom cause more serious problems.

The lower esophageal sphincter regulates the flow of food from the esophagus into the stomach. Both intrinsic and extrinsic mechanisms function in maintaining the anti-reflux function of the lower esophageal sphincter. The circular muscles of the distal esophagus constitute the intrinsic mechanisms, and the portion of the diaphragm that surrounds the esophagus constitutes the extrinsic mechanism. The oblique muscles of the stomach, located below the lower esophageal sphincter, form a flap that contributes to the antireflux function of the internal sphincter. Relaxation of the lower esophageal sphincter is a brain stem reflex that is mediated by the vagus nerve in response to a number of afferent stimuli. Transient relaxation with reflux is common after meals. Gastric distention and meals high in fat increase the frequency of relaxation. Normally, refluxed material is returned to the stomach by secondary peristaltic waves in the esophagus, and swallowed saliva neutralizes and washes away the refluxed acid.
Gastroesophageal Reflux Disease

According to the Montreal definition, gastroesophageal reflux disease (GERD) is a disorder involving the reflux of stomach contents that causes unfavorable symptoms or complications for the person such as regurgitation and heartburn. It is thought to be associated with transient relaxations of weak or incompetent lower esophageal sphincter. This allows reflux to occur and, in addition, decreased clearance of the refluxed acid from the esophagus after it has occurred. It results in irritant effects of the refluxate. In most cases, reflux occurs during transient relaxation of the esophagus. Delayed gastric emptying also may contribute to reflex by increasing gastric volume and pressure with greater chance for reflux. Esophageal mucosal injury is related to the destructive nature of the refluxate and the amount of time it is in contact with mucosa. Acidic gastric fluids (pH < 4.0) are particularly damaging. The gastroesophageal reflex normally is cleared and neutralized by esophageal peristalsis and salivary bicarbonate. Decreased salivation and salivary buffering capacity may contribute to impaired clearing of acid reflux from the esophagus.

Clinical Manifestations. The most frequent symptom of GERD is heartburn. It frequently is severe, occurring 30 to 60 minutes after eating. It often is made worse by bending at the waist and recumbency and usually is relieved by sitting upright. The severity of heartburn is not indicative of the extent of mucosal injury. Only a small percentage of people who complain of heartburn have mucosal injury. Often, the heartburn occurs during the night. Antacids give prompt, although transient, relief. Other symptoms include belching and chest pain. The pain usually is located in the epigastric or retrosternal area and often radiates to the throat, shoulder, or back. Because of its location, the pain may be confused with angina. The reflux of gastric contents also may produce respiratory symptoms such as asthma, chronic cough, and laryngitis, but it is important to note that the presence of these symptoms is often multifactorial in addition to the diagnosis or GERD. The proposed mechanisms of reflux-associated asthma and chronic cough include microaspiration and macroaspiration, laryngeal injury, and vagal-mediated bronchospasm.

Reflex esophagitis involves mucosal injury to the esophagus, hyperemia, and inflammation. Complications, such as strictures and Barrett esophagus, can result from persistent reflux, which produces a cycle of mucosal damage that causes hyperemia, edema, and erosion of the luminal surface. strictures are caused by a combination of scar tissue, spasm, and edema. They produce narrowing of the esophagus and cause dysphagia when the lumen becomes sufficiently constricted. Barrett esophagus (Fig. 45.4) is characterized by a reparative process in which the squamous mucosa that normally lines the esophagus gradually is replaced by abnormal columnar epithelium resembling that in the stomach or intestines. It is associated with increased risk for development of esophageal adenocarcinoma.

Diagnosis. Diagnosis of gastroesophageal reflux depends primarily on a history of reflux symptomatology and the use of optional diagnostic methods, including acid suppression trials, esophagoscopy, and ambulatory esophageal pH monitoring. Acid suppression trials involve administering a proton pump inhibitor medication for 7 to 14 days to determine if the symptoms are alleviated. Esophagoscopy involves the passage of a flexible fiberoptic endoscope into the esophagus for the purpose of visualizing the lumen of the upper GI tract. It also permits performance of a biopsy, if indicated. For 24-hour pH monitoring, a small tube with a pH electrode is passed through the nose and down into the esophagus. Data from the electrode are recorded in a small, lightweight box worn on a belt around the waist and later are analyzed by computer. The device allows the person to indicate position changes, meals, heartburn, or pain, which then can be correlated with episodes of acid reflux.

Treatment. The treatment of gastroesophageal reflux usually focuses on conservative measures. These measures include avoidance of positions and conditions that increase gastric reflux. Avoidance of large meals and foods that reduce lower esophageal sphincter tone (e.g., caffeine, fats, chocolate), alcohol, and smoking is recommended. It is recommended that meals be eaten sitting up and that the recumbent position be avoided for several hours after a meal. Bending for long periods should be avoided because it tends to increase intra-abdominal pressure and cause gastric reflux. Sleeping with the head elevated helps to prevent reflux during the night. This is
best accomplished by placing blocks under the head of the bed or by using a wedge-shaped bolster to elevate the head and shoulders by at least 6 inches. Weight loss usually is recommended in overweight people.

Antacids or a combination of antacids and alginic acid also are recommended for mild disease. Alginic acid produces a foam when it comes in contact with gastric acid; if reflux occurs, the foam rather than acid rises into the esophagus. Histamine-2 receptor (H2)–blocking antagonists, which inhibit gastric acid production, is another recommended treatment. The proton pump inhibitors act by inhibiting the gastric proton pump, which regulates the final pathway for acid secretion. These agents may be used for people who continue to have daytime symptoms, recurrent strictures, or large esophageal ulcerations. Surgical treatment may be indicated in some people.

**Gastroesophageal Reflux in Children**

Gastroesophageal reflux is a common problem in infants and children. The small reservoir capacity of an infant’s esophagus coupled with frequent spontaneous reductions in sphincter pressure contributes to reflux. At least one episode of regurgitation a day occurs in as much as half of infants aged 0 to 3 months.18 By 8 months of age, it becomes less frequent, and it abates by 2 years of age19 as the child’s diet naturally advances and they are able to maintain a more upright posture. Although many infants have minor degrees of reflux, complications can occur in children with more frequent or persistent episodes. The condition occurs more frequently in children with cerebral palsy, Down syndrome, cystic fibrosis, and other neurologic disorders.

In most cases, infants with simple reflux are thriving and healthy, and symptoms resolve between 9 and 24 months of age. Pathologic reflux is classified into three categories:

1. Regurgitation and malnutrition
2. Esophagitis
3. Respiratory problems

**Clinical Manifestations.** Symptoms of reflux esophagitis include evidence of pain when swallowing, hematemesis, anemia due to esophageal bleeding, heartburn, irritable, and sudden or inconsolable crying. Children with gastroesophageal reflux often express feeding difficulties such as refusal and aversion to certain food textures.19 Tilting of the head to one side and arching of the back may be noted in children with severe reflux. The head positioning is thought to represent an attempt to protect the airway or reduce the pain-associated reflux. Sometimes regurgitation is associated with dental caries and recurrent otalgia. The ear pain is thought to occur through referral from the vagus nerve in the esophagus to the ear.

A variety of respiratory symptoms are caused by damage to the respiratory mucosa when gastric reflux enters the esophagus. Reflux may cause laryngospasm, apnea, and bradycardia. Asthma may co-occur with GERD in about 50% of asthmatic children.18 Asthmatic children who are particularly likely to have GERD as a provocative factor are those with symptoms of reflux, those with refractory or steroid-dependent asthma, and those with nocturnal worsening of symptoms.18

**Diagnosis and Treatment.** Diagnosis of gastroesophageal reflux in infants and children often is based on parental and clinical observations. The diagnosis may be confirmed by esophageal pH probe studies, barium fluoroscopic esophagography, and nuclear scintigraphy. In some cases, esophagoscopy may be used to demonstrate reflux and obtain a biopsy.

Various treatment methods are available for infants and children with gastroesophageal reflux. Small, frequent feedings are recommended because of the association between gastric volume and transient relaxation of the esophagus. Thickening an infant’s feedings has not been found to decrease the amount of regurgitation occurrences but decrease the volume of reflux.20 Prone positioning may decrease the likelihood of symptoms, but it has also been associated with increasing the risk for sudden infant death syndrome.20 In older infants and children, raising the head of the bed and keeping the child upright may help. Medications usually are not added to the treatment regimen until pathologic reflux has been documented by diagnostic testing. Antacids are the most commonly used antireflux therapy and are readily available over the counter. H2-receptor antagonists and proton pump inhibitors may be used in children with persistent reflux. Prokinetic agents (e.g., metoclopramide, a dopamine-2 and 5-hydroxytryptamine [5-HT3] receptor antagonist; bethanechol, a cholinergic agonist) are associated with significant side effects, and their use in treatment is not recommended.20

**Cancer of the Esophagus**

Carcinoma of the esophagus accounts for approximately 1% of all diagnosed cancers.21 It is more common in adults over the age of 65 years. It occurs three times more frequently in men than women, and its occurrence is equal between African Americans and whites.21

There are two types of esophageal cancer: squamous cell carcinoma and adenocarcinoma. Most squamous cell esophageal carcinomas are attributable to alcohol and tobacco use. Worldwide, squamous cell carcinomas are the most common type of esophageal cancers, but in the United States, there has been a significant increase in adenocarcinomas.22 Barrett esophagus and GERD are the two most common risk factors for esophageal adenocarcinoma.23

Progressive dysphagia is by far the most frequent complaint of people with esophageal cancer. It is apparent first with ingestion of bulky food, later with soft food, and finally with liquids. Unfortunately, it is a late manifestation of the disease. Unintentional weight loss, anorexia, fatigue, and pain on swallowing also may occur.

Treatment of esophageal cancer depends on tumor stage. Surgical resection provides a means of cure when done in early disease and palliation when done in late disease. Radiation may be used as an alternative to surgery. Chemotherapy may be used before surgery to decrease the size of the tumor, or it
may be used along with irradiation and surgery in an effort to increase survival.24

The prognosis for people with cancer of the esophagus, although poor, has improved. Even with modern forms of therapy, however, the long-term survival is limited because, in many cases, the disease has already metastasized by the time the diagnosis is made.

**IN SUMMARY**

The esophagus is a tube that connects the oropharynx with the stomach; it functions primarily as a conduit for passage of food from the pharynx to the stomach. Although relatively uncommon, congenital anomalies (i.e., EA and TEFs) must be corrected early because they cause aspiration of gastric and oral secretions and are incompatible with life. Dysphagia refers to difficulty in swallowing; it can result from altered nerve function or from disorders that produce narrowing of the esophagus. A diverticulum of the esophagus is an outpouching of the esophageal wall caused by a weakness of the muscularis layer. Longitudinal tears (Mallory-Weiss tears) at the esophagogastric junction can occur with severe bouts of retching or vomiting. They are most often encountered in people with chronic alcoholism, but may also occur during acute illness with severe vomiting. Hiatal hernia is characterized by a protrusion or herniation of the stomach through the esophageal hiatus of the diaphragm. There are two anatomic patterns of herniation: (1) the axial or sliding hiatal hernia, which is the most common type and is characterized by bell-shaped protrusion of the stomach above the diaphragm and (2) the nonaxial or paraesophageal hernia, in which a portion of the stomach enters the thorax through a widened opening.

Gastroesophageal reflux refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn. Although most persons experience occasional gastroesophageal reflux and heartburn, persistent reflux can result in a cycle of mucosal damage that causes hyperemia, edema, erosion luminal surface, and Barrett esophagus. Reflux can cause respiratory symptoms, including chronic cough, and serve as a potential trigger for asthma. Gastroesophageal reflux is a common problem in infants and children. Reflux commonly corrects itself with age, and symptoms abate in most children by 2 years of age. Although many infants have minor degrees of reflux, some infants and small children have significant reflux that interferes with feeding, causes esophagitis, and results in respiratory symptoms and other complications.

Carcinoma of the esophagus is more common in older adults and occurs more frequently in men than women. There are two types of esophageal cancer: squamous cell carcinoma and adenocarcinoma. Most squamous cell carcinomas are attributable to alcohol and tobacco use. Adenocarcinomas are more closely linked to gastroesophageal reflux and Barrett esophagus.

**DISORDERS OF THE STOMACH**

After completing this section of the chapter, you should be able to meet the following objectives:

- Differentiate between the causes and manifestations of acute and chronic gastritis.
- Characterize the proposed role of *Helicobacter pylori* in the development of chronic gastritis and peptic ulcer and cite methods for diagnosis and treatment of the infection.
- Cite the etiologic factors in ulcer formation related to Zollinger-Ellison syndrome and stress ulcer.

The stomach is a reservoir for contents entering the digestive tract. It lies in the upper abdomen, anterior to the pancreas, splenic vessels, and left kidney. Anteriorly, the stomach is bounded by the anterior abdominal wall and the left inferior lobe of the liver. While in the stomach, food is churned and mixed with hydrochloric acid and pepsin before being released into the small intestine. Normally, the mucosal surface of the stomach provides a barrier that protects it from the hydrochloric acid and pepsin contained in gastric secretions. Disorders of the stomach include gastritis, peptic ulcer, and gastric carcinoma.

**Gastric Mucosal Barrier**

The stomach lining usually is impermeable to the acid it secretes, a property that allows the stomach to contain acid and pepsin without having its walls digested. Several factors contribute to the protection of the gastric mucosa, including an exceptionally tight fitting and therefore impermeable epithelial cell surface covering. This is coupled with the tenacious, thick mucous that is secreted by cells, which creates a protective covering for the inner stomach wall that also contains bicarbonates that serve to maintain a neutral pH.2,25

These mechanisms are collectively referred to as the gastric mucosal barrier.

The cells of the gastric epithelia are connected by tight junctions that prevent acid penetration, and they are covered with an impermeable hydrophobic lipid layer that prevents diffusion of ionized water-soluble molecules. Aspirin is able to cross the lipid layer and cause damage to the superficial cells, which can result in acute erosions.26 Gastric irritation and occult bleeding due to gastric irritation occur in a significant number of persons who take aspirin on a regular basis. Alcohol, which like aspirin is lipid soluble, also disrupts the mucosal barrier. When aspirin and alcohol are taken in combination, the permeability of the gastric mucosal barrier is significantly increased and cellular damage occurs.27 Bile acids also attack the lipid components of the mucosal barrier and afford the potential for gastric irritation when there is reflux of duodenal contents into the stomach.
Gastritis refers to inflammation of the gastric mucosa. There are many causes of gastritis, most of which can be grouped as either acute or chronic gastritis.

**Acute Gastritis**

Acute gastritis is characterized by an acute mucosal inflammatory process, usually transient in nature. The inflammation may be accompanied by emesis, pain, and, in severe cases, hemorrhage and ulceration. This erosive form is an important cause of acute GI bleeding. The condition is most commonly associated with local irritants such as aspirin or other NSAIDs, alcohol, or bacterial toxins. Oral administration of corticosteroids may also be complicated by acute hemorrhagic gastritis. Any serious illness or trauma that is accompanied by profound physiologic stress that requires substantial medical or surgical treatment renders the gastric mucosa more vulnerable to acute hemorrhagic gastritis because of mucosal injury (discussed under stress ulcers). Uremia, treatment with cancer chemotherapy drugs, and gastric radiation are other causes of acute gastritis.

The complaints of people with acute gastritis vary. People with aspirin-related gastritis can be totally unaware of the condition or may complain only of heartburn or sour stomach. Gastritis associated with excessive alcohol consumption is often a different situation; it often causes transient gastric distress, which may lead to vomiting and, in more severe situations, to bleeding and hematemesis. Gastritis caused by the toxins of infectious organisms, such as the staphylococcal enterotoxins, usually has an abrupt and violent onset, with gastric distress and vomiting ensuing approximately 5 hours after the ingestion of a contaminated food source. Acute gastritis usually is a self-limiting disorder, with complete regeneration and healing occurring within several days of removal of the inciting agent.

**Chronic Gastritis**

Chronic gastritis is a separate entity from acute gastritis. It is characterized by the absence of grossly visible erosions and the presence of chronic inflammatory changes, leading eventually to atrophy of the glandular epithelium of the stomach. There are types of chronic gastritis: *H. pylori* autoimmune and multifocal atrophic gastritis and chemical gastropathy.

**Helicobacter pylori Gastritis.** Helicobacter pylori infection is the most common cause of chronic gastritis. The prevalence in the United States is associated with socioeconomic status, increased age, Hispanic and African-American ethnicity. Helicobacter pylori is present in two thirds of the world’s population. It has been suggested that transmission in industrialized countries is largely person to person by vomitus, saliva, or feces, whereas additional transmission routes such as water may be important in developing countries. In industrialized countries, the rate of infection with *H. pylori* has decreased substantially over the past several decades owing to improved sanitation.

Helicobacter pylori gastritis is a chronic inflammatory disease of the antrum and body of the stomach. Chronic infection with *H. pylori* can lead to gastric atrophy and peptic ulcer and is associated with increased risk of gastric adenocarcinoma and the creation of mucosa-associated lymphoid tissue, which can progress to lymphoma.
Eradication of \textit{H. pylori} has proved difficult. Treatment requires combination therapy that includes the use of antibiotics such as amoxicillin, tetracycline, aminoglycoside, or bismuth salts in combination with proton pump inhibitors such as lansoprazole and omeprazole. Treatment is usually continued for 10 to 14 days. \textit{Helicobacter pylori} mutate rapidly to develop antibiotic-resistant strains. The combination of two or more antimicrobial agents increases the rates of cure and reduces the risk of resistant strains developing. The proton pump inhibitors have direct antimicrobial properties against \textit{H. pylori}, and by raising the intragastric pH they suppress bacterial growth and optimize antibiotic efficacy. Bismuth has a direct antibacterial effect against \textit{H. pylori}.

\textbf{Chronic Autoimmune and Multifocal Gastritis.} \textit{Autoimmune gastritis}, which accounts for less than 10\% of cases of chronic gastritis, is a diffuse form of gastritis that is limited to the body and fundus of the stomach, with a lack or minimal involvement of the antrum. The disorder results from the presence of autoantibodies to components of gastric gland parietal cells and intrinsic factor. Gastric gland and mucosal atrophy lead to a loss of acid production. In the most severe cases, production of intrinsic factor is lost, leading to a vitamin B\textsubscript{12} deficiency and pernicious anemia. This type of chronic gastritis is associated with other autoimmune disorders such as Hashimoto thyroiditis, Addison disease, and Graves disease.

\textbf{Diagnosis and Treatment.} Methods for establishing the presence of \textit{H. pylori} infection include the carbon (C) urea breath test using a radioactive carbon isotope ($^{13}$C- or $^{14}$C-urea), serologic tests, the stool antigen test, and endoscopic biopsy for urease testing. Serologic titers of \textit{H. pylori} antibodies specifically isolate immunoglobulin G and A.

Eradication of \textit{H. pylori} has proved difficult. Treatment requires combination therapy that includes the use of antibiotics such as amoxicillin, tetracycline, aminoglycoside, or bismuth salts in combination with proton pump inhibitors such as lansoprazole and omeprazole. Treatment is usually continued for 10 to 14 days. \textit{Helicobacter pylori} mutate rapidly to develop antibiotic-resistant strains. The combination of two or more antimicrobial agents increases the rates of cure and reduces the risk of resistant strains developing. The proton pump inhibitors have direct antimicrobial properties against \textit{H. pylori}, and by raising the intragastric pH they suppress bacterial growth and optimize antibiotic efficacy. Bismuth has a direct antibacterial effect against \textit{H. pylori}.

\textbf{Chronic Autoimmune and Multifocal Gastritis.} \textit{Autoimmune gastritis}, which accounts for less than 10\% of cases of chronic gastritis, is a diffuse form of gastritis that is limited to the body and fundus of the stomach, with a lack or minimal involvement of the antrum. The disorder results from the presence of autoantibodies to components of gastric gland parietal cells and intrinsic factor. Gastric gland and mucosal atrophy lead to a loss of acid production. In the most severe cases, production of intrinsic factor is lost, leading to a vitamin B\textsubscript{12} deficiency and pernicious anemia. This type of chronic gastritis is associated with other autoimmune disorders such as Hashimoto thyroiditis, Addison disease, and Graves disease.

\textbf{Multifocal atrophic gastritis} is a disorder of uncertain etiology that affects the antrum and adjacent areas of the stomach. It is more common than autoimmune gastritis and is seen more frequently in whites than in other races. It is particularly common in Asia, Scandinavia, and parts of Europe and Latin America. As with autoimmune gastritis, it is associated with
reduced gastric acid secretion, but achlorhydria and pernicious anemia are uncommon.

Chronic autoimmune gastritis and multifocal atrophic gastritis usually cause few symptoms related directly to gastric changes. When severe parietal cell loss occurs in the presence of autoimmune gastritis, hypochlorhydria or achlorhydria and hypergastrinemia are characteristically present. More important is the relationship of chronic gastritis to the development of peptic ulcer and gastric carcinoma. The long-term risk of gastric cancer in people with autoimmune gastritis is miniscule.30

Chemical Gastropathy. Chemical gastropathy is a chronic gastric injury resulting from reflux of alkaline duodenal contents, pancreatic secretions, and bile into the stomach. It is most commonly seen in people who have had gastroduodenostomy or gastrojejunostomy surgery. A milder form may occur in people with gastric ulcer, gallbladder disease, or various motility disorders of the distal stomach.

Peptic Ulcer Disease

Peptic ulcer disease is a term used to describe a group of ulcerative disorders that occur in areas of the upper GI tract that are exposed to acid–pepsin secretions. It is related to a variety of causes, such as medication use and H. pylori infection.35 Peptic ulcer disease, with its remissions and exacerbations, is a chronic health problem.

Peptic Ulcers

The most common forms of peptic ulcer are duodenal and gastric ulcers. Approximately 10% of the population have or will develop a peptic ulcer.12 Duodenal ulcers occur five times more commonly than gastric ulcers. The peak age for peptic ulcer has progressively increased in the last 50 years and is now between 30 and 60 years of age for duodenal ulcers, although the disorder can occur in people of any age. Gastric ulcers are more prevalent among middle-aged and older adults. For duodenal ulcers, there is a male predominance, whereas the incidence of gastric ulcers is more equally distributed between men and women.12

A peptic ulcer can affect one or all layers of the stomach or duodenum (Fig. 45.6). The ulcer may penetrate only the mucosal surface, or it may extend into the smooth muscle layers. Occasionally, an ulcer penetrates the outer wall of the stomach or duodenum. Spontaneous remissions and exacerbations are common. Healing of the muscularis layer involves replacement with scar tissue. Although the mucosal layers that cover the scarred muscle layer regenerate, the regeneration often is less than perfect, which contributes to repeated episodes of ulceration.

Etiology and Pathogenesis. A variety of risk factors have been shown to have an association with peptic ulcer disease. The two most important are infection with the bacteria H. pylori and use of aspirin and other NSAIDs.35 Both H. pylori infection and exposure to NSAIDs have been shown to impair the mechanisms that protect the gastric mucosa from the destructive effects of the corrosive acid that is continually challenging the upper GI tract mucosa, and ulceration reflects a failure of these mechanisms.

The exact mechanism by which H. pylori promotes the development of peptic ulcer has not been fully elucidated. Helicobacter pylori’s ability to induce inflammation and stimulate the release of cytokines and other mediators of inflammation contributes to mucosal damage. Infection, predominantly in the antrum of the stomach, leads to hypergastrinemia and an increased acid production. Acid injury to the duodenum is thought to promote the development of gastric metaplasia, allowing the organism to colonize these areas and promote the development of duodenal ulcers.

![Figure 45.6](https://rubin.org/porth/ch045/Fig45.6.jpg) - Gastric and duodenal ulcers. (A) Gastric ulcer—there is a characteristic sharp demarcation from the surrounding mucosa, with radiating gastric folds. The base of the ulcer is gray owing to fibrin deposition. (B) Duodenal ulcer—there are two sharply demarcated duodenal ulcers surrounded by inflamed duodenal mucosa. The gastroduodenal junction is in the midportion of the photograph. (From Rubin E., Strayer D. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine. (6th ed., p. 625). Philadelphia, PA: Lippincott Williams & Wilkins.)
The pathogenesis of NSAID-induced ulcers is thought to involve mucosal injury and inhibition of prostaglandin synthesis.\textsuperscript{30} Aspirin appears to be the most ulcerogenic of the NSAIDs. Ulcer development in NSAID users is dose dependent, but some risk occurs even with aspirin doses of 81 mg/day.\textsuperscript{36} In contrast to peptic ulcer from other causes, NSAID-induced gastric injury often is without symptoms, and life-threatening complications can occur without warning. There is reportedly less gastric irritation with the newer class of NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2–selective NSAIDs), the principal enzyme involved in prostaglandin synthesis at the site of inflammation, than with the nonselective NSAIDs that also inhibit COX-1, the enzyme involved in prostaglandin production in the gastric mucosa.

Epidemiologic studies have identified independent factors that augment the effect of \textit{H. pylori} infection and NSAID-produced peptic ulcer disease. These factors include advancing age, a prior history of peptic ulcer, multiple NSAID use, and concurrent use of warfarin (an anticoagulant) and corticosteroid drugs. Smoking may augment the risk of peptic ulcer by impairing healing. Alcohol use may cause increased acid production.\textsuperscript{35} There is no convincing evidence that dietary factors play a role in development of peptic ulcer. There is increased incidence of peptic ulcer in families. This finding is likely due to familial clustering of \textit{H. pylori} infection, and inherited genetic factors reflecting responses to the organism likely play a secondary role.

\textbf{Clinical Manifestations.} The clinical manifestations of uncomplicated peptic ulcer focus on discomfort and pain. The pain, which is described as burning, gnawing, or cramp-like, usually is rhythmic and frequently occurs when the stomach is empty—between meals and at 1 or 2 o’clock in the morning. The pain usually is located over a small area near the midline in the epigastrium near the xiphoid and may radiate below the costal margins, into the back, or, rarely, to the right shoulder. Superficial and deep epigastric tenderness and voluntary muscle guarding may occur with more extensive lesions. An additional characteristic of ulcer pain is periodicity. The pain tends to recur at intervals of weeks or months. During an exacerbation, it occurs daily for a period of several weeks and then remits until the next recurrence. Characteristically, the pain is relieved by food or antacids.

The most common complications of peptic ulcer are hemorrhage, perforation and penetration, and gastric outlet obstruction. Hemorrhage is caused by bleeding from granularity tissue or from erosion of an ulcer into an artery or vein. Acute post hemorrhagic anemia is the second most common secondary diagnosis, when people are admitted to the hospital with peptic ulcer disease.\textsuperscript{37} Evidence of bleeding may consist of hematemesis or melena. Bleeding may be sudden, severe, and without warning, or it may be insidious, producing only occult blood in the stool. Up to 20% of people with bleeding ulcers have no antecedent symptoms of pain; this is particularly true in people using NSAIDs. Acute hemorrhage is evidenced by the sudden onset of weakness; dizziness; thirst; cold, moist skin; the desire to defecate; and the passage of loose, tarry, or even red stools and coffee-ground emesis. Signs of circulatory shock develop depending on the amount of blood lost.

Perforation occurs when an ulcer erodes through all the layers of the stomach or duodenum wall. When perforation occurs in older adults, their mortality is significantly increased. With perforation, GI contents enter the peritoneum and cause peritonitis. Radiation of pain into the back, severe night distress, and inadequate pain relief from eating foods or taking antacids in persons with a long history of peptic ulcer may signify perforation. Perforation is a process similar to perforation, but with penetration the ulcer crater erodes into adjacent organs, including the pancreas, liver, or biliary tree.\textsuperscript{35} Typically it has a subtle presentation marked by a gradual increase in severity and frequency of pain.

Outlet obstruction is caused by edema, spasm, or contraction of scar tissue and interference with the free passage of gastric contents through the pylorus or adjacent areas. The presentation of an obstruction is typically insidious, with symptoms of early satiety, feeling of epigastric fullness and heaviness after meals, gastroesophageal reflux, weight loss, and abdominal pain. With severe obstruction, there is vomiting of undigested food.

\textbf{Diagnosis and Treatment.} Diagnostic procedures for peptic ulcer include history taking, laboratory tests, radiologic imaging, and endoscopic examination. The history should include careful attention to aspirin and NSAID use. Peptic ulcer should be differentiated from other causes of epigastric pain. Laboratory findings of hypochromic anemia and occult blood in the stools indicate bleeding. Endoscopy (i.e., gastroscopy and duodenoscopy) can be used to visualize the ulcer area and obtain biopsy specimens to test for \textit{H. pylori} and exclude malignant disease. X-ray studies with a contrast medium such as barium are used to detect the presence of an ulcer crater and to exclude gastric carcinoma.

The treatment of peptic ulcer has changed dramatically over the past several decades and now aims to eradicate the cause and promote a permanent cure for the disease. Pharmacologic treatment focuses on eradicating \textit{H. pylori}, relieving ulcer symptoms, and healing the ulcer crater. Acid-neutralizing, acid-inhibiting drugs and mucosa-protective agents are used to relieve symptoms and promote healing of the ulcer crater. There is no evidence that special diets are beneficial in treating peptic ulcer. Aspirin and NSAID use should be avoided when possible.

There are two pharmacologic methods for reducing gastric acid content. The first involves the neutralization of gastric acid through the use of antacids, and the second a decrease in gastric acid production through the use of \textit{H}\textsubscript{2}-receptor antagonists or proton pump inhibitors. Essentially three types of antacids are used to relieve gastric acidity: calcium carbonate, aluminum hydroxide, and magnesium hydroxide. Many antacids contain a combination of ingredients, such as magnesium-aluminum hydroxide. \textit{Calcium preparations...
are constipating and may cause hypercalcemia and the milk-alkali syndrome. This syndrome is the third leading cause for hypercalcemia hospital admissions. Magnesium hydroxide is a potent antacid that also has laxative effects. Approximately 5% to 10% of the magnesium in this preparation is absorbed from the intestine; because magnesium is excreted through the kidneys, this formulation should not be used in persons with renal failure. Aluminum hydroxide reacts with hydrochloric acid to form aluminum chloride. It combines with phosphate in the intestine, and prolonged use may lead to phosphate depletion and osteoporosis. Because antacids can decrease the absorption, bioavailability, and renal elimination of a number of drugs, this should be considered when antacids are administered with other medications.

Histamine is the major physiologic mediator for hydrochloric acid secretion. The H₁-receptor antagonists block gastric acid secretion stimulated by histamine, gastrin, and acetylcholine. The absorption of the drug is not altered by the presence or absence of food in the stomach. The volume of gastric secretion and the concentration of pepsin also are reduced. The proton pump inhibitors block the final stage of hydrogen ion secretion by blocking the action of the gastric parietal cell proton pump.

Among the agents that enhance mucosal defenses are sucralfate and prostaglandin analogs. The drug sucralfate, which is a complex salt of sucrose containing aluminum and sulfate, selectively binds to damaged ulcer tissue and serves as a barrier to acid, pepsin, and bile. Sucralfate also can directly absorb bile salts and initiate the secretion of bicarbonate and mucus. The drug is not absorbed systemically. The drug requires an acid pH for activation and should not be administered with antacids or an H₂ antagonist. Misoprostol, a prostaglandin E derivative, promotes ulcer healing by stimulating mucus and bicarbonate secretion and by modestly inhibiting acid secretion. It is the only drug in this class approved by the U.S. Food and Drug Administration (FDA) for clinical use in the prevention of NSAID-induced peptic ulcers. The drug causes dose-dependent diarrhea, and because of its stimulant effect on the uterus, it is contraindicated in women of childbearing age.

The current surgical management of peptic ulcer disease is largely limited to treatment of complications. When surgery is needed, it usually is performed using minimally invasive methods. With bleeding ulcers, hemostasis often can be achieved by endoscopic methods, and endoscopic balloon dilation often is effective in relieving outflow obstruction.

**Zollinger-Ellison Syndrome**

The Zollinger-Ellison syndrome is a rare condition caused by a gastrin-secreting tumor (gastrinoma). In persons with this disorder, increased gastric acid secretion results in GERD or severe peptic ulcer disease. The tumors may be single or multiple; duodenal tumors account for 50% to 88% of this type of gastrinoma. Approximately 50% of gastrin-producing tumors are malignant. The increased gastric secretions cause symptoms related to peptic ulcer. Diarrhea may result from hypersecretion or from the inactivation of intestinal lipase and impaired fat digestion that occur with a decrease in intestinal pH.

Hypergastrinemia may also occur in an autosomal dominant disorder called the multiple endocrine neoplasia type 1 (MEN 1) syndrome, which is characterized by multiple endocrine neoplasms. The syndrome is characterized by hyperparathyroidism and multiple endocrine tumors, including gastrinomas. Approximately 20% to 25% of gastrinomas are due to MEN 1.

The diagnosis of the Zollinger-Ellison syndrome is based on elevated serum gastrin and basal gastric acid levels and elimination of the MEN 1 syndrome as a cause of the disorder. Computed tomography (CT), abdominal ultrasonography, and selective angiography are used to localize the tumor and determine if metastatic disease is present.

Treatment of Zollinger-Ellison syndrome involves control of gastric acid secretion by proton pump inhibitors and treatment of the malignant neoplasm. Surgical removal is indicated when the tumor is malignant and has not metastasized.

**Stress Ulcers**

A stress ulcer refers to GI ulcerations that develop in relation to major physiologic stress. People at high risk for development of stress ulcers include those with large-surface-area burns (Curling’s ulcer), trauma, sepsis, acute respiratory distress syndrome, severe liver failure, and major surgical procedures. These lesions occur most often in the fundus and body of the stomach and are thought to result from ischemia to the mucosal tissue and alterations in the gastric mucosal barrier. Another form of stress ulcer, called Cushing ulcer, consists of gastric, duodenal, and esophageal ulcers arising in persons with intracranial injury, operations, or tumors. They are thought to be caused by hypersecretion of gastric acid resulting from stimulation of vagal nuclei by increased intracranial pressure.

People admitted to hospital intensive care units are at particular risk for development of stress ulcers. Proton pump inhibitors are the first line of medications used in the prevention of stress ulcers.

**Cancer of the Stomach**

According to the International Agency for Research in Cancer, in 2008, gastric carcinoma was the fourth most common type of cancer in the world. Half of the global cases are reported in Eastern Asia. Less than 30% of all cases occur in developed countries, and the global incidence of occurrence in males over females is 2 to 1. In 2010, 21,000 new diagnoses of stomach cancer were predicted in the United States and almost 11,000 people were predicted to die because of the disease.

**Etiology and Pathogenesis**

Factors thought to increase the risk of gastric cancer include genetic factors, carcinogenic factors in the diet (e.g., N-nitroso compounds and benzopyrene found in smoked and preserved foods), autoimmune gastritis, and gastric adenomas or polyps.
The incidence of stomach cancer in the United States has significantly decreased since 1930, presumably because of improved storage of food with decreased consumption of salted, smoked, and preserved foods.\(^{46}\) Chronic infection with \textit{H. pylori} appears to serve as a cofactor in some types of gastric carcinomas. The bacterial infection causes gastritis, followed by atrophy, intestinal metaplasia, and carcinoma. This sequence of cellular events depends on both the presence of the bacterial proteins and the host immune response, with the latter being influenced by the host genetic background. In addition to genetics, the likelihood of developing gastric cancer from an \textit{H. pylori} infection is related to strain of \textit{H. pylori} infection, environmental factors, and the duration of infection.\(^{47}\) Autoimmune gastritis, like \textit{H. pylori} infection, increases the risk of gastric cancer, presumably due to chronic inflammation and intestinal metaplasia.\(^{48}\)

Between 50% and 60% of gastric cancers occur in the pyloric region or adjacent to the antrum. Compared with a benign ulcer, which has smooth margins and is concentrically shaped, gastric cancers tend to be larger, are irregularly shaped, and have irregular margins.

**Clinical Manifestations**

Unfortunately, stomach cancers often are asymptomatic until late in their course. Symptoms, when they do occur, usually are vague and include indigestion, anorexia, weight loss, vague epigastric pain, vomiting, and an abdominal mass. Because these symptoms are essentially nonspecific, early detection is difficult.

**Diagnosis and Treatment**

Diagnosis of gastric cancer is accomplished by a variety of techniques, including barium x-ray studies, endoscopic studies with biopsy, and cytologic studies (e.g., Papanicolaou smear) of gastric secretions.\(^{49}\) Cytologic studies can prove particularly useful as routine screening tests for persons with atrophic gastritis or gastric polyps. CT and endoscopic ultrasonography often are used to delineate the spread of a diagnosed stomach cancer.

Depending on the location and extent of the lesion, surgery in the form of radical subtotal gastrectomy usually is the treatment of choice. Irradiation and chemotherapy have not proved particularly useful as primary treatment modalities in stomach cancer. These methods usually are used for palliative purposes or to control metastatic spread of the disease.

**IN SUMMARY**

Disorders of the stomach include gastritis, peptic ulcer, and cancer of the stomach. Gastritis refers to inflammation of the gastric mucosa. Acute gastritis refers to a transient inflammation of the gastric mucosa; it is associated most commonly with local irritants such as bacterial endotoxins, caffeine, alcohol, and aspirin. Chronic gastritis is characterized by the absence of grossly visible erosions and the presence of chronic inflammatory changes leading eventually to atrophy of the glandular epithelium of the stomach. There are three main types of chronic gastritis: \textit{H. pylori} gastritis, autoimmune gastritis and multifocal atrophic gastritis, and chemical gastropathy. \textit{Helicobacter pylori} is an “S”-shaped bacterium that colonizes the mucus-secreting epithelial cells of the stomach. Infection increases the risk of chronic gastritis, peptic ulcer, gastric carcinoma, and low-grade B-cell lymphoma. Treatment of \textit{H. pylori} infection involves the use of multigang therapy aimed at increasing the pH of gastric secretions and antimicrobial agents designed to eradicate the organism.

**Peptic ulcer** is a term used to describe a group of ulcerative disorders that occur in areas of the upper GI tract that are exposed to acid–pepsin secretions, most commonly the duodenum and stomach. There are two main causes of peptic ulcer: \textit{H. pylori} infection and aspirin or NSAID use. The treatment of peptic ulcer focuses on eradication of \textit{H. pylori}, avoidance of gastric irritation from NSAIDs, and conventional pharmacologic treatment directed at symptom relief and ulcer healing.

The \textit{Zollinger-Ellison} syndrome is a rare condition caused by a gastrin-secreting tumor in which gastric acid secretion reaches such levels that ulceration becomes inevitable. Stress ulcers, also called \textit{Curling ulcers}, occur in relation to major physiologic stresses such as burns and trauma and are thought to result from ischemia, tissue acidosis, and bile salts entering the stomach in critically ill persons with decreased GI tract motility. Another form of stress ulcer, \textit{Cushing ulcer}, occurs in persons with intracranial trauma or surgery and is thought to be caused by hypersecretion of gastric acid resulting from stimulation of vagal nuclei by increased intracranial pressure.

Although the incidence of cancer of the stomach has declined over the past 50 years in the United States, it remains the leading cause of death worldwide. Because there are few early symptoms with this form of cancer, the disease often is far advanced at the time of diagnosis.

**DISORDERS OF THE SMALL AND LARGE INTESTINES**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the characteristics of Crohn disease and ulcerative colitis.
- Describe the pathogenesis of the symptoms associated with appendicitis.

There are many similarities in conditions that disrupt the integrity and function of the small and large intestines. The walls of the small and large intestines consist of five layers:
1. An inner mucosal layer, which lines the lumen of the intestine
2. A submucosal layer
3. A circular muscularis layer
4. A layer of longitudinal muscle fibers
5. An outer serosal layer

Among the conditions that cause altered intestinal function are irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), diverticulitis, appendicitis, disorders of bowel motility (i.e., diarrhea, constipation, and bowel obstruction), malabsorption syndrome, and cancers of the colon and rectum.

**Irritable Bowel Syndrome**

The term *irritable bowel syndrome* is used to describe a functional GI disorder characterized by a variable combination of chronic and recurrent intestinal symptoms not explained by structural or biochemical abnormalities. There is evidence to suggest that 10% to 15% of the U.S. population have the disorder and one in four people worldwide. Irritable bowel disease is characterized by persistent or recurrent symptoms of abdominal pain; altered bowel function; and varying complaints of flatulence, bloating, nausea and anorexia, constipation or diarrhea, and anxiety or depression. A hallmark of IBS is abdominal pain that is relieved by defecation and associated with a change in consistency or frequency of stools. Abdominal pain usually is intermittent, cramping, and in the lower abdomen. It does not usually occur at night or interfere with sleep. The condition is believed to result from dysregulation of intestinal motor activity and central neural functions modulated by the CNS. People with IBS tend to experience increased motility and abnormal intestinal contractions in response to psychological and physiologic stresses. The role that psychological factors play in the disease is uncertain. Although changes in intestinal activity are normal responses to stress, these responses appear to be exaggerated in persons with IBS. Women tend to be affected more often than men. Menarche often is associated with onset of the disorder. Women frequently notice an exacerbation of symptoms during the premenstrual period, suggesting a hormonal component.

**Clinical Manifestations and Diagnosis**

Because IBS lacks anatomic or physiologic markers, diagnosis is usually based on signs and symptoms of abdominal pain or discomfort, bloating, and constipation or diarrhea, or alternating bouts of constipation and diarrhea. A commonly used set of diagnostic criteria require continuous or recurrent symptoms of at least 12 weeks’ duration (which may be nonconsecutive) of abdominal discomfort or pain in the preceding 12 months, with two of three accompanying features: relief with defecation, onset associated with a change in bowel frequency, and onset associated with a change in form (appearance) of stool.

Other symptoms that support the diagnosis of IBS include abnormal stool frequency (more than three times per day or less than three times per week), abnormal stool form (lumpy/hard or loose/watery), abnormal stool passage (straining, urgency, or feeling of incomplete evacuation), passage of mucus, and bloating or feeling of abdominal distention. A history of lactose intolerance should be considered because intolerance to lactose and other sugars may be a precipitating factor in some people. The acute onset of symptoms raises the likelihood of organic disease, as does weight loss, anemia, fever, occult blood in the stool, nighttime symptoms, or signs and symptoms of malabsorption. These signs and symptoms require additional investigation of differential diagnoses.

**Treatment**

The treatment of IBS focuses on methods of stress management, particularly those related to symptom production. Reassurance is important. Usually, no special diet is indicated, although adequate fiber intake usually is recommended. Avoidance of offending dietary substances by following specific elimination diets that omit such foods as fatty and gas-producing foods, alcohol, and caffeine-containing beverages may be beneficial. Various pharmacologic agents, including antispasmodic and anticholinergic drugs, have been used with varying success in treatment of the disorder. Alosetron, a 5-HT3 antagonist, was the first specific drug to be approved by the FDA for the treatment of irritable bowel disease. It acts by reducing intestinal secretion, decreasing visceral afferent nerve activity (thereby reducing abdominal pain), and reducing intestinal motility. The drug, which was indicated for treatment of women with the severe diarrheal form of the disease, was removed from the market in late 2000 because of serious side effects involving ischemic colitis and severe constipation and then reintroduced in 2002 under a restricted prescribing program.

**Inflammatory Bowel Disease**

The term *inflammatory bowel disease* is used to designate two related inflammatory intestinal disorders: Crohn disease and ulcerative colitis. The worldwide prevalence of IBD is 396 in 10,000 persons. Although the two diseases differ sufficiently to be distinguishable, they have many features in common. Both diseases produce inflammation of the bowel, both lack confirming evidence of a proven causative agent, both have a pattern of familial occurrence, and both can be accompanied by systemic manifestations. Crohn disease most commonly affects the distal small intestine and proximal colon, but can affect any area of the GI tract from the esophagus to the anus, whereas ulcerative colitis is confined to the colon and rectum (Fig. 45.7). The distinguishing characteristics of Crohn disease and ulcerative colitis are summarized in Table 45.1.

**Etiology and Pathogenesis**

A remarkable feature of the GI tract is that the mucosal immune system is always ready to respond against ingested pathogens but is unresponsive to the normal intestinal microflora. According to the currently accepted hypothesis, this normal
state of homeostasis is disrupted in IBD, leading to unregulated and exaggerated immune responses. The question remains if the response is an appropriate defense mechanism to a pathogen or is the immune system responding in an inappropriate manner. Thus, as in many other autoimmune disorders, the pathogenesis of Crohn disease and ulcerative colitis involves a failure of immune regulation, genetic predisposition, and an environmental trigger, especially microbial flora.57

Genetic Susceptibility. The genetic basis of IBD has long been suspected. First-degree relatives of people diagnosed with IBD have a 30 to 100 times greater incidence of IBD.58 For Crohn disease, a recent study found a concordance rate of 27% in monozygotic twins and 2% in dizygotic twins.59 With ulcerative colitis, this genetic component was found to be weaker, but still present. These associations clearly indicate that genetic susceptibility plays an important role in the development of IBD. However, classic Mendelian inheritance patterns are not seen, and IBD therefore cannot be attributed to a single gene. Many candidate genes are known to be associated with, and likely to contribute to, the development of IBD. These include the human leukocyte antigen (HLA) associations. Accumulating evidence also suggests that both Crohn disease and ulcerative colitis are associated with profound disorders of mucosal immunity. The IBD1 locus on chromosome 16 has recently been shown to contribute to Crohn disease.60 The product of the implicated gene, NOD2 (so named because the coded protein has a nucleotide oligomerization domain) activates the nuclear factor kappa beta (NFκβ) transcription factor. The NOD2 protein is expressed in many types of leukocytes as well as epithelial cells and is thought to act as an intracellular receptor for lipopolysaccharides on microbes. On binding microbial products, it may trigger the NFκβ pathway, which leads to the production of cytokines and other proteins involved in the innate immune defense against microorganisms. The NOD2 mutations that are associated with Crohn disease may reduce the activity of the protein, resulting in persistence of intracellular microbes and prolonged immune responses. Another region studied extensively is IBD3 on chromosome 6. This is the area that includes the HLA complex that has been linked to Crohn disease and ulcerative colitis. Another area linked specifically to Crohn disease is on chromosome 5q (IBD5). This area is rich in genes encoding several cytokines that may contribute to the disease.

Role of Environmental Factors. Animal studies have definitively established the importance of the gut flora in IBD. The sites affected by IBD, the distal ileum and the colon, are awash with bacteria. Although it is unlikely that IBD is caused by microbes, it seems likely that microbes may provide the antigen trigger for an unregulated immune response. Another region studied extensively is smoking.57 Crohn disease is more commonly associated with people who currently smoke while ulcerative colitis is associated with people who have never smoked or have quit. The relationship between nicotine and IBD is thought to be due to coagulopathies occurring in the intestine or as a result of an immune response.

Clinical Manifestations

The clinical manifestations of both Crohn disease and ulcerative colitis are ultimately the result of activation of inflammatory cells with elaboration of inflammatory mediators that cause nonspecific tissue damage. Both diseases are characterized by remissions and exacerbations of diarrhea, fecal urgency, and weight loss. Acute complications, such as intestinal obstruction, may develop during periods of fulminating disease (Fig. 45.8).

A number of systemic manifestations have been identified in people with Crohn disease and ulcerative colitis. These include axial arthritis affecting the spine and sacroiliac joints and oligoarticular arthritis affecting the large joints of the arms and legs; inflammatory conditions of the eye, usually uveitis; skin lesions, especially erythema nodosum; stomatitis; and autoimmune anemia, hypercoagulability of blood, and sclerosing cholangitis. Occasionally, these systemic manifestations may herald the recurrence of intestinal disease. In children, growth retardation may occur, particularly if the symptoms are prolonged and nutrient intake has been poor.

Crohn Disease

Crohn disease is a recurrent, granulomatous type of inflammatory response that can affect any area of the GI tract. The terminal ileum or cecum is the most common portion of the bowel where inflammation occurs. It is a slowly progressive, relentless, and often disabling disease. The disease usually strikes people in their twenties or thirties, with women being affected slightly more often than men.

A characteristic feature of Crohn disease is the sharply demarcated, granulomatous lesions that are surrounded by normal-appearing mucosal tissue. When the lesions are multiple, they often are referred to as skip lesions because they are interspersed between what appear to be normal segments of the bowel. All the layers of the bowel are involved, with the submucosal layer affected to the greatest extent. The surface of the inflamed bowel usually has a characteristic “cobblestone” appearance resulting from the fissures and crevices that develop, surrounded by areas of submucosal edema. (Fig. 45.9). There usually is a relative sparing of the smooth muscle layers of the bowel, with marked inflammatory and fibrotic changes of the submucosal layer. The bowel wall, after a time, often becomes thickened and inflexible; its appearance has been likened to a lead pipe or rubber hose. The adjacent mesentery may become inflamed, and the regional lymph nodes and channels may become enlarged.

Clinical Manifestations. The clinical course of Crohn disease is variable; often, there are periods of exacerbations and remissions, with symptoms being related to the location of the lesions. The principal symptoms, which are dependent upon the area of the GI system that is affected, include diarrhea, abdominal pain, weight loss, fluid and electrolyte disorders, malaise, and low-grade fever. Because Crohn disease affects the submucosal layer to a greater extent than the mucosal layer, there is less bloody diarrhea than with ulcerative colitis. Ulceration of the perianal skin is common, largely because of the severity of the diarrhea. The absorptive surface of the intestine may be disrupted; nutritional deficiencies may occur, related to the specific segment of the intestine involved. When Crohn disease occurs in childhood, one of its major manifestations may be retardation of growth and significant malnutrition.

Complications of Crohn disease include fistula formation, abdominal abscess formation, and intestinal obstruction. Fistulas are tubelike passages that form connections between different sites in the GI tract. They also may develop between other sites, including the bladder, vagina, urethra, and skin. Perineal fistulas that originate in the ileum are relatively
establishing the presence and nature of fistulas. CT scans may be used to detect an inflammatory mass or abscess.

**Treatment.** Treatment methods focus on terminating the inflammatory response and promoting healing, maintaining adequate nutrition, and preventing and treating complications. Several medications have been successful in suppressing the inflammatory reaction, including the corticosteroids, sulfasalazine, metronidazole, azathioprine, 6-mercaptopurine, methotrexate, and infliximab. Surgical resection of damaged bowel, drainage of abscesses, or repair of fistula tracts may be necessary.

Sulfasalazine is a topically active agent that has a variety of anti-inflammatory effects. The beneficial effects of

common. Fistulas between segments of the GI tract may lead to malabsorption, syndromes of bacterial overgrowth, and diarrhea. They also can become infected and cause abscess formation.

**Diagnosis.** The diagnosis of Crohn disease requires a thorough history and physical examination. Sigmoidoscopy is used for direct visualization of the affected areas and to obtain biopsies. Measures are taken to exclude infectious agents as the cause of the disorder. This usually is accomplished by the use of stool cultures and examination of fresh stool specimens for ova and parasites. In people suspected of having Crohn disease, radiographic contrast studies provide a means for determining the extent of involvement of the small bowel and establishing the presence and nature of fistulas. CT scans may be used to detect an inflammatory mass or abscess.
sulfasalazine are attributable to one component of the drug, 5-aminosalicylic acid (5-ASA). Agents containing 5-ASA affect multiple sites in the arachidonic acid pathway critical to the pathogenesis of inflammation. Sulfasalazine contains 5-ASA with sulfapyridine linked to an azo bond. The drug is poorly absorbed from the intestine, and the azo linkage is broken down by the bacterial flora in the ileum and colon to release 5-ASA. Metronidazole is an antibiotic used to treat bacterial overgrowth in the small intestine. A recent meta-analysis found two thiopurine drugs, azathioprine and 6-mercaptopurine, to be effective in reducing the reoccurrence of Crohn disease.\(^6\) The use of methotrexate is another option for clinicians to choose instead of the thiopurine drugs, although the studies regarding its use are limited.\(^5\) Infliximab is a monoclonal antibody that targets the destruction of tumor necrosis factor (TNF), a mediator of the inflammatory response, whose expression is increased in inflammatory processes such as Crohn disease.\(^6\) It is the first drug approved specifically for Crohn disease and is used in the management of people with active moderate-to-severe Crohn disease who have had an inadequate response to corticosteroids or other immune modulators. Although infliximab is currently the only anti-TNF agent approved for treatment of persons with IBD, controlled studies of other anti-TNF and immunomodulating agents such as thalidomide, adalimumab, and certolizumab Pegol are ongoing.\(^6\)

Nutritional deficiencies are common in Crohn disease because of diarrhea, steatorrhea, and other malabsorption problems. A nutritious diet that is high in calories, vitamins, and proteins is recommended. Because fats often aggravate the diarrhea, it is recommended that they be avoided. Elemental diets, which are nutritionally balanced but residue free and bulk free, may be given during the acute phase of the illness. These diets are largely absorbed in the jejunum and allow the inflamed bowel to rest. Total parenteral nutrition (i.e., parenteral hyperalimentation) consists of intravenous administration of hypertonic glucose solutions to which amino acids and fats may be added. This form of nutritional therapy may be needed when food cannot be absorbed from the intestine. Because of the hypertonicity of these solutions, they must be administered through a large-diameter central vein.

**Ulcerative Colitis**

Ulcerative colitis is a nonspecific inflammatory condition of the colon. The disease is more common in the United States and Western countries. The disease may arise at any age, with a peak incidence between ages 15 and 25 years.\(^5\) Unlike Crohn disease, which can affect various sites in the GI tract, ulcerative colitis is confined to the rectum and colon. The disease usually begins in the rectum and spreads proximally, affecting primarily the mucosal layer, although it can extend into the submucosal layer. The length of proximal extension varies. It may involve the rectum alone (ulcerative proctitis), the rectum and sigmoid colon (proctosigmoiditis), or the entire colon (pancolitis). The inflammatory process tends to be confluent and continuous instead of skipping areas, as it does in Crohn disease.

Characteristic of the disease are the lesions that form in the crypts of Lieberkühn in the base of the mucosal layer. The inflammatory process leads to the formation of pinpoint mucosal hemorrhages, which in time suppurate and develop into *crypt abscesses*. These inflammatory lesions may become necrotic and ulcerate. Although the ulcers usually are superficial, they often extend, causing large denuded areas (Fig. 45.10). As a result of the inflammatory process, the mucosal layer often develops tonguelike projections that resemble polyps and therefore are called *pseudopolyps*. The bowel wall thickens in response to repeated episodes of colitis.

**Clinical Manifestations.** Ulcerative colitis typically presents as a relapsing disorder marked by attacks of diarrhea. The diarrhea may persist for days, weeks, or months and then subside, only to recur after an asymptomatic interval of several months to years or even decades. Because ulcerative colitis affects the mucosal layer of the bowel, the stools typically contain blood and mucus. Nocturnal diarrhea usually occurs when daytime symptoms are severe. There may be mild abdominal cramping and fecal incontinence. Anorexia, weakness, and fatigability are common.

Based on clinical and endoscopic findings, the disease is characterized by how much of the colon is affected and the extent of the inflammation. Severity is defined as mild, moderate, severe, or fulminant.\(^5\) The most common form of the disease is the mild form, in which the person has less than four stools daily, with or without blood, no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR). People with moderate disease have more than four stools daily, but have minimal signs of toxicity. Severe disease is manifested by more than six bloody stools daily, and evidence of toxicity as demonstrated by fever, tachycardia, anemia, and elevated ESR (Fig. 45.11). People with fulminant disease have features that include more than 10 bowel move-
Treatment depends on the extent of the disease and severity of symptoms. It includes measures to control the acute manifestations of the disease and prevent recurrence. Some people with mild-to-moderate symptoms are able to control their symptoms simply by avoiding caffeine, lactose (milk), highly spiced foods, and gas-forming foods. Fiber supplements may be used to decrease diarrhea and rectal symptoms. Surgical treatment (i.e., removal of the rectum and entire colon) with the creation of an ileostomy or ileoanal anastomosis may be required for people who do not respond to medications and conservative methods of treatment. The medications used in treatment of ulcerative colitis are similar to those used in the treatment of Crohn disease. They include the nonabsorbable 5-ASA compounds (e.g., mesalamine, olsalazine). The corticosteroids are used selectively to lessen the acute inflammatory response. Many of these medications can be administered rectally by suppository.

or enema. Immunomodulating drugs and anti-TNF therapies may be used to treat persons with severe colitis.

Cancer of the colon is one of the feared long-term complications of ulcerative colitis. Ulcerative colitis is characterized by deoxyribonucleic acid (DNA) damage with microsatellite instability in mucosa cells. More recently, genomic instability was detected in nondysplastic areas of people with ulcerative colitis, suggesting that these people have DNA repair deficiency and genomic instability throughout the intestinal tract. In a meta-analysis focusing on studies involving people with ulcerative colitis, the cumulative risk for people to have colorectal cancer was 1.6% by 10 years, 8.6% by 20 years, and 18.4% by 30 years. All people with the diagnosis should receive a colonoscopy for screening purposes within 8 years after they begin to have symptoms. The frequency of surveillance colonoscopies is often every 1 to 3 years and is dependent upon the results of the examinations and biopsies obtained.

**Infectious Enterocolitis**

A number of microbial agents, including viruses, bacteria, and protozoa, can infect the GI tract, causing diarrhea and sometimes ulcerative and inflammatory changes in the small or large intestine. Infectious enterocolitis is a global problem, causing more than 12,000 deaths per day among children in developing countries. Although far less common in industrialized countries, these disorders still have infection rates second only to the common cold. Most infections are spread by the oral–fecal route, often through contaminated water or food.

**Viral Infection**

Most viral infections affect the superficial epithelium of the small intestine, destroying these cells and disrupting their absorptive function. Repopulation of the small intestinal villi with immature enterocytes and preservation of crypt secretory cells leads to net secretion of water and electrolytes compounded by incomplete absorption of nutrients and osmotic diarrhea. Symptomatic disease is caused by several distinct viruses, including the rotavirus, which most commonly affects children 6 to 24 months of age; the norovirus (or Norwalk), which is responsible for the majority of nonbacterial food-borne epidemic gastroenteritis in all age groups; and enteric adenoviruses, which primarily affect children younger than 24 months.

**Rotavirus.** Worldwide, rotavirus is the leading cause of severe diarrhea and is estimated to cause 527,000 children under the age of 5 to die each year. Prior to 2006, the disease was responsible for 400,000 doctor visits and 20 to 60 deaths in children below the age of 5 in the United States. In 2006, RotaTeq, a live oral vaccine for rotavirus was approved by the FDA. A different live vaccine was approved in 1998 but was withdrawn from the market less than a year later when several infants developed intussusception after receiving the vaccine.

The disease tended to be most severe in children 3 to 24 months of age. Infants younger than 3 months of age are relatively protected by transplacental antibodies and possibly by breast-feeding. The virus spreads via a fecal–oral route, and outbreaks are common in children in day care centers. The virus is shed before and for days after clinical illness. Very few infectious virions are needed to cause disease in a susceptible host.

Rotavirus infection typically begins after an incubation period of 1 to 3 days, with mild-to-moderate fever and vomiting, followed by onset of frequent watery stools. The fever and vomiting usually disappear on about the second day, but the diarrhea continues for 5 to 7 days. Dehydration may develop rapidly, particularly in infants. Treatment is largely supportive. Avoiding and treating dehydration are the main goals.

**Bacterial Infection**

Infectious enterocolitis can be caused by a number of bacteria. There are several pathogenic mechanisms for bacterial enterocolitis: ingestion of preformed toxins that are present in contaminated food; infection by toxigenic organisms that proliferate in the gut lumen and produce an enterotoxin; and infection by enteroinvasive organisms, which proliferate in the lumen and invade and destroy mucosal epithelial cells. The pathogenic effects of bacterial infections depend on the ability of the organism to adhere to the mucosal epithelial cells, elaborate enterotoxins, and then invade the mucosal epithelial cells.

In general, bacterial infections produce more severe effects than viral infections. The complications of bacterial enterocolitis result from massive fluid loss or destruction of intestinal mucosa and include dehydration, sepsis, and perforation. Among the organisms that cause bacterial enterocolitis are Staphylococcus aureus (toxins associated with “food poisoning”), Escherichia coli, Shigella species, Salmonella, and Campylobacter. Two particularly serious forms of bacterial enterocolitis are caused by Clostridium difficile and E. coli O157:H7.

**Clostridium difficile Colitis.** Clostridium difficile colitis is associated with antibiotic therapy. Clostridium difficile is a gram-positive, spore-forming bacillus that is part of the normal flora in 1% to 3% of humans. The spores are resistant to the acid environment of the stomach and convert to vegetative forms in the colon. Treatment with broad-spectrum antibiotics predisposes to disruption of the normal protective bacterial flora of the colon, leading to colonization by C. difficile along with the release of toxins that cause mucosal damage and inflammation. Almost any antibiotic may cause C. difficile colitis, but broad-spectrum antibiotics with activity against gram-negative enteric bacteria are the most frequent agents. After antibiotic therapy has made the bowel susceptible to infection, colonization by C. difficile occurs by the oral–fecal route. Clostridium difficile infection usually is acquired in the hospital, where the organism is commonly encountered.
In general, *C. difficile* is noninvasive. Development of *C. difficile* colitis and diarrhea requires an alteration in the normal gut flora, acquisition and germination of the spores, overgrowth of *C. difficile*, and toxin production. The toxins bind to and damage the intestinal mucosa, causing hemorrhage, inflammation, and necrosis. The toxins also interfere with protein synthesis, attract inflammatory cells, increase capillary permeability, and stimulate intestinal peristalsis. The infection commonly manifests with diarrhea that is mild to moderate and sometimes is accompanied by lower abdominal cramping. Typically symptoms begin within 4 to 9 days after an antibiotic treatment has been started and, in most cases, systemic manifestations are absent, and the symptoms subside after the antibiotic has been discontinued.75

A more severe form of colitis, *pseudomembranous colitis*, is characterized by an adherent inflammatory membrane overlying the areas of mucosal injury. It is a life-threatening form of the disease. People with the disease are acutely ill, with lethargy, fever, tachycardia, abdominal pain and distention, and dehydration. The smooth muscle tone of the colon may be lost, resulting in toxic dilation of the colon. Prompt therapy is needed to prevent perforation of the bowel.

The diagnosis of *C. difficile*-associated diarrhea requires a careful history, with particular emphasis on antibiotic use. Diagnostic findings include a history of antibiotic use and laboratory tests that confirm the presence of *C. difficile* toxins in the stool. Treatment includes the immediate discontinuation of antibiotic therapy. Specific treatment aimed at eradicating *C. difficile* is used when symptoms are severe or persistent. Metronidazole is the drug of choice, with vancomycin being reserved for people who cannot tolerate metronidazole, do not respond to the drug, or have severe symptoms. Metronidazole can be given intravenously or oral. When given oral, it is absorbed from the upper GI tract and may cause side effects, such as nausea. Vancomycin can be given orally or via an enema. It is poorly absorbed systemically, and its actions are limited to the GI tract, resulting in a smaller number of side effects.76

**Escherichia coli O157:H7 Infection.** *Escherichia coli* O157:H7 has become recognized as an important cause of epidemic and sporadic colitis.77 *Escherichia coli* O157:H7 is a strain of *E. coli* found in the feces and contaminated milk of healthy dairy and beef cattle, but it also has been found in contaminated pork, poultry, and lamb. Infection usually is by food-borne transmission, often by ingesting undercooked hamburger. The organism also can be transferred to nonmeat products such as fruits and vegetables. Transmission has also been reported in persons swimming in a fecally contaminated lake as well as among visitors to farms and petting zoos, where children are in direct contact with animals. Person-to-person transmission may occur, particularly in nursing homes, day care settings, and hospitals. The very young and the very old are particularly at risk for the infection and its complications.

The infection may cause no symptoms or cause a variety of manifestations, including acute, nonbloody diarrhea; hemorrhagic colitis; hemolytic uremic syndrome (HUS); and thrombotic thrombocytopenic purpura. The infection often presents with abdominal cramping and watery diarrhea and subsequently may progress to bloody diarrhea. The diarrhea commonly lasts 5 to 10 days.78

Most strains of *E. coli* are harmless. However, enterohemorrhagic *E. coli* can release *Shigella*-like toxins that attach to and damage the mucosal lining of the intestine. Subsequently, the *Shigella*-like toxins gain access to the circulatory system and travel in the plasma and on the surface of platelets and monocytes. The *Shigella*-like toxins bind to high-affinity galactose-containing receptors in the membranes of glomerular, cerebral, or microvascular endothelial cells; renal mesangial and tubular cells; and monocytes and platelets.79 Two complications of the infection, HUS and thrombotic thrombocytopenic purpura, reflect the effects of the *Shigella*-like toxins. The HUS is characterized by hemolytic anemia, thrombocytopenia, and renal failure. It occurs predominantly in infants and young children and is the most common cause of acute renal failure in children. A recent study found that HUS patients had a mortality rate of 4.6%.80 Thrombotic thrombocytopenic purpura is manifested by thrombocytopenia, renal failure, fever, and neurologic manifestations. It often is regarded as the severe end of the disease that leads to HUS plus neurologic problems.

No specific therapy is available for *E. coli* O157:H7 infection. Treatment is largely symptomatic and directed toward treating the effects of complications. The use of antibiotics or antimotility/antidiarrheal agents in the early stages of diarrhea has been shown to increase the risk of HUS because the gut is exposed to a greater amount of toxins for a longer time.

Because of the seriousness of the infection and its complications, education of the public about techniques for decreasing primary transmission of the infection from animal sources is important. Undercooked meats and unpasteurized milk are sources of transmission. Food handlers and consumers should be aware of the proper methods for handling uncooked meat to prevent cross-contamination of other foods. Particular attention should be paid to hygiene in day care centers and nursing homes, where the spread of infection to the very young and very old may result in severe complications.

**Protozoan Infection**

Amebiasis refers to an infection by *Entamoeba histolytica* involving the colon and occasionally the liver.89 Humans are the only known reservoir for *E. histolytica*, which reproduce in the colon and pass in the feces. Although *E. histolytica* infection occurs worldwide, it is more common and more severe in tropical and subtropical areas, where crowding and poor sanitation prevail. Intestinal amebiasis ranges from completely asymptomatic infection to serious dysenteric disease.

*Entamoeba histolytica* has two distinct stages: the trophozoites (amoeboid form) and cysts.80 The trophozoites thrive in the colon and feed on bacteria and human cells. They may colonize any portion of the large bowel, but the area of maximum disease is usually the cecum. Persons with symptomatic disease pass both cysts and trophozoites in their feces, but quickly die when exposed to air outside of the body. Only the
cysts are infectious because they survive gastric acidity, which destroys the trophozoites. Once established, the trophozoites invade the crypts of colonic glands and burrow down into the submucosa; the organism then fans out to create a flask-shaped ulcer with a narrow neck and broad base. *Entamoeba histolytica* that have invaded into the submucosal veins of the colon enter the portal vein and embolize to the liver to produce solitary and, less often, multiple discrete hepatic abscesses.\textsuperscript{82} Some people have an acute onset of diarrhea as early as 8 days (commonly 2 to 4 weeks) after infection.\textsuperscript{83} Others may be asymptomatic or have only mild intestinal symptoms for months or several years before either intestinal symptoms or liver abscesses appear. Manifestations include abdominal discomfort, tenderness, cramps, and fever, often accompanied by nausea, vomiting, and passage of malodorous flatus. There may be frequent passage of liquid stools containing bloody mucus, but the duration of diarrhea is not usually so prolonged as to cause dehydration. The infection often persists for months or years, causing emaciation and anemia. In severe cases, massive destruction of the colonic mucosa may lead to hemorrhage, perforation, or peritonitis. People with amebic liver abscesses often present with severe right upper quadrant pain, low-grade fever, and weight loss.\textsuperscript{82}

Diagnostic methods include microscopic examination of the stool for *E. histolytica*, serum antibody tests, and colonoscopy with specimen collection or biopsy. Treatment includes use of the antimicrobial agents tinidazole and metronidazole, which act against the trophozoites, and diloxanide (not available in the United States), which is effective against the cysts.

### Diverticular Disease

Diverticulosis is a condition that commonly occurs on the distal descending and sigmoid colon, in which the mucosal layer of the colon herniates through the muscularis layer.\textsuperscript{84} There are often multiple diverticula, most of which occur in the sigmoid colon (Fig. 45.12). Diverticular disease is common in Western society, affecting approximately 40% of the population by age 60 and 60% of the population by age 80.\textsuperscript{84} Although the disorder is prevalent in the developed countries of the world, it is almost nonexistent in many African nations and underdeveloped countries. This suggests that factors such as lack of fiber in the diet, a decrease in physical activity, and poor bowel habits (e.g., neglecting the urge to defecate), along with the effects of aging, contribute to the development of the disease.

In the colon, the longitudinal muscle does not form a continuous layer, as it does in the small bowel. Instead, there are three separate longitudinal bands of muscle called the *taeniae coli*. In a manner similar to the small intestine, bands of circular muscle constrict the large intestine. As the circular muscle contracts at each of these points (approximately every 2.5 cm), the lumen of the bowel becomes constricted, so that it is almost occluded. The combined contraction of the circular muscle and the lack of a continuous longitudinal muscle layer cause the intestine to bulge outward into pouches called haustra. Diverticula develop between the longitudinal muscle bands of the haustra, in the area where the blood vessels pierce the circular muscle layer to bring blood to the mucosal layer. An increase in intraluminal pressure in the haustra provides the force for creating these herniations. The increase in pressure is thought to be related to the volume of the colonic contents. The scantier the contents, the more vigorous are the contractions and the greater is the pressure in the haustra.

Most people with diverticular disease remain asymptomatic.\textsuperscript{86} The disease often is found when x-ray studies are done for other purposes. When symptoms do occur, they often are attributed to IBS or other causes. Ill-defined lower abdominal discomfort, a change in bowel habits (e.g., diarrhea, constipation), bloating, and flatulence are common.

Diverticulitis is a complication of diverticulosis in which there is inflammation and gross or microscopic perforation of the diverticulum. One of the most common complaints of diverticulitis is pain in the lower left quadrant, accompanied by nausea and vomiting, tenderness in the lower left quadrant, a slight fever, and an elevated white blood cell count.\textsuperscript{87} These symptoms usually last for several days, unless complications occur, and usually are caused by localized inflammation of the diverticula with perforation and development of a small, localized abscess. Complications include perforation with peritonitis, hemorrhage, and bowel obstruction. Fistulas can form, involving the bladder (i.e., vesicosigmoid fistula) but sometimes involving the skin, perianal area, vagina or small bowel. Pneumaturia (i.e., air in the urine) is a sign of vesico-sigmoid fistula.

The diagnosis of diverticular disease is based on history and presenting clinical manifestations. The disease may be confirmed by CT scans or ultrasonographic studies. CT scans are the safest and most cost-effective method.\textsuperscript{87} Although barium enema was used in the past, it is no longer recommended because of the risk of extravasation of contrast material if perforation has occurred.\textsuperscript{87} Flat abdominal radiographs may be used to detect complications associated with acute diverticulitis.

![FIGURE 45.12 • Location of diverticula in the sigmoid colon.](image-url)
The usual treatment for diverticular disease is to prevent symptoms and complications. This includes increasing the bulk in the diet and bowel retraining so that the person has at least one bowel movement each day. The increased bulk promotes regular defecation and increases colonic contents and colon diameter, thereby decreasing intraluminal pressure. Acute diverticulitis is treated by withholding solid food and administering a broad-spectrum antibiotic.87 Hospitalization may be required for people who show significant inflammation, are unable to tolerate oral fluids, are febrile, or have signs and symptoms that suggest systemic involvement.87 Immunomodulatory agents such as mesalamine and probiotics are two therapies that are becoming more frequently used to manage diverticular disease.87,88 Surgical treatment is reserved for people experiencing nonresolving symptoms and complications.84

Appendicitis
Acute appendicitis is extremely common. In the United States, there is a 12% risk of developing appendicitis for males and a 25% risk for females.89 The appendix becomes inflamed, swollen, and gangrenous, and it eventually perforates if not treated. Appendicitis is related to intraluminal obstruction with a fecalith (i.e., hard piece of stool), gallstones, tumors, parasites, or lymphatic tissue. Appendicitis usually has an abrupt onset, with pain referred to the epigastric or periumbilical area. This pain is caused by stretching of the appendix during the early inflammatory process. At approximately the same time that the pain appears, there are one or two episodes of nausea. Initially, the pain is vague, but over a period of 2 to 12 hours, it gradually increases and may become colicky. When the inflammatory process has extended to involve the serosal layer of the appendix and the peritoneum, the pain becomes localized to the lower right quadrant. There may be an elevated white blood cell count but not in all cases.90 Palpation of the abdomen usually reveals a deep tenderness in the lower right quadrant, which is confined to a small area approximately the size of the fingertip. It usually is located at approximately the site of the inflamed appendix. The person with appendicitis often is able to place his or her finger directly over the tender area. Rebound tenderness, which is pain that occurs when pressure is applied to the area and then released, and spasm of the underlying abdominal muscles are common. Diagnosis is usually based on history and findings on physical examination. Ultrasonography or CT may be used to confirm the diagnosis in cases where alternative causes of abdominal pain are suspected.91 Treatment consists of surgical removal of the appendix. Complications include peritonitis, localized periappendiceal abscess formation, and septicemia.

Alterations in Intestinal Motility
The movement of contents through the GI tract is controlled by neurons located in the submucosal and myenteric plexuses of the gut. The axons from the cell bodies in the myenteric plexus innervate the circular and longitudinal smooth muscle layers of the gut. These neurons receive impulses from local receptors located in the mucosal and muscle layers of the gut and extrinsic input from the parasympathetic and sympathetic nervous systems. As a general rule, the parasympathetic nervous system tends to increase the motility of the bowel, whereas sympathetic stimulation tends to slow its activity.

The colon has sphincters at both ends: the ileocecal sphincter, which separates it from the small intestine, and the anal sphincter, which prevents the movement of feces to the outside of the body. The colon acts as a reservoir for fecal material. Normally, approximately 400 mL of water, 55 mEq of sodium, 30 mEq of chloride, and 15 mEq of bicarbonate are absorbed each day in the colon. At the same time, approximately 5 mEq of potassium is secreted into the lumen of the colon. The amount of water and electrolytes that remains in the stool reflects the absorption or secretion that occurs in the colon. The average adult ingesting a typical American diet evacuates approximately 100 to 200 g of stool each day.

KEY POINTS

**DISORDERS OF GASTROINTESTINAL MOTILITY**

- The luminal contents move down the GI tract as a result of peristaltic movements regulated by a complex interaction of electrical, neural, and hormonal control mechanisms.
- Local irritation and the composition and constituents of GI contents influence motility through the submucosal afferent neurons of the enteric nervous system. GI wall distention, chemical irritants, osmotic gradients, and bacterial toxins exert many of their effects on GI motility through these afferent pathways.

**Diarrhea**

The usual definition of diarrhea is excessively frequent passage of loose or unformed stools. The complaint of diarrhea is a general one and can be related to a number of pathologic and nonpathologic factors. Diarrhea can be acute or chronic and can be caused by infectious organisms, food intolerance, drugs, or intestinal disease. Acute diarrheas that last less than 4 days are predominantly caused by infectious agents and follow a self-limited course.92

**Acute Diarrhea.** Diarrhea that is acute in onset and persists for less than 2 weeks is commonly caused by infectious agents (see previous discussion of infectious enterocolitis). Acute diarrhea is commonly divided into noninflammatory (large-volume) and inflammatory (small-volume) diarrhea, based on the characteristics of the diarrheal stool. Enteric organisms cause diarrhea by several ways. Some are noninvasive and do not cause inflammation, but secrete toxins that stimulate fluid
secretion. Others invade and destroy intestinal epithelial cells, thereby altering fluid transport so that secretory activity continues while absorption activity is halted.

Noninflammatory diarrhea is associated with large-volume watery and nonbloody stools, periumbilical cramps, bloating, and nausea or vomiting. It is commonly caused by toxin-producing bacteria (e.g., *S. aureus*, enterotoxigenic *E. coli*, *Cryptosporidium parvum*, *Vibrio cholerae*) or other agents (e.g., viruses, *Giardia*) that disrupt the normal absorption or secretory process in the small bowel. Prominent vomiting suggests viral enteritis or *S. aureus* food poisoning. Although typically mild, the diarrhea (which originates in the small intestine) can be voluminous and result in dehydration with hypokalemia and metabolic acidosis (*i.e.*, cholera). Because tissue invasion does not occur, leukocytes are not present in the feces.

Inflammatory diarrhea is usually characterized by the presence of fever and bloody diarrhea (dysentery). It is caused by invasion of intestinal cells (e.g., *Shigella, Salmonella, Yersinia*, and *Campylobacter*) or the toxins associated with the previously described *C. difficile* or *E. coli O157:H7* infection. Because infections associated with these organisms predominantly affect the colon, the diarrhea is frequent and small in volume and is associated with left lower quadrant cramps, urgency, and tenesmus. Infectious dysentery must be distinguished from acute ulcerative colitis, which may present with bloody diarrhea, fever, and abdominal pain. Diarrhea that persists for 14 days is not attributable to bacterial pathogens (except for *C. difficile*), and the person should be evaluated for chronic diarrhea.

**Chronic Diarrhea.** Diarrhea is considered to be chronic when the symptoms persist for 4 weeks or greater. Chronic diarrhea is often associated with conditions such as IBD, IBS, malabsorption syndrome, endocrine disorders (hyperthyroidism, diabetic autonomic neuropathy), or radiation colitis. There are four major causes of chronic diarrhea: presence of hyperosmotic luminal contents, increased intestinal secretory processes, inflammatory conditions, and infectious processes (Chart 45.1). Factitious diarrhea is caused by indiscriminate use of laxatives or excessive intake of laxative-type foods.

In osmotic diarrhea, water is pulled into the bowel by the hyperosmotic nature of its contents to such a quantity that the colon is unable to reabsorb the excess fluid. It occurs when osmotically active particles are not absorbed. In persons with lactase deficiency, the lactose in milk cannot be broken down and absorbed. Magnesium salts, which are contained in milk of magnesia and many antacids, are poorly absorbed and cause diarrhea when taken in sufficient quantities. Another cause of osmotic diarrhea is decreased transit time, which interferes with absorption. Osmotic diarrhea usually disappears with fasting.

Secretory diarrhea occurs when the secretory processes of the bowel are increased. Secretory diarrhea also occurs when excess bile acids remain in the intestinal contents as they enter the colon. This often happens with disease processes of the ileum because bile salts are absorbed there. It also may occur with bacterial overgrowth in the small bowel, which interferes with bile absorption. Some tumors, such as those of the Zollinger-Ellison syndrome and carcinoid syndrome, produce hormones that cause increased secretory activity of the bowel.

**Inflammatory diarrhea** commonly is associated with acute or chronic inflammation or intrinsic disease of the colon, such as ulcerative colitis or Crohn disease. Inflammatory diarrhea usually is evidenced by frequency and urgency and colicky abdominal pain. It commonly is accompanied by tenesmus (*i.e.*, painful straining at stool), fecal soiling of clothing, and awakening during the night with the urge to defecate.

Chronic parasitic infections may cause chronic diarrhea through a number of mechanisms. Pathogens most commonly associated with chronic diarrhea include the protozoans *Giardia*, *E. histolytica*, and *Cyclospora*. Immunocompromised persons are particularly susceptible to infectious organisms that can cause acute and chronic diarrhea, including *Cryptosporidium*, cytomegalovirus (CMV), and *Mycobacterium avium-intracellulare* complex.

**Diagnosis and Treatment.** The diagnosis of diarrhea is based on complaints of frequent stools and a history of accompanying factors such as concurrent illnesses, medication use, and exposure to potential intestinal pathogens. Disorders such as IBD and celiac disease should be considered. If the onset of diarrhea is related to travel outside the United States, the possibility of traveler’s diarrhea must be considered.

Although most acute forms of diarrhea are self-limited and require no treatment, diarrhea can be particularly serious in infants and small children, persons with other illnesses, elderly persons, and even previously healthy persons if it

continues for any length of time. Thus, the replacement of fluids and electrolytes is considered to be a primary therapeutic goal in the treatment of diarrhea.

Drugs used in the treatment of diarrhea include diphenoxylate (Lomotil) and loperamide (Imodium), which are opium-like drugs. These drugs decrease GI motility and stimulate water and electrolyte absorption. Adsorbents, such as kaolin and pectin, adsorb irritants and toxins from the bowel. These ingredients are included in many over-the-counter antidiarrheal preparations because they adsorb toxins responsible for certain types of diarrhea. Bismuth subsalicylate (Pepto-Bismol) can be used to reduce the frequency of unformed stools and increase stool consistency, particularly in cases of traveler’s diarrhea. The drug is thought to inhibit intestinal secretion caused by enterotoxigenic *E. coli* and cholera toxins. Antidiarrheal medications should not be used in persons with bloody diarrhea, high fever, or signs of toxicity because of the risk of worsening the disease. Antibiotics should be reserved for use in persons with identified enteric pathogens.

**Acute Diarrheal Disease in Children.** Globally, 1.5 million deaths a year are attributed to diarrhea in children under the age of 5 years. Although diarrheal diseases are less prevalent in the United States than in other countries, they place a burden on the health care system. Diarrhea is also the leading cause of malnutrition in children and most frequently affects children under the age of 2 years.86

The causes of acute diarrhea in children vary with location, time of year, and population studied. There is increasing recognition of a widening array of enteric pathogens that cause acute diarrhea in children. Viruses are the most common pathogen causing diarrheal illness.89

Rotaviruses and noroviruses are the frequently observed pathogens. Other viruses that have been observed in the stools of children include astroviruses and enteric adenoviruses. Many of these pathogens are transmitted easily through food and water or from one person to another. Prevention remains the most vital measure in managing diarrheal disease in children. Important measures to prevent spread of pathogens include proper sanitation methods for food processing and preparation, sanitary water supplies, proper hand hygiene, exclusion of infected people from handling food or providing health care, and exclusion of people with diarrhea from using public recreational water (i.e., swimming pools, ponds, and lakes).

The main objectives in the approach to a child with acute diarrhea are to assess the degree of dehydration, prevent spread of the infection, determine the nature of the etiologic agent, and provide specific therapy as needed. The hydration status of children can be assessed on the basis of easily observed signs and symptoms. Questions about oral intake, frequency and volume of stool output, general appearance and activity of the child, and frequency of urination provide essential information about hydration. Thirst, dry mucous membranes, and decreased skin turgor are common symptoms of dehydration.99 Data should be obtained about day care attendance, recent travel to a diarrhea-endemic area, use of antimicrobial drugs, and exposure to contaminated water, unwashed fruits or vegetables, or improperly cooked meats because they may indicate the cause of the disorder. Fever is suggestive of an inflammatory process but also occurs with dehydration.99

Management of dehydration remains the cornerstone of treatment of children with diarrhea. Infants in particular are more susceptible to dehydration because of their greater surface area, higher metabolic rate, and inability effectively to concentrate their urine. Oral replacement therapy (ORT) is usually the method of choice for infants and children with uncomplicated diarrhea that can be treated at home.

First applied to the treatment of diarrhea in developing countries, ORT can be regarded as a case of reverse technology, in which the protocols originally implemented in these countries have changed health care in industrialized countries as well.100 Complete ORT solutions contain carbohydrate, sodium, potassium, chloride, and base to replace that lost in the diarrheal stool.100 Commonly used beverages such as apple juice and cola drinks, which have increased osmolarity because of their high carbohydrate content and low electrolyte content, are not recommended. The effectiveness of ORT is based on the coupled transport of sodium and glucose or other actively transported small organic molecules (see Chapter 44). Bottled ORT solutions are available but can be costly, particularly in cases where large amounts of replacement fluids are needed. The cost can represent a sizable burden for socioeconomically disadvantaged families. Less expensive, premeasured packets and recipes for preparing replacement solutions are available. The use of ORT for treatment of diarrhea in infants and small children is often labor intensive, requiring frequent feeding, sometimes using a spoon or a nasogastric feeding tube.99 More importantly, the diarrhea does not promptly cease after ORT has been instituted; this can be discouraging for parents and caregivers who desire early results from their efforts. Children who are severely dehydrated with changes in vital signs or mental status require emergency intravenous fluid resuscitation. After initial treatment with intravenous fluids, these children can be given ORT.

Evidence suggests that feeding should be continued during diarrheal illness, particularly in children.100 It has been shown that unrestricted diets do not worsen the course or symptoms of mild diarrhea and can decrease stool output.101 Starch and simple proteins are thought to provide cotransport molecules with little osmotic activity, increasing fluid and electrolyte uptake by intestinal cells. The luminal contents associated with early refeeding are also a known growth factor for enterocytes and help facilitate repair after injury. It is recommended that children who require rehydration therapy because of diarrhea be fed an age-appropriate diet. Although there is little agreement on which foods are best, fatty foods and foods high in simple sugars are best avoided. Almost all infants with acute gastroenteritis can tolerate breast-feeding. For formula-fed infants, diluted formula does not provide an advantage over full-strength formula.
Constipation can be defined as the infrequent, incomplete, or difficult passage of stools. The difficulty with this definition arises from the many individual variations of function that are normal. What is considered normal for one person (e.g., two or three bowel movements per week) may be considered evidence of constipation by another. Constipation can occur as a primary disorder of intestinal motility, as a side effect of drugs, as a problem associated with another disease condition, or as a symptom of obstructing lesions of the GI tract. Some common causes of constipation are failure to respond to the urge to defecate, inadequate fiber in the diet, inadequate fluid intake, weakness of the abdominal muscles, inactivity and bed rest, pregnancy, and hemorrhoids. The pathophysiology of constipation can be classified into three broad categories: normal-transit constipation, slow-transit constipation, and disorders of defecatory or rectal evacuation. Normal-transit constipation (or functional constipation) is characterized by perceived difficulty in defecation and usually responds to increased fluid and fiber intake. Slow-transit constipation, which is characterized by infrequent bowel movements, is often caused by alterations in the motor function of the colon. Hirschsprung disease is an extreme form of slow-transit constipation in which the ganglion cells in the distal colon are absent because of a defect that occurred during embryonic development; the bowel narrows at the area that lacks ganglionic cells. Although most persons with this disorder present in infancy or early childhood, some with a relatively short segment of involved colon do not have symptoms until later in life. Defecatory disorders are most commonly due to deficiencies in muscle coordination involving the pelvic floor or anal sphincter.

Diseases associated with chronic constipation include neurologic diseases such as spinal cord injury, Parkinson disease, and multiple sclerosis; endocrine disorders such as hypothyroidism; and obstructive lesions in the GI tract. Drugs such as narcotics, anticholinergic agents, calcium channel blockers, diuretics, calcium (antacids and supplements), iron supplements, and aluminum antacids tend to cause constipation. Older adults with long-standing constipation and straining with defecation may develop dilation of the rectum, colon, or both. This condition allows large amounts of stool to accumulate with little or no sensation. Constipation, in the context of a change in bowel habits, may be a sign of colorectal cancer.

Diagnosis of constipation usually is based on a history of infrequent stools, straining with defecation, the passing of hard and lumpy stools, or the sense of incomplete evacuation with defecation. Rectal examination is used to determine whether fecal impaction, anal stricture, or rectal masses are present. Constipation as a sign of another disease condition should be ruled out. Tests that measure colon transit time and defecatory function are reserved for refractory cases.

The treatment of constipation usually is directed toward relieving the cause. A conscious effort should be made to respond to the defecation urge. A time should be set aside after a meal, when mass movements in the colon are most likely to occur, for a bowel movement. Mimicking a squatting position while sitting on the toilet by elevating the feet may assist in promoting a bowel movement. Adequate fluid intake and bulk in the diet should be encouraged. Moderate exercise is essential, and people on bed rest benefit from passive and active exercises. Laxatives and enemas should be used judiciously. They should not be used on a regular basis to treat simple constipation because they interfere with the defecation reflex and actually may damage the rectal mucosa.

Fecal Impaction

Fecal impaction is the retention of hardened or putty-like stool in the rectum and colon, which interferes with normal passage of feces. If not removed, it can cause partial or complete bowel obstruction. It may occur in any age group but is more common in incapacitated older adults. Fecal impaction may result from painful anorectal disease, tumors, or neurogenic disease; use of constipating antacids or bulk laxatives; a low-residue diet; drug-induced colonic stasis; or prolonged bed rest and debility. In children, a habitual neglect of the urge to defecate in the school setting because of cleanliness of the facilities, modesty, or play interference may promote impaction.

The manifestations may be those of severe constipation, but frequently there is a history of watery diarrhea, fecal soiling, and fecal incontinence. This is caused by increased secretory activity of the bowel, representing the body’s attempt to break up the mass so that it can be evacuated. The abdomen may be distended, and there may be blood and mucus in the stool. The fecal mass may compress the urethra, giving rise to urinary incontinence. Fecal impaction should be considered in an elderly or immobilized person who develops watery stools with fecal or urinary incontinence.

Digital examination of the rectum is done to assess for the presence of a fecal mass. The mass may need to be broken up and dislodged manually or with the use of a sigmoidoscope. Oil enemas often are used to soften the mass before removal. The best treatment is prevention.

Intestinal Obstruction

Intestinal obstruction designates an impairment of movement of intestinal contents in a cephalocaudad direction. The causes can be categorized as mechanical or paralytic. Strangulation with necrosis of the bowel may occur and lead to perforation, peritonitis, and sepsis.

Mechanical obstruction can result from a number of conditions, intrinsic or extrinsic, that encroach on the patency of the bowel lumen (Fig. 45.13). Postoperative causes such as external hernia (i.e., inguinal, femoral, or umbilical) and postoperative adhesions are responsible for 75% of intestinal obstruction occurrences. Less common causes are strictures, tumors, foreign bodies, intussusception, and volvulus.
Mechanical bowel obstruction may be a simple obstruction, in which there is no alteration in blood flow, or a strangulated obstruction, in which there is impairment of blood flow and necrosis of bowel tissue.

Paralytic, or adynamic, obstruction results from neurogenic or muscular impairment of peristalsis. Paralytic ileus is seen most commonly after abdominal surgery, but it also accompanies inflammatory conditions of the abdomen, intestinal ischemia, pelvic fractures, and back injuries. It occurs early in the course of peritonitis and can result from chemical irritation caused by bile, bacterial toxins, electrolyte imbalances as in hypokalemia, and vascular insufficiency.

The major effects of both types of intestinal obstruction are abdominal distention and loss of fluids and electrolytes (Fig. 45.15). Gases and fluids accumulate in the area; if untreated, the distention resulting from bowel obstruction tends to perpetuate itself by causing atony of the bowel and further distention. Distention is further aggravated by the accumulation of gases. As the process continues, the distention moves proximally (i.e., toward the mouth), involving additional segments of bowel. Either form of obstruction eventually may lead to strangulation (i.e., interruption of blood flow), gangrenous changes, and, ultimately, perforation of the bowel.

The increased pressure in the intestine tends to compromise mucosal blood flow, leading to necrosis and movement of blood into the luminal fluids. This promotes rapid growth of bacteria in the obstructed bowel, which has the potential to move into the lymph system and surrounding organs. The movement of the bacteria outside of the digestive tract results in increased inflammation, which can result in further ischemia and organ failure.

The manifestations of intestinal obstruction depend on the degree of obstruction and its duration. With acute obstruction, the onset usually is sudden and dramatic. With chronic conditions, the onset often is more gradual.
The cardinal symptoms of intestinal obstruction are pain, absolute constipation, abdominal distention, sign of fluid volume deficit, and vomiting. With mechanical obstruction, the pain is severe and colicky, in contrast with the continuous pain and silent abdomen of paralytic ileus. There also is borborygmi (i.e., rumbling sounds made by propulsion of gas in the intestine); audible, high-pitched peristalsis; and peristaltic rushes that tend to associate with episodes of abdominal pain. Visible peristalsis may appear along the course of the distended intestine. Extreme restlessness and conscious awareness of intestinal movements are experienced along with weakness, perspiration, and anxiety. Should strangulation of the bowel occur, the symptoms change. The character of the pain shifts from the intermittent colicky pain caused by the hyperperistaltic movements of the intestine to a severe and steady type of pain. Vomiting and fluid and electrolyte disorders occur with both types of obstruction.

Diagnosis of intestinal obstruction usually is based on history and physical findings. Plain film radiography of the abdomen may be used to determine the presence of an obstruction as well as differentiate between partial and complete obstruction by analysis of gas patterns within the bowel. CT scans and ultrasonography may also be used to detect the presence of mechanical obstruction.

Treatment depends on the cause and type of obstruction. Correction of fluid and electrolyte imbalances to baseline levels and measurement of output using a Foley catheter are recommended. Most cases of adynamic obstruction respond to decompression of the bowel through nasogastric suction. Strangulation and complete bowel obstruction require surgical intervention. Intraoperatively, the bowel is observed for return of normal color and peristalsis. If necrotic tissue present, it is resected, and an anastomosis is made.

**Peritonitis**

Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation. Most commonly, enteric bacteria enter the peritoneum because of a defect in the wall of one of the abdominal organs. Causes of peritonitis include perforated peptic ulcer, ruptured appendix, perforated diverticulum, gangrenous bowel, pelvic inflammatory disease, and gangrenous gallbladder. Other environmental causes are abdominal trauma, foreign body ingestion, and infected peritoneal dialysis catheters. Generalized peritonitis, although no longer the overwhelming problem it once was, is still a leading cause of death after abdominal surgery.

The peritoneum has several characteristics that increase its vulnerability to or protect it from the effects of peritonitis. One weakness of the peritoneal cavity is that it is a large, unbroken space that favors the dissemination of contaminants. For the same reason, it has a large surface area that permits rapid absorption of bacterial toxins into the blood. The peritoneum is particularly well adapted for producing an inflammatory response as a means of controlling infection. It tends, for example, to exude a thick, sticky, and fibrinous substance that adheres to other structures, such as the mesentery and omentum, and that seals off the perforated viscus and aids in localizing the process. Localization is enhanced by sympathetic stimulation that limits intestinal motility. Although the diminished or absent peristalsis that occurs tends to give rise to associated problems, it does inhibit the movement of contaminants throughout the peritoneal cavity.

One of the most important manifestations of peritonitis is the translocation of extracellular fluid into the peritoneal cavity (through weeping or serous fluid from the inflamed peritoneum) and into the bowel as a result of bowel obstruction. Nausea and vomiting cause further losses of fluid. The fluid loss may encourage development of hypovolemia and shock. The onset of peritonitis may be acute, as with a ruptured appendix, or it may have a more gradual onset, as occurs in pelvic inflammatory disease. Pain and tenderness are common symptoms. The pain usually is more intense over the inflamed area. The person with peritonitis usually lies still because any movement aggravates the pain. Breathing often is shallow to prevent movement of the abdominal muscles. The abdomen usually is rigid and sometimes described as boardlike because of reflex muscle guarding. Vomiting is common. Fever, an elevated white blood cell count, tachycardia, and hypotension are common. Hiccups may develop because of irritation of the phrenic nerve. Paralytic ileus occurs shortly after the onset of widespread peritonitis and is accompanied by abdominal distention. Peritonitis that progresses and is untreated leads to toxemia and shock.
Malabsorption is the failure to transport dietary constituents, such as fats, carbohydrates, proteins, vitamins, and minerals, from the lumen of the intestine into the extracellular fluid compartment for transport to the various parts of the body. It can selectively affect a single component, such as vitamin B₁₂, or lactose, or its effects can extend to all the substances absorbed in a specific segment of the intestine. When one segment of the intestine is affected, another may compensate. For example, the ileum may compensate for malabsorption in the proximal small intestine by absorbing substantial amounts of fats, carbohydrates, and amino acids. Similarly, the colon, which normally absorbs water, sodium, chloride, and bicarbonate, can compensate for small intestine malabsorption by absorbing additional end products of bacterial carbohydrate metabolism.

The conditions that impair one or more steps involved in digestion and absorption of nutrients can be divided into three broad categories: intraluminal maldigestion, disorders of transepithelial transport, and lymphatic obstruction. Intraluminal maldigestion involves a defect in processing of nutrients in the proximal part of the small intestine, where the exposure to antigens, including transglutaminase, endomysium, and gliadin. The resultant immune response produces an intense inflammatory reaction that results in loss of absorptive villi from the small intestine (Fig. 45.16). When the resulting lesions are extensive, they may impair absorption of macronutrients (i.e., fats, carbohydrates, fats) and micronutrients (i.e., vitamins and minerals). Small bowel involvement is most prominent in the proximal part of the small intestine, where the exposure to gluten is greatest.

There are a number of populations who are at higher risk for celiac disease. These include persons with type 1 diabetes mellitus, other autoimmune endocrinopathies, dermatitis herpetiformis, first- and second-degree relatives of people with celiac disease, and people with Turner syndrome. Various malignancies also appear to be a direct result of celiac disease, in that the increased incidence seen in people with celiac disease returns to that of the general population after several years of a gluten-free diet. These malignancies include head and neck squamous cell carcinoma, small intestinal adenocarcinoma, and non-Hodgkin lymphoma.

The classic form of celiac disease presents in infancy and manifests as failure to thrive, diarrhea, muscle wasting, abdominal distention, and, occasionally, severe malnutrition. Beyond infancy, the manifestations tend to be less dramatic. Older children may present with anemia, constitutional short

stature, dental enamel defects, and constipation. In adults, GI symptoms may manifest as diarrhea, constipation, or other symptoms of malabsorption such as bloating, flatus, or belching.

The diagnosis of celiac disease is based on clinical manifestations, supported by serologic tests and confirmed by intestinal biopsy. Based on very high sensitivities, the best available tests are the immunoglobulin (Ig) A antihuman tissue transglutaminase (TTG) and IgA endomysial antibody immunofluorescence (EMA) tests. Biopsies of the proximal small bowel are indicated in people with a positive celiac disease antibody test. Usually, additional laboratory tests are done to determine if the disorder has resulted in nutritional disorders such as iron deficiency anemia.

The primary treatment of celiac disease consists of removal of gluten and related proteins from the diet. Gluten is the primary protein in wheat, barley, and rye. Oat products, which are nontoxic, may be contaminated with wheat during processing. Many gluten-free types of bread, cereals, cookies, and other products are available. Meats, vegetables, fruits, and dairy products are free of gluten as long as they are not contaminated during processing. Complete exclusion of dietary gluten generally results in rapid and complete healing of the intestinal mucosa.
Neoplasms

Epithelial cell tumors of the intestines are a major cause of morbidity and mortality worldwide. The colon is the site of more primary neoplasms than any other organ in the body.\(^{121}\) Although the small intestine accounts for approximately 75% of the length of the GI tract, it is an uncommon site of benign or malignant tumors.

**Adenomatous Polyps**

By far, the most common types of neoplasms of the intestine are adenomatous polyps. A GI polyp can be described as a mass that protrudes into the lumen of the gut.\(^{12}\) Polyps can be subdivided according to their attachment to the bowel wall (sessile [raised mucosal nodules] or pedunculated [attached by a stalk]), their histopathologic appearance (hyperplastic or adenomatous), and their neoplastic potential (benign or malignant).\(^{12}\)

Adenomatous polyps (adenomas) are benign neoplasms that arise from the mucosal epithelium of the intestine. They are composed of neoplastic cells that have proliferated in excess of those needed to replace the cells that normally are shed from the mucosal surface (Fig. 45.17). The pathogenesis of adenoma formation involves neoplastic alteration in the replication of the crypt epithelial cells. There may be diminished apoptosis, persistence of cell replication, and failure of cell maturation and differentiation of the cells that migrate to the surface of the crypts.\(^{9}\) Normally, DNA synthesis ceases as the cells reach the upper two thirds of the crypts, after which they mature, migrate to the surface, and become senescent. They then become apoptotic and are shed from the surface.\(^{12}\) Adenomas arise from a disruption in this sequence, such that the epithelial cells retain their proliferative ability throughout the entire length of the crypt. Alterations in cell differentiation can lead to dysplasia and progression to the development of invasive carcinoma.

More than half of all adenomatous polyps are located in the rectosigmoid colon and can be detected by rectal examination or sigmoidoscopy.\(^{12}\) The remainder are evenly distributed throughout the rest of the colon. Adenomas can range in size from a barely visible nodule to a large, sessile mass. They can be classified as tubular, villous, or tubulovillous adenomas.

**Tubular adenomas**, which constitute approximately 65% of benign large bowel adenomas, typically are smooth-surfaced spheres, usually less than 2 cm in diameter, that are attached to the mucosal surface by a stalk.\(^{12}\) Although most tubular adenomas display little epithelial dysplasia, approximately 20% show a range of dysplastic changes, from mild nuclear changes to frank invasive carcinoma. **Villus adenomas** constitute 10% of adenomas of the colon.\(^{12}\) They are found predominantly in the rectosigmoid colon. They typically are broad-based, elevated lesions, with a shaggy, cauliflower-like surface. In contrast to tubular adenomas, villous adenomas are more likely to contain malignant cells. When invasive carcinoma develops, there is no stalk to isolate the tumor and invasion is directly into the wall of the colon. **Tubulovillous adenomas** manifest...
both tubular and villous architecture. They are intermediate between tubular and villous adenomas in terms of invasive carcinoma risk.

Most cases of colorectal cancer begin as benign adenomatous colonic polyps. The frequency of polyps increases with age, and the prevalence of adenomatous polyps significantly increases after 60 years of age. Men and women are equally affected. The peak incidence of adenomatous polyps precedes by some years the peak for colorectal cancer. Programs that provide careful follow-up for persons with adenomatous polyps and removal of all suspect lesions have substantially reduced the incidence of colorectal cancer.

Colorectal Cancer

Colorectal cancer is the third most common cancer in men and women and the third leading cause of cancer death in the United States. The annual incidence of colon and rectal cancer in the United States is approximately 141,210, with 49,380 deaths. The death rate for colorectal cancer has been steadily declining since the early 1980s. This may be due to a decreased number of cases, earlier diagnosis, and improved treatments.

The cause of cancer of the colon and rectum is largely unknown. Its incidence increases with age, as evidenced by the fact that approximately 90% of people who develop this form of cancer are older than 50 years of age. Its incidence is increased among people with a family history of cancer, people with Crohn disease or ulcerative colitis, and those with familial adenomatous polyposis of the colon. People with a familial risk—those who have two or more first- or second-degree relatives (or both) with colorectal cancer—make up approximately 20% of all people with colorectal cancer. Familial adenomatous polyposis is a rare autosomal dominant trait linked to a mutation in the long arm of chromosome 5. People with the disorder develop multiple adenomatous polyps of the colon at an early age. Carcinoma of the colon is inevitable, often by 40 years of age, unless a total colectomy is performed.

Diet also is thought to play a role. Attention has focused on dietary fat intake, refined sugar intake, fiber intake, and the adequacy of such protective micronutrients as vitamins A, C, and E in the diet. It has been hypothesized that a high level of fat in the diet increases the synthesis of bile acids in the liver, which may be converted to potential carcinogens by bacterial flora in the colon. Bacterial organisms in particular are suspected of converting bile acids to carcinogens. Their proliferation is enhanced by a high dietary level of refined sugars. Dietary fiber is thought to increase stool bulk and thereby dilute and remove potential carcinogens. Refined diets often contain reduced amounts of vitamins A, C, and E, which may act as oxygen free radical scavengers.

Reports indicate that aspirin may protect against colorectal cancer. Although the mechanism of aspirin's action is unknown, it may be related to its effect on the synthesis of prostaglandins, one or more of which may be involved in signal systems that influence cell proliferation or tumor growth. Aspirin inhibits cyclooxygenase, the enzyme that catalyzes the conversion of arachidonic acid in cell membranes to prostaglandins. One form of cyclooxygenase, COX-2, promotes inflammation and cell proliferation, and colorectal cancers often overexpress this enzyme. Regular use of aspirin appears to reduce the risk of colorectal cancers that overexpress COX-2, but not the risk of colorectal cancers with weak or absent expression of COX-2. Supplemental folate and calcium, selected vitamins, and postmenopausal hormone

![Diagram of the histogenesis of adenomatous polyps of the colon.](image-url)
replacement therapy (estrogen)\textsuperscript{127} also have been proposed as potential chemoprotective agents. All of these agents will require more extensive study before they can be recommended for long-term chemoprevention of colorectal cancer.

Usually, cancer of the colon and rectum is present for a long time before it produces symptoms. Bleeding is a highly significant early symptom and usually is the one that causes people to seek medical care. Other symptoms include a change in bowel habits, diarrhea or constipation, and sometimes a sense of urgency or incomplete emptying of the bowel. Pain usually is a late symptom.

The prognosis for people with colorectal cancer depends largely on the extent of bowel involvement and on the presence of metastasis at the time of diagnosis. Colorectal cancer commonly is classified into four TNM (tumor, node, and metastasis) stages. In this system, a stage I tumor is limited to invasion of the mucosal and submucosal layers of the colon and has a 5-year survival rate of 90% to 100%.\textsuperscript{14} A stage II (lymph node–negative) tumor infiltrates into, but not through, the muscularis propria and has a 5-year survival rate of 80%.\textsuperscript{14} With a stage III (lymph node–positive) tumor, in which there is invasion of the serosal layer and regional lymph node involvement, the 5-year survival rate is 30% to 50%.\textsuperscript{14} Stage IV (metastatic) tumors penetrate the serosa or adjacent organs and have a much poorer prognosis.

**Screening, Diagnosis, and Treatment.** The single most important prognostic indicator of colorectal cancer is the extent (stage) of the tumor at time of diagnosis.\textsuperscript{12} Therefore, the challenge is to discover the tumors at their earliest stages. Among the methods used for the detection of colorectal cancers are the digital rectal examination and the fecal occult blood test, usually done during routine physical examinations; x-ray studies using barium (e.g., barium enema); and flexible sigmoidoscopy and colonoscopy.\textsuperscript{121} Digital rectal examinations are most helpful in detecting neoplasms of the rectum. Rectal examination should be considered a routine part of a good physical examination. The American Cancer Society recommends that all asymptomatic men and women older than 40 years of age should have a digital rectal examination performed annually as a part of their physical examination. Beginning at 50 years of age, both men and women should follow one of these five screening options: fecal occult blood test every year; flexible sigmoidoscopy examination every 5 years; annual fecal occult blood test for blood and flexible sigmoidoscopy every 5 years; double-contrast barium enema every 5 years; or a colonoscopy every 10 years.\textsuperscript{121} People with increased risk for colorectal cancer should be screened earlier and more often. Colonoscopy is recommended whenever a screening test is positive.

Almost all cancers of the colon and rectum bleed intermittently, although the amount of blood is small and usually not apparent in the stools. It therefore is feasible to screen for colorectal cancers using commercially prepared tests for occult blood in the stool.\textsuperscript{14,122} Two slides must be prepared from three consecutive bowel movements. To reduce the likelihood of false-positive test results, people are instructed to avoid NSAIDs such as ibuprofen and aspirin for 7 days before testing; to avoid vitamin C in excess of 250 mg from either supplements or citrus fruits for 3 days before testing; and to avoid red meats for 3 days before testing. The most commonly used tests are guaiac-based fecal occult blood tests, which are uncomplicated and can be processed in a health care provider’s office. There are also immunochemistry-based tests that may be processed in a laboratory or in the health care provider’s office, but they are less commonly used. People with a positive fecal occult blood test should be referred to their physician for further study. Usually, a physical examination, rectal examination, and flexible sigmoidoscopy or colonoscopy are done.

Flexible sigmoidoscopy involves examination of the rectum and sigmoid colon with a hollow, lighted tube that is inserted through the rectum. The procedure is performed without sedation and is well tolerated. Approximately 40\% of cancers and polyps are out of the reach of the sigmoidoscope, emphasizing the need for fecal occult blood tests. Polyps can be removed or tissue can be obtained for biopsy during the procedure.

Colonoscopy provides a means for direct visualization of the rectum and colon. The colonoscope consists of a flexible, 4-cm-diameter glass fiber bundle that contains approximately 250,000 glass fibers and has a lens at either end to focus and magnify the image. Light from an external source is transmitted by the fiberoptic-viewing bundle. Instruments are available that afford direct examination of the sigmoid colon or the entire colon. This method is used for screening people at high risk for development of cancer of the colon (e.g., those with ulcerative colitis) and for those with symptoms. Colonoscopy also is useful for obtaining a biopsy and for removing polyps. Although this method is one of the most accurate for detecting early colorectal cancers, it is not suitable for mass screening because it is expensive and time consuming and must be done by a person who is highly trained in the use of the instrument.

The only recognized treatment for cancer of the colon and rectum is surgical removal.\textsuperscript{129} Preoperative radiation therapy may be used and has in some cases demonstrated increased 5-year survival rates. Postoperative adjuvant chemotherapy may be used. Radiation therapy and chemotherapy are used as palliative treatment methods.

**IN SUMMARY**

Disorders of the small and large intestines include IBS, IBD, diverticular disease, disorders of motility (i.e., diarrhea, constipation, fecal impaction, and intestinal obstruction), alterations in intestinal absorption, and colorectal cancer.

IBS is a functional disorder characterized by a variable combination of chronic and recurrent intestinal symptoms not explained by structural or biochemical abnormalities. The term *inflammatory bowel disease* is used to designate
two inflammatory conditions: Crohn disease, which affects the small and large bowel, and ulcerative colitis, which affects the colon and rectum. Both are chronic diseases characterized by remissions and exacerbations of diarrhea, weight loss, fluid and electrolyte disorders, and systemic signs of inflammation.

Infectious forms of enterocolitis include viral (e.g., rotavirus), bacterial (e.g., C. difficile and E. coli O157:H7), and protozoal (E. histolytica) infections. Diverticular disease includes diverticulosis, which is a condition in which the mucosal layer of the colon herniates through the muscularis layer, and diverticulitis, in which there is inflammation and gross or microscopic perforation of the diverticulum.

Diarrhea and constipation represent disorders of intestinal motility. Diarrhea is characterized by excessively frequent passage of stools. It can be acute or chronic and can be caused by infectious organisms, food intolerance, drugs, or intestinal disease. Acute diarrheas that last less than 4 days are predominantly caused by infectious agents and follow a self-limited course. Chronic diarrhea persists beyond 3 to 4 weeks and is caused by the presence of hyperosmotic luminal contents, increased intestinal secretory processes, inflammatory conditions, and infectious processes. Constipation can be defined as the frequent passage of stools; it commonly is caused by failure to respond to the urge to defecate, inadequate fiber or fluid intake, weakness of the abdominal muscles, inactivity and bed rest, pregnancy, hemorrhoids, and GI disease. Fecal impaction is the retention of hardened or putty-like stool in the rectum and colon, which interferes with normal passage of feces. Intestinal obstruction designates an impairment of movement of intestinal contents in a cephalocaudal direction as the result of mechanical or paralytic mechanisms. Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation resulting from perforation of the viscera or abdominal organs.

Malabsorption results from the impaired absorption of nutrients and other dietary constituents from the intestine. It can involve a single dietary constituent, such as vitamin B<sub>12</sub>, or extend to involve all of the substances absorbed in a particular part of the small intestine. Malabsorption can result from disease of the small bowel and disorders that impair digestion and, in some cases, obstruct the lymph flow by which fats are transported to the general circulation. Celiac disease is an immune-mediated disorder triggered by ingestion of gluten-containing grains (including wheat, barley, and rye).

Colorectal cancer, the second most common fatal cancer, is seen most commonly in people older than 50 years of age. Most, if not all, cancers of the colon and rectum arise in preexisting adenomatous polyps. Programs that provide careful follow-up for people with adenomatous polyps and removal of all suspect lesions have substantially reduced the incidence of colorectal cancer.

**REVIEW EXERCISES**

1. A 40-year-old man reports to his health care provider complaining of “heartburn” that occurs after eating and also wakes him up at night. He is overweight, admits to enjoying fatty foods, and usually lies down on the sofa and watches TV after dinner. He also complains that lately he has been having a cough and some wheezing. A diagnosis of GERD was made.
   A. Explain the cause of heartburn and why it becomes worse after eating.
   B. People with GERD are advised to lose weight, avoid eating fatty foods, remain sitting after eating, and to sleep with their head slightly elevated. Explain the possible relationship between these situations and the occurrence of reflux.
   C. Explain the possible relationship between GERD and the respiratory symptoms this man is having.

2. A 36-year-old woman who has been taking aspirin for back pain experiences a sudden episode of tachycardia and feeling faint, accompanied by the vomiting of a coffee-ground emesis and the passing of a tarry stool. She relates that she has not had any signs of a “stomach ulcer” such as pain or vomiting after eating and also w

3. A 29-year-old woman has been diagnosed with Crohn disease. Her medical history reveals that she began having symptoms of the disease at 24 years of age and that her mother died of complications of the disease at 54 years of age. She complains of diarrhea and chronic cramping abdominal pain.
   A. Define the term inflammatory bowel disease and compare the pathophysiologic processes and manifestations of Crohn disease and ulcerative colitis.
   B. Describe the possible association between genetic and environmental factors in the pathogenesis of Crohn disease.
   C. Relate the use of the monoclonal antibody infliximab to the pathogenesis of the inflammatory lesions that occur in Crohn disease.

UNIT XI Disorders of Gastrointestinal Function

Chapter 45  Disorders of Gastrointestinal Function 1207

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
The liver, the gallbladder, and the exocrine pancreas are classified as accessory organs of the gastrointestinal tract. In addition to producing digestive secretions, the liver and the pancreas have other important functions. The endocrine pancreas, for example, supplies the insulin and glucagon needed in cell metabolism, whereas the liver synthesizes glucose, plasma proteins, and blood clotting factors and is responsible for the degradation and elimination of drugs and hormones, among other functions. This chapter focuses on functions and disorders of the liver, the biliary tract and gallbladder, and the exocrine pancreas.
The liver is the largest visceral organ in the body, weighing approximately 1.3 kg (3 lb) in the adult. It is located below the diaphragm and occupies much of the right hypochondrium (Fig. 46.1). A tough fibroelastic capsule, called the Glisson capsule, surrounds the liver. The liver is anatomically divided into two large lobes (the right and left lobes) and two smaller lobes (the caudate and quadrate lobes). Except for the portion that is in the epigastric area, the liver is contained within the rib cage, and cannot normally be palpated in healthy people.

The liver receives 25% of the resting cardiac output. The liver is unique among the abdominal organs in having a dual blood supply consisting of a venous (portal) supply through the hepatic portal vein and an arterial supply through the hepatic artery. Approximately 25% of blood per minute enters the liver through the hepatic artery; the remaining 75% enters by way of the valveless portal vein. The venous blood delivered by the hepatic portal vein comes from the digestive tract and major abdominal organs, including the pancreas and spleen (Fig. 46.2). The portal blood supply carries nutrient and toxic materials absorbed in the intestine, blood cells and their breakdown products from the spleen, and insulin and glucagon from the pancreas. Although the blood from the portal vein is incompletely saturated with oxygen, it supplies approximately 75% of the oxygen needs of the liver.1

The venous outflow from the liver is carried by the valveless hepatic veins, which empty into the inferior vena cava just below the level of the diaphragm. The pressure difference between the hepatic vein and the portal vein normally is such that the liver has the ability to store approximately 500 to 1000 mL of blood. This blood can be shifted back into the general circulation during periods of hypovolemia and shock. In right heart failure in which the pressure in the vena cava increases, blood backs up and accumulates in the liver.

The lobules are the functional units of the liver. Each lobule is a cylindrical structure that measures approximately 0.8 to 2 mm in diameter and several millimeters in length. There are approximately 50,000 to 100,000 lobules in the liver. Each lobule is organized around a central vein that empties into the hepatic veins and from there into the vena cava. The terminal bile ducts and small branches of the portal vein and hepatic artery are located at the periphery of the lobule. Plates of hepatic cells radiate centrifugally from the central vein like spokes on a wheel (Fig. 46.3). These hepatic plates are separated by wide, thin-walled sinusoidal capillaries, called sinusoids, which extend from the periphery of the lobule to its central vein. The sinusoids are supplied by blood from the portal vein and hepatic artery. The sinusoids are in intimate contact with the hepatocytes and provide for the exchange of substances between the blood and liver cells. The sinusoids are lined with two types of cells: the typical capillary endothelial cells and Kupffer cells. Kupffer cells are reticuloendothelial cells that are capable of removing and phagocytizing old and defective blood cells, bacteria, and other foreign material from the portal blood as it flows through the sinusoid. This phagocytic action removes enteric
Chapter 46  Disorders of Hepatobiliary and Exocrine Pancreas Function

bacilli and other harmful substances that filter into the blood from the intestine.

A major exocrine function of the liver is bile secretion. Small tubular channels, called bile canaliculi, which lie between the cell membranes of adjacent hepatocytes, also supply the lobules. The bile produced by the hepatocytes flows into the canaliculi and then to the periphery of the lobules, draining into progressively larger ducts, until it reaches the right and left hepatic ducts. The intrahepatic and extrahepatic bile ducts often are collectively referred to as the hepatobiliary tree. These ducts unite to form the common duct (see Fig. 46.1). The common duct, which is approximately 10 to 15 cm long, descends and passes behind the pancreas and enters the descending duodenum. The pancreatic duct joins the common duct at a short dilated tube called the hepatopancreatic ampulla (ampulla of Vater), which empties into the duodenum through the duodenal papilla. Muscle tissue at the junction of the papilla, sometimes called the sphincter of Oddi, regulates the flow of bile into the duodenum. When this sphincter is closed, bile moves back into the common duct and gallbladder.

**Metabolic Functions of the Liver**

The liver is one of the most versatile and active organs in the body. It produces bile; metabolizes hormones and drugs; synthesizes proteins, glucose, and clotting factors; stores vitamins and minerals; changes ammonia produced by deamination of amino acids to urea; and converts fatty acids to ketones. The liver also degrades excess nutrients and converts them into substances essential to the body. In its capacity for metabolizing drugs and hormones, the liver serves as an excretory organ. In this respect, the bile, which carries the end products of substances metabolized by the liver, is much like the urine, which carries the body wastes filtered by the kidneys. The functions of the liver are summarized in Table 46.1.

Carbohydrate Metabolism

The liver plays an essential role in carbohydrate metabolism and glucose homeostasis (Fig. 46.4). The liver cells have the ability to store large amounts of glucose as glycogen through a process called glycogenesis. When blood glucose levels are low, glycogen is converted back to glucose through glycogenolysis involving an enzyme phosphatase that is specific to liver cells. The liver also synthesizes glucose from amino acids, glycerol, and lactic acid as a means of maintaining blood glucose during periods of fasting or increased need. The liver also converts excess carbohydrates to triglycerides for storage in adipose tissue.

Protein Synthesis and Conversion of Ammonia to Urea

The liver is an important site for protein synthesis and degradation. It produces the proteins for its own cellular needs and secretory proteins that are released into the circulation. The most important of these secretory proteins is albumin. Albumin contributes significantly to the plasma colloidal osmotic pressure and to the binding and transport of numerous substances, including some hormones, fatty acids, bilirubin, and other anions. The liver also produces other important proteins, such as fibrinogen and the blood clotting factors.

Through a variety of anabolic and catabolic processes, the liver is the major site of amino acid interconversion (Fig. 46.5). Hepatic catabolism and degradation involve two major reactions: transamination and deamination. In transamination, an amino group (NH₂) is transferred to an acceptor substance. As a result of transamination, amino acids can participate in the intermediary metabolism of carbohydrates and lipids. During periods of fasting or starvation, amino acids are used for producing glucose (i.e., gluconeogenesis). Most of the nonessential amino acids are synthesized in the liver by transamination. The process of transamination is catalyzed by aminotransferases, enzymes that are found in high amounts in the liver.

Oxidative deamination involves the removal of the amino groups from amino acids and conversion of amino acids to ketoacids and ammonia. This occurs mainly by transamination, in which the amino groups are removed and then transferred to another acceptor substance. The acceptor substance can then transfer the amino group to still another substance or release it as ammonia. Because ammonia is very toxic to body tissues, particularly neurons, the ammonia that is released during deamination is rapidly removed from the blood by the liver and converted to urea. Essentially all urea formed in the body is synthesized by the urea cycle in the liver and then excreted by the kidneys. Although urea is mostly excreted by the kidneys, some diffuses into the intestine, where it is converted to ammonia by enteric bacteria. The intestinal production of ammonia also results from bacterial deamination of unabsorbed amino acids and proteins derived from the diet, exfoliated cells, or blood in the gastrointestinal tract. Ammonia produced in the intestine is absorbed into the portal circulation and transported to the liver, where it is converted to urea before being released into the systemic circulation. Intestinal production of ammonia is increased after ingestion of high-protein foods and gastrointestinal bleeding. In advanced liver disease, urea synthesis often is impaired, leading to an accumulation of blood ammonia.
Pathways of Lipid Metabolism

Although most cells of the body metabolize fat, certain aspects of lipid metabolism occur mainly in the liver, including the oxidation of free fatty acids to ketoacids that supply energy for other body functions; synthesis of cholesterol, phospholipids, and lipoproteins; and formation of triglycerides from carbohydrates and proteins (Fig. 46.6). To derive energy from triglycerides, the molecule must first be split into glycerol and fatty acids, and then the fatty acids must be split into two-carbon acetyl-coenzyme A (acetyl-CoA) units by a process called beta oxidation. Acetyl-CoA is readily channeled into the citric acid cycle to produce adenosine triphosphate (ATP). Because the liver cannot use all the acetyl-CoA that is formed, it converts the excess into acetoacetic acid, a highly soluble ketoacid that is released into the bloodstream and transported to other tissues, where it is used for energy. During periods of starvation, ketones become a major source of energy as fatty acids released from adipose tissue are converted to ketones by the liver.

Acetyl-CoA units from fat metabolism also are used to synthesize cholesterol and bile acids in the liver. Cholesterol can be used in several ways by the liver. It can be esterified and stored; it can be exported bound to lipoproteins; or it can be converted to bile acids. The rate-limiting step in cholesterol synthesis is that which is catalyzed by 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA reductase). The HMG-CoA reductase inhibitors, or statins (fluvarstatin, lovastatin, pravastatin, and atorvastatin), are used to treat high cholesterol levels by inhibiting this step in cholesterol synthesis.

Almost all the fat synthesis in the body from carbohydrates and proteins occurs in the liver. Whenever a greater quantity of carbohydrates enters the body than can be immediately used, the excess is converted to triglycerides in the liver. The triglycerides formed in the liver are transported mainly in low-density lipoproteins (LDLs) to the adipose tissue, where they are stored.

**Bile Production and Cholestasis**

The secretion of bile is essential for digestion of dietary fats and absorption of fats and fat-soluble vitamins from the intestine. The liver produces approximately 500 to 600 mL of yellow-green bile daily. Bile contains water, bile salts, bilirubin, cholesterol, and certain by-products of metabolism. Of these, only bile salts, which are formed from cholesterol, are important in digestion. The other components of bile depend on the secretion of sodium, chloride, bicarbonate, and potassium by the bile ducts.

Bile salts serve an important function in digestion; they aid in emulsifying dietary fats, and they are necessary for the formation of the micelles that transport fatty acids and fat-soluble vitamins to the surface of the intestinal mucosa for absorption. The system for the recirculation of bile, the enterohepatic circulation, involves multiple components. The liver, biliary tract, gallbladder, portal venous circulation, small intestine, colon, and kidneys, all play a role to varying degrees. Greater than 90% of bile salts that enter the intestine are reabsorbed into the portal circulation by an active transport process that takes place in the distal ileum. From the portal circulation, the bile salts move into the liver cells and are recycled. Normally, bile salts travel this entire circuit approximately 17 times before being expelled in the feces.

**Cholestasis**

Cholestasis represents a decrease in bile flow through the intrahepatic canaliculi and a reduction in secretion of water, bilirubin, and bile acids by the hepatocytes. As a result, the materials normally transferred to the bile, including bilirubin, cholesterol, and bile acids, accumulate in the blood. The condition may be caused by intrinsic liver disease, in which case it is referred to as intrahepatic cholestasis, or by obstruction of the large bile ducts, a condition known as extrahepatic cholestasis.

A number of mechanisms are implicated in the pathogenesis of cholestasis. Primary biliary cirrhosis (an autoimmune disease) and primary sclerosing cholangitis are caused by disorders of the small intrahepatic canaliculi and bile ducts. In the case of extrahepatic obstruction, which can be caused by conditions such as cholelithiasis, common duct strictures, or
obstructing neoplasms, the effects begin with increased pressure in the large bile ducts. Genetic disorders that can result in cholestasis include benign recurrent cholestasis, Byler syndrome, and Alagille syndrome. Benign recurrent cholestasis involves the transport of bile into the canaliculi. Byler syndrome is also known as progressive familial intrahepatic cholestasis type I. The gene mutation responsible for the disease results in diarrhea, pruritis, and liver failure. The gene is also located in the small bowel and pancreas, which affects the gastrointestinal and endocrine systems. Alagille syndrome is an autosomal dominant disease that involves the intrahepatic hypoplasia specifically of the interlobar bile ducts. Patients with the syndrome present with cardiac and eye abnormalities along with skeletal abnormalities, specifically in the facial bones.

The morphologic features of cholestasis depend on the underlying cause. Common to all types of obstructive and hepatocellular cholestasis is the accumulation of bile pigment in the liver. Elongated green-brown plugs of bile are visible in the dilated bile canaliculi. Rupture of the canaliculi leads to extravasation of bile and subsequent degenerative changes in the surrounding hepatocytes. Prolonged obstructive cholestasis leads not only to fatty changes in the hepatocytes but to destruction of the supporting connective tissue, giving rise to reservoirs of bile containing cellular debris and pigment. Unrelieved obstruction leads to biliary tract fibrosis and ultimately to end-stage biliary cirrhosis.

Pruritus is the most common presenting symptom in people with cholestasis, probably related to an elevation in plasma bile acids. Skin xanthomas (focal accumulations of cholesterol) may occur, the result of hyperlipidemia and impaired excretion of cholesterol. A characteristic laboratory finding is an elevated serum alkaline phosphatase level, an enzyme present in the bile duct epithelium and canalicular membrane of hepatocytes. Other manifestations of reduced bile flow relate to intestinal absorption, including nutritional deficiencies of the fat-soluble vitamins A, D, and K.

Bilirubin Elimination and Jaundice

Bilirubin is the final product of the breakdown of heme contained in aged red blood cells. Bilirubin is the substance that gives bile its color. In the process of degradation, the hemoglobin from the red blood cell is broken down to form biliverdin, which is rapidly converted to free bilirubin (Fig. 46.7). Free bilirubin, which is insoluble in plasma, is transported in the blood attached to plasma albumin. Even when it is bound to albumin, this bilirubin is still called free bilirubin, to distinguish it from conjugated bilirubin. As it passes through the liver, free bilirubin is absorbed through the hepatocytes’ cell membrane and released from its albumin carrier molecule. Inside the hepatocytes, free bilirubin is converted to conjugated bilirubin, making it soluble in bile. Conjugated bilirubin is secreted as a constituent of bile, and in this form it passes through the bile ducts into the small intestine. In the intestine, approximately one half of the bilirubin is converted into a highly soluble substance called urobilinogen by the intestinal flora. Approximately one fifth of the urobilinogen produced is either absorbed into the portal circulation and the remaining is excreted in the feces. Most of the urobilinogen that is absorbed is returned to the liver to be reexcreted into the bile.

Usually, only a small amount of bilirubin is found in the blood; the normal level of total serum bilirubin is less than 1.5 mg/dL (17 to 20.5 µmol). Laboratory measurements of bilirubin usually measure the free and the conjugated bilirubin as well as the total bilirubin. These are reported as the direct (conjugated) bilirubin and the indirect (unconjugated or free) bilirubin.

Jaundice

Jaundice (i.e., icterus) or a yellowish discoloration of the skin and deep tissues results from abnormally high levels of bilirubin in the blood. Jaundice occurs when there is an imbalance
between the synthesis of bilirubin and the clearance of bilirubin. Jaundice becomes evident when the serum bilirubin levels rise above 2 to 2.5 mg/dL (34.2 to 42.8 µmol).5,10 Because normal skin has a yellow cast, the early signs of jaundice often are difficult to detect, especially in persons with dark skin. Bilirubin has a special affinity for elastic tissue. The sclera of the eye, which contains a high proportion of elastic fibers, usually is one of the first structures in which jaundice can be detected (Fig. 46.8).

The five major causes of jaundice are excessive destruction of red blood cells, impaired uptake of bilirubin by the liver cells, decreased conjugation of bilirubin, obstruction of bile flow in the canaliculi of the hepatic lobules or in the intrahepatic or extrahepatic bile ducts, and excessive extrahepatic production of bilirubin.12 From an anatomic standpoint, jaundice can be categorized as prehepatic, hepatic, and posthepatic. Chart 46.1 lists the common causes of prehepatic, hepatic, and posthepatic jaundice.

The major cause of prehepatic jaundice is excessive hemolysis of red blood cells. Hemolytic jaundice occurs when red blood cells are destroyed at a rate in excess of the liver’s ability to remove the bilirubin from the blood. It may follow a hemolytic blood transfusion reaction, due to the decreased lifespan of the donated red blood cells, or may occur in diseases such as hereditary spherocytosis, in which the red cell membranes are defective, or in hemolytic disease of the newborn. When internal hemorrhage occurs, there can also be excess bilirubin production with the reabsorption of the blood. In addition, diseases resulting in ineffective erythropoiesis can also increase bilirubin production.10 Neonatal hyperbilirubinemia results from increased production of bilirubin in newborn infants and their limited ability to excrete it from 0 to 14 days old.10 Premature infants are at particular risk because their red cells have a shorter life span and higher turnover rate. In prehepatic jaundice, there is mild jaundice, the unconjugated bilirubin is elevated, the stools are of normal color, and there is no bilirubin in the urine.

Intrahepatic or hepatocellular jaundice is caused by disorders that directly affect the ability of the liver to remove bilirubin from the blood or conjugate it so it can be eliminated in the bile. Gilbert disease is inherited as a dominant trait and results in a reduced, by 66% on average, removal of bilirubin from the blood. The disorder is benign and fairly common with a prevalence rate of approximately 8%.12 Affected people have no symptoms other than a slightly elevated unconjugated bilirubin and mild jaundice. Conjugation of bilirubin is impaired whenever liver cells are damaged, when transport of bilirubin into liver cells becomes deficient, or when the enzymes needed to conjugate the bile are lacking. Liver diseases such as hepatitis and cirrhosis are the most common causes of intrahepatic jaundice. Drugs such as the anesthetic agent halothane, oral contraceptives, estrogen, anabolic steroids, isoniazid, rifampin, and chlorpromazine may also be implicated in this type of jaundice. Intrahepatic or hepatocellular jaundice usually interferes with all phases of bilirubin metabolism—uptake, conjugation, and excretion. Both conjugated and unconjugated bilirubin are elevated, the urine often is dark because of bilirubin in the urine, and the serum alkaline phosphatase is slightly elevated.

Posthepatic or obstructive jaundice, also called cholestatic jaundice, occurs when bile flow is obstructed between
the liver and the intestine, with the obstruction located at any point between the junction of the right or left hepatic duct and the point where the bile duct opens into the intestine. Among the causes are strictures of the bile duct, gallstones, and tumors of the bile duct or the pancreas. Conjugated bilirubin levels usually are elevated; the stools are clay colored because of the lack of bilirubin in the bile; the urine is dark; the levels of serum alkaline phosphatase are markedly elevated; and the aminotransferase levels are slightly increased. Blood levels of bile acids often are elevated in obstructive jaundice. As the bile acids accumulate in the blood, pruritus develops. A history of pruritus preceding jaundice is common in obstructive jaundice.

**Tests of Hepatobiliary Function**

The history and physical examination, in most instances, provide clues about liver function. Diagnostic tests help to evaluate liver function and confirm the diagnosis of liver disease. Laboratory tests commonly are used to assess liver function and confirm the diagnosis of liver disease.

Liver function tests, including serum levels of liver enzymes, are used to aid in the diagnosis of disease, differentiate between different disorders, determine the severity of present disease, and monitor responses to established treatment. Elevated serum enzyme test results usually indicate liver injury earlier than other indicators of liver function. The key enzymes are alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which are present in liver cells. ALT is liver specific, whereas AST is derived from organs other than the liver. In most cases of liver damage, there are parallel rises in ALT and AST. The most dramatic rise is seen in cases of acute hepatocellular injury, as occurs with viral hepatitis, hypoxic or ischemic injury, acute toxic injury, or Reye syndrome.

The liver’s synthetic capacity is reflected in measures of serum protein levels and prothrombin time (i.e., synthesis of coagulation factors). Hypoalbuminemia due to depressed synthesis of serum protein levels and prothrombin time (PT) syndrome.

Tests of Hepatobiliary Function

The hepatobiliary system consists of the liver, gallbladder, and bile ducts. The liver is the largest and, in functions, one of the most versatile organs in the body. It is located between the gastrointestinal tract and the systemic circulation; venous blood from the intestine flows through the liver before it is returned to the heart. In this way, nutrients can be removed for processing and storage, and bacteria and other foreign matter can be removed by Kupffer cells before the blood is returned to the systemic circulation.

The liver synthesizes fats, glucose, and plasma proteins. Other important functions of the liver include the deamination of amino acids, conversion of ammonia to urea, and the interconversion of amino acids and other compounds that are important to the metabolic processes of the body. The liver produces approximately 500 to 600 mL of yellow-green bile daily. Bile serves as an excretory vehicle for bilirubin, cholesterol, and certain products of organic metabolism, and it contains bile salts that are essential for digestion of fats and absorption of fat-soluble vitamins. The liver also removes, conjugates, and secretes bilirubin into the bile. Jaundice occurs when bilirubin accumulates in the blood. It can occur because of excessive red blood cell destruction, failure of the liver to remove and conjugate the bilirubin, or obstructed biliary flow.

Liver function tests, including serum aminotransferase levels, are used to assess injury to liver cells. Serum bilirubin, GGT, 5′-nucleotidase, and alkaline phosphatase are used as measures of hepatic excretory function. Ultrasoundography, CT scans, and MRI are used to evaluate liver structures. Angiography may be used to visualize the hepatic or portal circulation, and a liver biopsy obtains tissue specimens for microscopic examination.
The structures of the hepatobiliary system are subject to many of the same pathologic conditions that affect other body systems: injury from drugs and toxins; infection, inflammation, and immune responses; metabolic disorders; and neoplasms. This section focuses on alterations in liver function due to drug-induced injury; viral and autoimmune hepatitis; intrahepatic biliary tract disorders; alcohol-induced liver disease; cirrhosis, portal hypertension, and liver failure; and cancer of the liver.

**Hepatotoxic Disorders**

By virtue of its many enzyme systems that are involved in biochemical transformations and modifications, the liver has an important role in the metabolism of many drugs and chemical substances. The liver is particularly important in terms of metabolizing lipid-soluble substances that cannot be directly excreted by the kidneys. The liver is central to the metabolic disposition of virtually all drugs and foreign substances. Therefore, drug-induced liver toxicity is a potential complication of many medications.

**Drug and Hormone Metabolism**

Three major types of reactions are involved in the hepatic detoxification and metabolism of drugs and other chemicals:

1. Phase 1 reactions, which involve chemical modification or inactivation of a substance
2. Phase 2 reactions, which involve conversion of lipid-soluble substances to water-soluble derivatives
3. Phase 3 reactions, which involve the substance, its metabolites, or conjugates being secreted as bile

All three types of reactions may be linked, depending upon the composition of the substance being eliminated. For example, many phase 1 reactants are not water soluble and must therefore undergo a subsequent phase 2 reaction to be eliminated. These reactions, which are called biotransformations, are important considerations in drug therapy.

**Phase 1 Reactions.** Phase 1 reactions result in chemical modification of reactive drug groups by oxidation, reduction, hydroxylation, or other chemical reactions. Most drug-metabolizing enzymes are located in the lipophilic membranes of the smooth endoplasmic reticulum of liver cells. When these membranes are broken down and separated in the laboratory, they re-form into vesicles called microsomes. The enzymes in these membranes are often referred to as microsomal enzymes. The enzymes involved in most phase 1 oxidation–reduction processes are products of a gene superfamily that has nearly 300 members. These genes code for a group of microsomal isoenzymes that make up the cytochrome (CYP) P450 system. (The name cytochrome P450 is derived from the spectral properties [absorb light at 450 nm] of the hemoproteins that participate in oxidation–reduction processes.) The gene products of many of the CYP genes have been identified and traced to the metabolism of specific drugs and to potential interactions among drugs. Each family of genes is responsible for certain drug-metabolizing processes, and each member of the family undertakes specific drug-metabolizing functions. For example, the CYP3 gene family contains an A subfamily and several genes numbered 1, 2, 3, and so forth. For example, the primary enzyme for the metabolism of erythromycin in humans is CYP 3A4.

Many gene members of the CYP system can have their activity induced or suppressed as they undergo the task of metabolizing drugs. For example, drugs such as alcohol and barbiturates can induce certain members to increase enzyme production, accelerating drug metabolism and decreasing the pharmacologic action of the drug and of coadministered drugs that use the same member of the CYP system. In the case of drugs metabolically transformed to reactive intermediates, enzyme induction may exacerbate drug-mediated tissue toxicity. Enzymes in the cytochrome system also can be inhibited by drugs. For example, imidazole-containing drugs such as cimetidine (a histamine type 2 receptor–blocking drug that is used to reduce gastric acid secretion) and ketoconazole (an antifungal agent) effectively inhibit the metabolism of testosterone. Environmental pollutants also are capable of inducing CYP gene activity. For example, exposure to benzo[a]pyrene, which is present in tobacco smoke, charcoal-broiled meat, and other organic pyrolysis products, is known to induce members of the CYP family and alter the rates of metabolism of some drugs.

**Phase 2 Reactions.** Phase 2 reactions, which involve the conversion of lipid-soluble derivatives to water-soluble substances, may follow phase 1 reactions or proceed independently.
Conjugation, catalyzed by endoplasmic reticulum enzymes that couple the drug with an activated endogenous compound to render it more water soluble, is one of the most common phase 2 reactions. Although many water-soluble drugs and endogenous substances are excreted unchanged in the urine or bile, lipid-soluble substances tend to accumulate in the body unless they are converted to less active compounds or water-soluble metabolites. In general, the conjugates are more soluble than the parent compound and are pharmacologically inactive. Because the endogenous substrates used in the conjugation process are obtained from the diet, nutrition plays a critical role in phase 2 reactions.

An alternative cytochrome P450–dependent conjugation pathway is important in detoxifying reactive metabolic intermediates. This pathway uses a thiol, or sulfur-containing substance, called glutathione, which is used in conjugating drugs that form potentially harmful electrophilic groups. Glutathione is depleted in the detoxification process and must be constantly replenished by compounds from the diet or by cysteine-containing drugs such as N-acetylcysteine. The glutathione pathway is central to the detoxification of a number of compounds, including the over-the-counter pain medication acetaminophen (e.g., Tylenol). Acetaminophen metabolism involves a phase 2 reaction. Normally, the capacity of the phase 2 reactants is much greater than that required for metabolism recommended doses of the drug. However, in situations of acetaminophen overdose, the capacity of the phase 2 system is exceeded, and the drug is transformed into toxic metabolites that cause necrosis of the liver if allowed to accumulate. In this situation, the glutathione pathway plays a critical role in the detoxification of these metabolites. Because the glutathione stores are rapidly depleted, the drug N-acetylcysteine, which serves as a glutathione substitute, is used as a treatment for acetaminophen overdose. Chronic alcohol ingestion decreases glutathione stores and increases the risk of acetaminophen toxicity.

Phase 3 Reactions. Phase 3 reactions involve the secretion of drugs, drug metabolites, or drug conjugates into bile. ATP-binding cassette (ABC) proteins are intricately involved in this process. One example is multidrug resistance proteins 1, 2, and 3, which transport cationic drugs and their conjugates into bile.

In addition to its role in metabolism of drugs and chemicals, the liver also is responsible for hormone inactivation or modification. Insulin and glucagon are inactivated by proteolysis or deamination. Thyroxine and triiodothyronine are metabolized by reactions involving deiodination. Steroid hormones such as the glucocorticoids are first inactivated by a phase 1 reaction and then conjugated by a phase 2 reaction.

Drug-Induced Liver Disease

As the major drug-metabolizing and detoxifying organ in the body, the liver is subject to potential damage from the enormous array of pharmaceutical and environmental chemicals. Many of the widely used therapeutic drugs, including over-the-counter “natural” products, can cause hepatic injury. In a recent multicenter study, 10% of 300 cases of drug-induced liver injury were attributed to use of herbal products.

Numerous host factors contribute to the susceptibility to drug-induced liver disease, including genetic predisposition, age differences, underlying chronic liver disease, diet and alcohol consumption, and the use of multiple interacting drugs. In a recent study examining 1198 patients with acute liver failure, drug-induced liver injury was found to be the cause of failure in 11.1% of cases. Early identification of drug-induced liver disease is important because withdrawal of the drug is curative in most cases.

Drugs and chemicals can exert their effects by causing hepatocyte injury and death or by cholestatic liver damage due to injury of biliary drainage structures. Drug reactions can be predictable based on the drug’s chemical structure and metabolites or unpredictable (idosyncratic) based on individual characteristics of the person receiving the drug.

Direct Hepatotoxic Injury. Some drugs are known to have toxic effects on the liver based on their chemical structure and the way they are metabolized in the liver. Direct hepatic damage often is age and dose dependent. Direct hepatotoxic reactions usually are a recognized characteristic of certain drugs. They usually result from drug metabolism and the generation of toxic metabolites. Because of the greater activity of the drug-metabolizing enzymes in the central zones of the liver, these agents typically cause centrilobular necrosis. Acetaminophen, antimicrobials, psychotrophic agents, lipid-lowering agents, and nonsteroidal anti-inflammatory drugs (NSAIDs) are most commonly associated with acute liver injury. Acetaminophen toxicity is characterized by marked elevations in ALT and AST values with minimally elevated alkaline phosphatase. Bilirubin levels invariably are increased, and the prognosis often is worse when hepatocellular necrosis is accompanied by jaundice.

Idiosyncratic Reactions. In contrast to direct hepatotoxic drug reactions, idiosyncratic reactions are unpredictable, not related to dose, and sometimes accompanied by features suggesting an allergic reaction. In some cases, the reaction results directly from a metabolite that is produced only in certain people based on a genetic predisposition. For example, certain people are capable of rapid acetylation of isoniazid, an antituberculosis drug.

Cholestatic Reactions. Cholestatic drug reactions result in decreased secretion of bile or obstruction of the biliary tree. Acute intrahepatic cholestasis is one of the most frequent types of idiosyncratic drug reactions. Among the drugs credited with causing cholestatic drug reactions are estradiol; chlorpromazine, an antipsychotic drug; and some of the antibiotics, including amoxicillin/clavulanic acid, erythromycin, and nafcillin. Typically, cholestatic drug reactions are characterized by an early onset of jaundice and pruritus, with little
alteration in the person’s general feeling of well-being. The symptoms of acute drug-induced cholestasis subside once the drug is withdrawn, but the biliary secretory function returns at a slower rate than does the function of the liver itself.22

Chronic Hepatitis. Some drugs produce a more indolent form of liver damage that closely resembles autoimmune hepatitis. Early identification of drug-related chronic hepatitis often is difficult. Cirrhosis may develop before the hepatitis is diagnosed. Identifying the responsible drug that caused the liver damage may be difficult retrospectively if the person has been consuming alcohol or taking several drugs.

**KEY POINTS**

**DISEASES OF THE LIVER**

- Diseases of hepatocytes impair the metabolic and synthetic functions of the liver, causing disorders in carbohydrate, protein, and fat metabolism; metabolism and removal of drugs, hormones, toxins, ammonia, and bilirubin from the blood; and the interconversion of amino acids and synthesis of proteins. Elevations in serum aminotransferase levels signal the presence of hepatocyte damage.

- Diseases of the biliary drainage system obstruct the flow of bile and interfere with the elimination of bile salts and bilirubin, producing cholestatic liver damage because of the backup of bile into the lobules of the liver. Elevations in bilirubin and alkaline phosphatase signal the presence of cholestatic liver damage.

**Viral Hepatitis**

Hepatitis refers to inflammation of the liver. It can be caused by hepatotropic viruses that primarily affect liver cells or hepatocytes, autoimmune mechanisms, or reactions to drugs and toxins, or be secondary to other systemic disorders. Viruses causing systemic disease that can involve the liver include Epstein-Barr virus (infectious mononucleosis), which may cause a mild hepatitis during the acute phase; cytomegalovirus (particularly in newborns and immunosuppressed persons); herpesviruses; and enteroviruses.

The known hepatotropic viruses include hepatitis A virus (HAV), hepatitis B virus (HBV), the hepatitis B–associated delta virus (HDV), hepatitis C virus (HCV), and hepatitis E virus (HEV). Although all of these viruses cause acute hepatitis, they differ in the mode of transmission and incubation period; mechanism, degree, and chronicity of liver damage; and ability to evolve to a carrier state. The presence of viral antigens and their antibodies can be determined through laboratory tests. Epidemiologic studies have indicated that some cases of infectious hepatitis are due to other agents. A viral agent similar to HCV has been cloned and was identified as hepatitis G virus (HGV), also referred to as GBV-C.23 Evidence of HGV has been found in 2% of blood donors in the United States.24 However, HGV is not linked to liver disease or exacerbations of liver disease.21

**Etiology and Pathogenesis**

There are two mechanisms of liver injury in viral hepatitis: direct cellular injury and immune responses against the viral antigens. The mechanisms of injury have been most closely studied in HBV. It is thought that the extent of inflammation and necrosis depends on the person’s immune response. Accordingly, a prompt immune response during the acute phase of the infection would be expected to cause cell injury but at the same time eliminate the virus. Thus, people who respond with fewer symptoms and a marginal immune response are less likely to eliminate the virus, and hepatocytes expressing the viral antigens persist, leading to the chronic or carrier state. Fulminant hepatitis would be explained in terms of an accelerated immune response with severe liver necrosis.

The clinical course of viral hepatitis involves a number of syndromes, including asymptomatic infection with only serologic evidence of disease; acute hepatitis; the carrier state without clinically apparent disease or with chronic hepatitis; chronic hepatitis with or without progression to cirrhosis; or fulminating disease with rapid onset of liver failure. Not all hepatotropic viruses provoke each of the clinical syndromes.

**Clinical Manifestations**

The manifestations of acute viral hepatitis can be divided into three phases: the prodromal or preicterus period, the icterus period, and the recovery period. The manifestations of the prodromal period vary from abrupt to insidious, with general malaise, myalgia, arthralgia, easy fatigability, and anorexia.25 Gastrointestinal symptoms such as nausea, vomiting, and diarrhea or constipation may also occur.25 Serum levels of AST and ALT show variable increases during the preicterus phase of acute hepatitis and precede a rise in bilirubin that accompanies the onset of the icterus or jaundice phase of infection. The icterus phase, if it occurs, usually follows the prodromal phase by 7 to 14 days. People have tenderness around the area of the liver, mild weight loss, and spider angiomomas.25 Jaundice is less likely to occur with HCV infection.26 The recovery phase is characterized by an increased sense of well-being, return of appetite, and disappearance of jaundice. The acute illness usually subsides gradually over 2 to 12 weeks period, with complete clinical recovery in 1 to 4 months depending on the type of hepatitis.25 Infection with HBV and HCV can produce a carrier state in which the person does not have symptoms but harbors the virus and can therefore transmit the disease.27,28 Evidence also indicates a carrier state for HDV infection. There is no carrier state for HAV infection. There are two types of carriers: healthy carriers who have few or no ill effects and those with chronic disease who may or may not have symptoms. Factors that increase the risk of becoming a carrier are age at time of infection and immune status. The carrier state for infections that occur early in life, as in
infants of HBV-infected mothers, may be as high as 90%. Other people at high risk of becoming carriers are those with impaired immunity, those who have received multiple transfusions or blood products, those who are on hemodialysis, and drug addicts.

**Hepatitis A**

Hepatitis A is caused by the HAV, a small, unenveloped, single-stranded ribonucleic acid (RNA) virus. It usually is a benign, self-limited disease, although it can cause acute fulminant hepatitis and death or need for transplantation in 0.15% to 0.2% of cases.

**Etiology and Pathogenesis.** Hepatitis A is contracted primarily by the fecal–oral route. It has a brief incubation period of 14 to 28 days. The virus replicates in the liver, is excreted in the bile, and is shed in the stool. The fecal shedding of HAV occurs during the first 2 weeks of the illness. The disease often occurs sporadically or in epidemics. Drinking contaminated milk or water and eating shellfish from infected waters are fairly common routes of transmission. At special risk are people traveling abroad who have not previously been exposed to the virus. Because young children are asymptomatic, they play an important role in the spread of the disease. Institutions housing large numbers of people (usually children) sometimes are stricken with an epidemic of hepatitis A. Oral behavior and lack of toilet training promote viral infection among children attending preschool day care centers, who then carry the virus home to older siblings and parents. Hepatitis A usually is not transmitted by transfusion of blood or plasma derivatives, presumably because its short period of viremia usually coincides with clinical illness, so that the disease is apparent and blood donations are not accepted.

**Clinical Manifestations.** The onset of symptoms usually is abrupt and includes fever, malaise, nausea, anorexia, abdominal discomfort, dark urine, and jaundice. The presentation of symptoms is dependent upon age, with the severity of symptoms increasing in older age groups. Children younger than 6 years often are asymptomatic, and few develop jaundice. The illness in older children and adults usually is symptomatic and jaundice occurs in approximately 70% of cases. Symptoms usually last approximately 2 months but can last longer. HAV does not cause chronic hepatitis or induce a carrier state.

**Serologic Markers.** Antibodies to HAV (anti-HAV) appear early in the disease and tend to persist in the serum (Fig. 46.9). The IgM antibodies usually appear during the first week of symptomatic disease and slowly decline over a period of 3 to 4 months. Their presence coincides with a decline in fecal shedding of the virus. Peak levels of immunoglobulin G (IgG) antibodies occur after 1 month of illness and may persist for life; they provide long-term protective immunity against reinfection. The presence of IgM anti-HAV is indicative of acute hepatitis A, whereas IgG anti-HAV merely documents past infection.

**Immunization.** A hepatitis A vaccine is available. Immunization is intended to replace the use of immune globulin in people at high risk for HAV exposure. These include international travelers to regions where sanitation is poor and endemic HAV infections are high, children living in communities with high rates of HAV infection, homosexually active men, and users of illicit drugs. People with preexisting chronic liver disease also may benefit from immunization. A public health benefit also may be derived from vaccinating people with increased potential for transmitting the disease (e.g., food handlers). The Centers for Disease Control and Prevention (CDC) has recently recommended vaccination of children in states, counties, and communities with high rates of infection. Because the vaccine is of little benefit in prevention of hepatitis in people with known HAV exposure, IgG is recommended for these people.

**Hepatitis B**

Hepatitis B is caused by the HBV, a double-stranded deoxyribonucleic acid (DNA) virus. The complete virion, also called a Dane particle, consists of an outer envelope and an inner nucleocapsid that contains HBV DNA and DNA polymerase (Fig. 46.10). HBV infection can produce acute hepatitis, chronic hepatitis, progression of chronic hepatitis to cirrhosis, fulminant hepatitis with massive hepatic necrosis, and the carrier state. It also participates in the development of hepatitis D (delta hepatitis).

Worldwide, 350 million people have long-term hepatitis B infections. In the United States, the incidence of acute hepatitis B has declined by 82% since 1991, due to a national initiative. In 2006, the overall incidence (1.6 cases per 100,000) was the lowest ever recorded and represents a decline of 81% since the national childhood vaccination strategy was implemented in 1991. Although incidence has declined among people between the ages of 25 and 44 years, rates in this age group, particularly among males, still remains substantially higher than in other age groups, indicating a need for vaccination programs that target high-risk populations.
Hepatitis B has a longer incubation period and represents a more serious health problem than hepatitis A. The virus usually is transmitted through inoculation with infected blood or serum. However, the viral antigen can be found in most body secretions and can be spread by oral or sexual contact. In the United States, most people with hepatitis B acquire the infection as adults or adolescents. The disease is highly prevalent among injecting drug users, heterosexuals with multiple sex partners, and men who have sex with men.38,39 Health care workers are at risk owing to blood exposure and accidental needle injuries. Although the virus can be spread through transfusion or administration of blood products, routine screening methods have appreciably reduced transmission through this route. The risk of hepatitis B in infants born to HBV-infected mothers ranges from 10% to 85%, depending on the mother’s HBV status. Infants who become infected through this route have a 90% risk of becoming chronic carriers, and up to 25% will die of chronic liver disease as adults.39

Serologic Markers. Three well-defined antigens are associated with the virus: a core antigen, HBcAg, which is contained in the nucleocapsid; a longer polypeptide transcript with precore and core regions, designated HBeAg; and a surface antigen, HBsAg, which is found in the outer envelope of the virus. The precore region directs the HBeAg polypeptide toward the blood, whereas the HBcAg remains in the hepatocytes to direct the assembly of new virions.

The HBV antigens evoke specific antibodies: anti-HBs, anti-HBc, and anti-HBe. These antigens (HBcAg does not circulate freely in the blood) and their antibodies serve as serologic markers for following the course of the disease.40 (see Fig. 46.10). The HBsAg is the viral antigen measured most routinely in blood. It appears before onset of symptoms, peaks during overt disease, and then declines to undetectable levels in 3 to 6 months. Persistence beyond 6 months indicates continued viral replication, infectivity, and risk of chronic hepatitis. HBeAg appears in the serum soon after HBsAg and signifies active viral replication. IgM anti-HBe becomes detectable shortly before the onset of symptoms, concurrent with onset of an elevation in serum transaminases. Over the months, the IgM antibody is replaced by IgG anti-HBc. Anti-HBe is detectable shortly after the disappearance of HBeAg, and its appearance signals the onset of resolution of the acute illness. IgG anti-HBs, a specific antibody to HBsAg, occurs in most individuals after clearance of HBsAg. Development of anti-HBs signals recovery from HBV infection, noninfectivity, and protection from future HBV infection. Anti-HBs is the antibody present in persons who have been successfully immunized against HBV.

The presence of viral DNA (HBV DNA) in the serum is the most certain indicator of hepatitis B infection. It is transiently present during the presymptomatic period and for a brief time during the acute illness. The presence of DNA polymerase, the enzyme used in viral replication, usually is transient but may persist for years in persons who are chronic carriers and is an indication of continued infectivity.

Immunization. Hepatitis B vaccine provides long-term protection (up to 20 years in some cases) against HBV infection.37 HBsAg is the antigen used for hepatitis B vaccines. Vaccines available in the United States use recombinant DNA technology to express HBsAg in yeast, which is then purified by biochemical and biophysical methods. The vaccine is available as a single-antigen formulation and also in fixed combination with other vaccines. A hepatitis B immunoglobulin (HBIG) is available.34 Prepared from plasma donors with high concentrations of anti-HBs, it is used as an adjunct to hepatitis B vaccine for postexposure immunoprophylaxis to prevent HBV infection in high-risk populations.

The CDC recommends vaccination of all children 0 to 18 years of age as a means of preventing HBV transmission.37 The vaccine also is recommended for all unvaccinated adults who fall into one of the following categories:

1. Those who are at high risk for infection by sexual exposure, including sex partners of HBsAg-positive people, sexually active people who are not in a long-term mutually monogamous relationship, people seeking evaluation for treatment of sexually transmitted diseases, and men who have sex with men.
2. Those who are at high risk for infection by percutaneous or mucosal exposure to blood, including current
and recent injecting drug abusers, household contacts of HBsAg-positive persons, residents and staff of institutions for the developmentally disabled, health care and public safety workers with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids, and people with chronic kidney disease (predialysis, hemodialysis, peritoneal dialysis, and home dialysis patients).

3. **Others**, including international travelers to regions with high or intermediate levels of endemic HBV infection, people with chronic liver disease, people with human immunodeficiency virus (HIV) infection, and all other people seeking protection from HBV infection. The CDC also recommends that all pregnant women be routinely tested for HBsAg during an early prenatal visit and that infants born to HBsAg-positive mothers receive appropriate doses of HBIG and hepatitis B vaccine.

HBIG may be effective for unvaccinated people who are exposed to the infection if given within 7 days of exposure. Hepatitis vaccination is recommended for preexposure and postexposure prophylaxis.

**Hepatitis C**

The HCV is the most common cause of chronic hepatitis, cirrhosis, and hepatocellular cancer in the world. Approximately 3.2 to 5.0 million Americans are infected with HCV. Before 1990, the main route of transmission of HCV was through contaminated blood transfusions or blood products. With implementation of HCV testing in blood banks, the risk of HCV infection from blood transfusion is almost nonexistent in the United States and other developed countries. However, unsafe medical procedures and unscreened blood transfusions may be the most important sources of HCV infections in less developed countries of the world. Currently, recreational injecting drug use is the most common mode of HCV transmission to infants born to HBsAg-positive mothers receive appropriate doses of HBIG and hepatitis B vaccine.

HCV is a single-stranded RNA virus, with properties similar to those of the flaviviruses, a genus of the family of Flaviviridae that includes yellow fever and St. Louis encephalitis viruses. The genome contains a single open reading frame that encodes a polyprotein of about 3000 amino acids. The transcript is cleaved into single proteins, including three structural proteins (one core and two envelope proteins) and four nonstructural proteins. The virus is genetically unstable, which leads to multiple genotypes and subtypes. Six different genotypes and more than 70 subtypes of the virus have been recognized. Genotype 1a and b account for the majority of infections in the United States. It is likely that the wide diversity of genotypes contributes to the pathogenicity of the virus, allowing it to escape the actions of host immune mechanisms and antiviral medications, and to difficulties in developing a preventive vaccine. Development of a vaccine and treatment measures has also been hampered by the lack of a reliable, reproducible, and efficient culture system for propagating the virus.

**Clinical Manifestations.** The incubation period for HCV infection ranges from 2 to 26 weeks (average, 6 to 12 weeks). Most children and adults who acquire the infection usually are asymptomatic. Jaundice is uncommon, and only 10% of symptomatic adults have jaundice. These symptoms usually last for 2 to 12 weeks. Fulminant hepatic failure is rare, and only a few cases have been reported. A minority of persons who are newly infected with HCV will clear the infection, but most (85% to 90%) go on to develop chronic hepatitis. Factors associated with spontaneous clearing of HCV infection appear to include younger age, female sex, and certain histocompatibility genes. The most serious consequences of chronic HCV infection are progressive liver fibrosis leading to cirrhosis, end-stage liver disease, and hepatocellular cancer. Host factors that may exacerbate the progression of liver disease include older age at onset of infection, male sex, an immunosuppressed state, concurrent HBV infection, alcohol consumption, and hepatotoxic medications.

**Serologic Markers.** Both antibody and viral tests are available for detecting the presence of HCV infection (Fig. 46.11). False-negative results can occur in immunocompromised people and early in the course of the disease before antibodies develop. Direct measurement of HCV in the serum remains the most accurate test for infection. The viral tests are highly sensitive and specific, but more costly than antibody tests. With newer antibody testing methods, infection often can be detected as early as 6 to 8 weeks after exposure, and as early
as 1 to 2 weeks with viral tests that use polymerase chain reaction methods. Unlike hepatitis B, antibodies to HCV are not protective, but they serve as markers for the disease.45

**Hepatitis D and E**

Hepatitis D virus, of the Deltaviridae family, is the sole RNA virus of the genus.34 Hepatitis D is an incomplete virus, in that it requires the assistance of HBV in order to replicate.48 It can cause acute or chronic hepatitis. Infection depends on concomitant infection with HBV, specifically the presence of HBsAg.33 Acute hepatitis D occurs in two forms: co-primary infection that occurs simultaneously with acute hepatitis B, and a superinfection in which hepatitis D is imposed on chronic hepatitis B infection.34 The delta agent often increases the severity of HBV infection. It can convert mild HBV infection into severe, fulminating hepatitis, cause acute hepatitis in asymptomatic carriers, or increase the tendency for progression to chronic hepatitis and cirrhosis.

The routes of transmission of hepatitis D are similar to those for hepatitis B. In the United States, infection is restricted largely to people at high risk for HBV infection, particularly injecting drug users. The greatest risk is in HBV carriers. These people should be informed about the dangers of HDV superinfection.

Hepatitis D is diagnosed by detection of antibody to HDV (anti-HDV) in the serum or HDV RNA in the serum. There is no specific treatment for hepatitis D. Because the infection is linked to hepatitis B, prevention of hepatitis D should begin with prevention of hepatitis B through vaccination.

HEV is an unenveloped, single-stranded RNA virus. It is transmitted by the fecal–oral route and causes manifestations of acute hepatitis that are similar to hepatitis A. Genotype 3 of the virus has been linked to chronic HEV infection. Solid organ transplant recipients, HIV infection, chemotherapy, and hematological conditions have been found with chronic forms of the disease.49,50 The distinguishing feature of HEV is the high mortality rate. Among pregnant women in regions such as South Asia where the disease is quite prevalent, the mortality rate is 51%, owing to the development of fulminant hepatitis.51 Reported cases in the United States involve people who have recently been in an endemic area. People with no history of travel are affected in very rare instances.52

**Chronic Viral Hepatitis**

Chronic hepatitis is defined as a chronic inflammatory reaction of the liver of more than 3 to 6 months’ duration. It is characterized by persistently elevated serum aminotransferase levels and characteristic histologic findings on liver biopsy. The clinical features of chronic viral hepatitis are highly variable and not predictive of outcome. The most common symptoms are fatigue, malaise, loss of appetite, and occasional bouts of jaundice. Elevation of serum aminotransferase concentrations depends on the level of disease activity.

Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis, and hepatocellular cancer in the world and now ranks as the chief reason for liver transplantation in adults.53 Of the hepatotropic viruses, only three are known to cause chronic hepatitis—HBV, HCV, and HDV. Hepatitis B, which is less likely than hepatitis C to progress to chronic infection, accounts for 5% to 10% of chronic liver disease and cirrhosis in the United States.33 It is characterized by the persistence of HBV DNA and usually by HBeAg in the serum, indicating active viral replication. Many people are asymptomatic at the time of diagnosis, and elevated serum aminotransferase levels are the first sign of infection. Chronic hepatitis D infection depends on concurrent infection with HBV.

Chronic hepatitis C accounts for most cases of chronic viral hepatitis. HCV infection becomes chronic in 60% to 85% of cases.48 Chronic HCV infection often smolders over a period of years, silently destroying liver cells. Most people with chronic hepatitis C are asymptomatic, and diagnosis usually follows a finding of elevated serum aminotransferase levels or complaints of fatigue or nonspecific weakness. Because the course of acute hepatitis C often is mild, many persons do not recall the events of the acute infection.

**Treatment.** There are no simple and effective treatment methods for chronic viral hepatitis. Drugs used in the treatment of chronic HBV include interferons (recombinant interferon-2α and peginterferon) and the nucleotide and nucleotide analog antiretroviral agents (lamivudine, entecavir, and tenofovir).34,53 Persons with active viral replication may be treated with peginterferon (pegylated interferon alfa-2a). Peginterferons have a prolonged serum half-life and are given once a week.34 Up to 40% of treated patients respond with sustained normalization of liver enzyme levels, disappearance of HBeAg and HBV DNA from the serum, appearance of anti-HBe, and improved survival.51 Nucleoside and nucleotide analogs may be used instead of interferon for treatment of chronic HBV infection and are better tolerated. Lamivudine can be given orally and usually is well tolerated, but has a higher rate of viral resistance, a lower durable rate of response, and a greater need for prolonged therapy compared with interferon. Entecavir, another nucleoside analog, can be used in the treatment of persons who are resistant to lamivudine or have cirrhosis. Tenofovir, a drug used for treatment of HIV infection, also has considerable activity against HBV. Other antiviral agents are under study, and strategies using multiple drugs are likely to be investigated. In persons with concurrent hepatitis D infection, interferon therapy may lead to normalization of aminotransferase levels, histologic improvement, and elimination of HDV RNA from the serum in approximately 50% of cases, but relapse is common after the therapy is stopped.53 Lamivudine is not effective in chronic hepatitis D.

The current treatment for untreated people with chronic hepatitis C is a combination of the new pegylated forms of interferon (alpha-2b or alpha-2a) plus ribavirin (a nucleoside analog).53 Treatment with peginterferon and ribavirin is costly, and side effects, which include flulike symptoms, are almost universal. More serious side effects, which include psychiatric symptoms (depression), thyroid dysfunction, and bone marrow depression, are less common.53 Although most persons with
HCV infection are candidates for treatment, many have other health problems that are contraindications to therapy.

Liver transplantation is a treatment option for end-stage liver disease due to viral hepatitis. Liver transplantation has been more successful in people with hepatitis C than those with hepatitis B. Although the graft often is reinfected, the disease seems to progress more slowly.

Autoimmune Hepatitis

Autoimmune hepatitis is a severe type of chronic hepatitis of unknown origin that is associated with interface hepatitis, circulating autoantibodies, and hypergammaglobulinemia. Although the disorder is usually seen in young women, it can occur in either sex at any age.

Clinical and laboratory observations have led to the hypothesis that autoimmune hepatitis is a multifactorial disorder, with genetic and environmental factors playing important roles. Most knowledge of the genetics of the disease comes from the human leukocyte antigen (HLA) genes that reside on the short arm of chromosome 6. The environmental agents assumed to induce autoimmune hepatitis have not been delineated, but include viruses and chemical agents.

Two distinct types of autoimmune hepatitis have been identified. Type I autoimmune hepatitis, the most common form of the disease, is characterized by increased levels of anti–smooth muscle and antinuclear autoantibodies. Approximately 78% of cases occur in women and 38% have other autoimmune diseases. Susceptibility to type I autoimmune hepatitis resides mainly with the HLA-DRB1 gene. Type II autoimmune hepatitis occurs mainly in children 2 to 14 years of age and is characterized by the presence of antibody to liver and kidney microsomes and liver cytosol. The disorder is often accompanied by other autoimmune disorders, especially type 1 diabetes mellitus, vitiligo, and thyroiditis. The genetic component for this type of autoimmune hepatitis is less well defined.

Clinical Manifestations

Clinical manifestations of the disorder cover a spectrum that extends from no apparent symptoms to signs of inflammatory liver disease or cirrhosis. Physical examination may reveal no abnormalities, but may also reveal hepatomegaly, splenomegaly, jaundice, and signs and symptoms of chronic liver disease. In asymptomatic cases, the disorder may be discovered when abnormal serum enzyme levels are identified during performance of routine screening tests.

Diagnosis and Treatment

The differential diagnosis includes measures to exclude other causes of liver disease, including hepatitis B and C. A characteristic laboratory finding is that of a marked elevation in serum gamma globulins. A biopsy is used to confirm the diagnosis.

Corticosteroid and immunosuppressant drugs are the treatment of choice for this type of hepatitis. Although some people remain in remission after drug treatment is withdrawn, most require long-term maintenance treatment. Liver transplantation may be required for people who are refractory to or intolerant of immunosuppressive therapy and in whom end-stage liver disease develops.

Intrahepatic Biliary Disorders

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Among the causes of intrahepatic biliary disease are primary biliary cirrhosis and secondary biliary cirrhosis.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic disease of the liver characterized by the autoimmune destruction of intrahepatic bile ducts causing cholestasis. The disease is seen most commonly in women 40 to 60 years of age. Familial occurrences of the disease are found between parents and children and among siblings. However, unlike other autoimmune disorders, there is little, if any, association with any particular HLA alleles. In addition, with the possible exception of a reportedly higher risk of a polymorphism of the gene for the vitamin D receptor, there are no clear genetic influences for the disorder. As with other autoimmune disorders, possible environmental triggers include infectious and chemical agents.

Clinical Manifestations. The disorder is characterized by an insidious onset and progressive scarring and destruction of liver tissue. The liver becomes enlarged and takes on a green hue because of the accumulated bile. The earliest symptoms are unexplained pruritus or itching, weight loss, and fatigue, followed by dark urine and pale stools. Osteoporosis occurs in 51% of women with the disorder. Jaundice is a late manifestation of the disorder, as are other signs of liver failure. Serum alkaline phosphatase levels are elevated in people with primary biliary cirrhosis.

Diagnosis and Treatment. Diagnosis of the disease occurs when the person has two of the three following signs and symptoms: destruction of bile ducts and presence of nonsuppurative cholangitis on liver biopsy, cholestasis with alkaline phosphatase elevation for at least 6 months, and presence of antimitochondrial antibodies in blood tests.

Treatment is largely symptomatic. Ursodeoxycholic acid (ursodiol), the only drug approved for treating PBC, increases bile flow, decreases the toxicity of bile contents, and has been shown to decrease the rate of clinical deterioration. Cholestyramine, a bile acid–binding drug, may prove beneficial for treatment of pruritus. Colchicine, which acts to prevent leukocyte migration and phagocytosis, and methotrexate, a drug with immunosuppressive properties, have also resulted in reported benefits in terms of symptom relief. Corticosteroids have been shown to improve liver histology and serum liver function test, but involve serious long-term side effects. Liver transplantation remains the only treatment...
Secondary Biliary Cirrhosis

Secondary biliary cirrhosis results from prolonged obstruction of the extrahepatic tree. The most common cause is choledolithiasis. Other causes of secondary biliary cirrhosis are malignant neoplasms of the biliary tree or head of the pancreas and structures of the common duct caused by previous surgical procedures. Extrahepatic biliary cirrhosis may benefit from surgical procedures designed to relieve the obstruction.

Alcohol-Induced Liver Disease

The spectrum of alcoholic liver diseases includes fatty liver disease, alcoholic hepatitis, and cirrhosis. Most deaths from alcoholic cirrhosis are attributable to liver failure, bleeding esophageal varices, or kidney failure. It has been estimated that there are 14 million alcoholics in the United States. Approximately 10% of alcoholics develop cirrhosis with continued heavy drinking.

Metabolism of Alcohol

Alcohol is a food substance. It supplies calories but cannot be broken down or stored as protein, fat, or carbohydrate. As a food, the metabolism of alcohol yields 7.1 kcal/g. Between 80% and 90% of the alcohol a person drinks is metabolized by the liver. The rest is excreted through the lungs, kidneys, and skin.

Alcohol (ethanol) metabolism proceeds simultaneously by two pathways: the alcohol dehydrogenase (ADH) system, located in the cytoplasm of the hepatocytes, and the microsomal ethanol-oxidizing system (MEOS), located in the endoplasmic reticulum. ADH and MEOS pathways produce specific metabolic and toxic disturbances. A third and minor pathway, the catalase pathway, located in the peroxisomes, can break down ethanol in unusual circumstances.

The major pathway for ethanol metabolism involves ADH, an enzyme that catalyzes the conversion of alcohol to acetaldehyde. In the ADH-mediated oxidation of alcohol, both acetaldehyde and hydrogen are produced. The hydrogen (H\(^+\)) is transferred to the cofactor nicotinamide adenine dinucleotide (NAD), which is converted to its reduced form (NADH). The formed acetaldehyde again loses hydrogen and is metabolized to acetate, much of which is released in the bloodstream. As a result, ethanol metabolism generates an excess of NADH, which is thought to contribute to the liver damage that often accompanies excess alcohol consumption.

NAD is also necessary for many other metabolic processes, including the metabolism of pyruvates, urates, and fatty acids. Because alcohol competes for the use of NAD, it tends to disrupt other metabolic functions of the liver.

The preferential use of NAD for alcohol metabolism can result in increased production and accumulation of lactic acid in the blood. By reducing the availability of NAD, alcohol also impairs the liver’s ability to form glucose from amino acids and other glucose precursors. Alcohol-induced hypoglycemia can develop when excessive alcohol ingestion occurs during periods of depleted liver glycogen stores.

The MEOS pathway, which is located in the smooth endoplasmic reticulum, produces acetaldehyde and free radicals. Prolonged and excessive alcohol ingestion results in enzyme induction and increased activity of the MEOS. One of the most important enzymes of the MEOS, a member of the CYP P450 system, also oxidizes a number of other compounds, including various drugs (e.g., acetaminophen, isoniazid), toxins (e.g., carbon tetrachloride, halothane), vitamins A and D, and carcinogenic agents (e.g., aflatoxin, nitrosamines). Increased activity of this system enhances the susceptibility of persons with heavy alcohol consumption to the hepatotoxic effects of other substances.

Alcoholic Liver Disease

The metabolism of alcohol leads to chemical attack on certain membranes of the liver, but whether the damage is caused by acetaldehyde or other metabolites is unknown. Acetaldehyde, for example, has multiple toxic effects on liver cells and liver function. Age and sex play a role in metabolism of alcohol and production of harmful metabolites. The ADH system is depressed by testosterone. Thus, women tend to produce greater amounts of acetaldehyde and are more predisposed to alcohol-induced liver damage than men. Age also appears to affect the alcohol-metabolizing abilities of the liver and the resistance to hepatotoxic effects. Furthermore, genetic factors may influence the severity of alcohol-induced liver disease. ADH has multiple isoenzymes, the genetic polymorphism of which is now being studied in terms of possible clinical implications.
ethiclnicly, but the high end of the range is about 80 g/day for 10 to 12 years. This amount of alcohol can be in the form of 8 oz of 86 proof (41% alcohol) whiskey, two bottles of wine, or six 12-oz bottles of beer. Even after alcohol intake has stopped and all alcohol has been metabolized, the processes that damage liver cells may continue for many weeks and months. Clinical and chemical effects often become worse before the disease resolves. The accumulation of fat usually disappears within a few weeks, and cholestasis and inflammation also subside with time. However, fibrosis and scarring remain. The liver lobules become distorted as new liver cells regenerate and form nodules.

Although the mechanism by which alcohol exerts its toxic effects on liver structures is somewhat uncertain, the changes that develop can be divided into three stages: fatty changes, alcoholic hepatitis, and cirrhosis.

Fatty liver is characterized by the accumulation of fat in hepatocytes, a condition called steatosis (Fig. 46.12). The liver becomes yellow and enlarges owing to excessive fat accumulation. The pathogenesis of fatty liver is not completely understood and can depend on the amount of alcohol consumed, dietary fat content, body stores of fat, hormonal status, and other factors. There is evidence that ingestion of large amounts of alcohol can cause fatty liver changes even with an adequate diet. The fatty changes that occur with ingestion of alcohol usually do not produce symptoms and are reversible after the alcohol intake has been discontinued.

Alcoholic hepatitis is the intermediate stage between fatty changes and cirrhosis. It often is seen after an abrupt increase in alcohol intake and is common in “spree” drinkers.

A recent review found it has a mortality rate of approximately 34%. Alcoholic hepatitis is characterized by inflammation and necrosis of liver cells. This stage usually is characterized by hepatic tenderness, pain, anorexia, nausea, fever, jaundice, ascites, and liver failure, but some people may be asymptomatic. The condition is always serious and sometimes fatal. The immediate prognosis correlates with severity of liver cell injury. In some cases, the disease progresses rapidly to liver failure and death. In people who survive and continue to drink, the acute phase often is followed by persistent alcoholic hepatitis with progression to cirrhosis in a matter of 1 to 2 years.

Alcoholic cirrhosis is the end result of repeated bouts of drinking-related liver injury and designates the onset of end-stage alcoholic liver disease. The gross appearance of the early cirrhotic liver is one of fine, uniform nodules on its surface. The condition has traditionally been called micronodular or Laennec cirrhosis. With more advanced cirrhosis, regenerative processes cause the nodules to become larger and more irregular in size and shape. As this occurs, the nodules cause the liver to become relobulized through the formation of new portal tracts and venous outflow channels. The nodules may compress the hepatic veins, curtail blood flow out of the liver and producing portal hypertension, extrahepatic portosystemic shunts, and cholestasis.

Nonalcoholic Fatty Liver Disease

The term nonalcoholic fatty liver disease (NAFLD) is caused by metabolic dysfunction that affects the liver. In the United States, it is the most frequently occurring form of chronic liver disease. The condition can range from simple steatosis (fatty infiltration of the liver) to nonalcoholic steatohepatitis (steatosis with inflammation and hepatocyte necrosis). Although steatosis alone does not appear to be progressive, approximately 10% to 15% of people with nonalcoholic steatohepatitis progress to cirrhosis. Obesity, type 2 diabetes, the metabolic syndrome, and hyperlipidemia are coexisting conditions frequently associated with fatty liver disease. The condition is also associated with other nutritional abnormalities, surgical conditions, drugs, and occupational exposure to toxins. Both rapid weight loss and parenteral nutrition may lead to NAFLD. Jejunoileal bypass, a surgical procedure used for weight loss, has largely been abandoned for this reason.

Pathogenesis. The pathogenesis of NAFLD is thought to involve both lipid accumulation within hepatocytes and formation of free radicals, in a manner similar to that which occurs with alcohol metabolism. The primary metabolic abnormalities leading to lipid accumulation are poorly understood but are thought to include alterations in pathways for uptake, synthesis, degradation, or secretion of hepatic lipids resulting from insulin resistance. Obesity increases the synthesis and reduces the oxidation of free fatty acids. Type 2 diabetes or insulin resistance also increases adipose tissue lipolysis and the subsequent production of free fatty acids. When the capacity of the liver to export triglyceride is exceeded, excess fatty acids contribute to the formation of fatty liver. Both ketones and

**FIGURE 46.12** Alcoholic fatty liver. A photomicrograph shows the cytoplasm of almost all the hepatocytes to be distended by fat, which displaces the nucleus to the periphery (arrow). (From Rubin E., Strayer D. (2011). Rubin's pathology: Clinicopathologic foundations of medicine (6th ed., p. 708). Philadelphia, PA: Lippincott-Raven.)
free fatty acids are inducers of previously described CYP P450 enzymes of the MEOS pathway, which results in free radical formation, including hydrogen peroxide and superoxide. Abnormal lipid peroxidation ensues, followed by direct hepatocyte injury, release of toxic by-products, inflammation, and fibrosis.

**Clinical Manifestations.** NAFLD is usually asymptomatic, although fatigue and discomfort in the right upper quadrant of the abdomen may be present. Mildly to moderately elevated serum levels of AST, ALT, or both are the most common and often the only abnormal laboratory findings. Other abnormalities, including hypoalbuminemia, a prolonged prothrombin time, and hyperbilirubinemia, may be present in persons with cirrhotic-stage liver disease. The diagnosis of NAFLD requires liver biopsy and exclusion of alcohol as a cause of the disorder.

**Treatment.** The aim of treatment is to slow progression of NAFLD and to prevent liver-related illness. Both weight loss and exercise improve insulin resistance and are recommended in conjunction with treatment of associated metabolic disturbances. Alcohol use should be avoided. Disease progression is slow and the magnitude of disease-related morbidity and mortality is uncertain. A recent study has shown the use of statins and antioxidants such as vitamin A and E have been effective in reducing the odds of having hepatic steatosis in patients with NAFLD. Liver transplantation is an alternative for some people with end-stage liver disease, but NAFLD may reoccur in up to 39% of people post liver transplantation.

**Cirrhosis, Portal Hypertension, and Liver Failure**

**Cirrhosis**

Cirrhosis represents the end stage of chronic liver disease, in which much of the functional liver tissue has been replaced by fibrous tissue. Although cirrhosis usually is associated with alcoholism, it can develop in the course of other disorders, including viral hepatitis, toxic reactions to drugs and chemicals, biliary obstruction, and NAFLD. Cirrhosis also accompanies metabolic disorders that cause the deposition of minerals in the liver. Two of these disorders are hemochromatosis (i.e., iron deposition) and Wilson disease (i.e., copper deposition).

Cirrhosis is characterized by diffuse fibrosis and conversion of normal liver architecture into nodules containing proliferating hepatocytes encircled by fibrosis. The formation of nodules, which vary in size from very small (<3 mm, micronodules) to large (several centimeters, macronodules), represents a balance between regenerative activity and constrictive scarring. The fibrous tissue that replaces normally functioning liver tissue forms constrictive bands that disrupt flow in the vascular channels and biliary duct systems of the liver. The disruption of vascular channels predisposes to portal hypertension and its complications; obstruction of biliary channels and exposure to the destructive effects of bile stasis; and loss of liver cells, leading to liver failure.

**Clinical Manifestations.** The manifestations of cirrhosis are variable, ranging from asymptomatic hepatomegaly to hepatic failure (Fig. 46.13). Often there are no symptoms until the disease is far advanced. The most common signs and symptoms of cirrhosis are weight loss (sometimes masked by ascites), weakness, and anorexia. Diarrhea frequently is present, although some persons may complain of constipation. Hepatomegaly and jaundice also are common signs of cirrhosis. There may be abdominal pain because of liver enlargement or stretching of the Glisson capsule. This pain is located in the epigastric area or in the upper right quadrant and is described as dull, aching, and causing a sensation of fullness.

The late manifestations of cirrhosis are related to portal hypertension and liver cell failure. Splenomegaly, ascites, and
portosystemic shunts (i.e., esophageal varices, hemorrhoids, and caput medusae) result from portal hypertension. Other complications include bleeding due to decreased clotting factors, thrombocytopenia due to splenomegaly, gynecomastia and a feminizing pattern of pubic hair distribution in men because of testicular atrophy, spider angiomas, palmar erythema, and encephalopathy with asterixis and neurologic signs.

### Portal Hypertension

Portal hypertension is characterized by increased resistance to flow in the portal venous system and sustained portal vein pressure. Normally, venous blood returning to the heart from the abdominal organs collects in the portal vein and travels through the liver before entering the vena cava. Portal hypertension can be caused by a variety of conditions that increase resistance to hepatic blood flow, including prehepatic, posthepatic, and intrahepatic obstructions (with hepatic referring to the liver lobules rather than the entire liver). Prehepatic causes of portal hypertension include portal vein thrombosis and external compression due to cancer or enlarged lymph nodes that produce obstruction of the portal vein before it enters the liver.

Posthepatic obstruction refers to any obstruction to blood flow through the hepatic veins beyond the liver lobules, either within or distal to the liver. It is caused by conditions such as thrombosis of the hepatic veins, veno-occlusive disease, and severe right-sided heart failure that impede the outflow of venous blood from the liver. Budd-Chiari syndrome refers to congestive disease of the liver caused by occlusion of multiple hepatic veins or the hepatic portion of the inferior vena cava. The principal cause of the Budd-Chiari syndrome is thrombosis of the hepatic veins, in association with diverse conditions such as polycythemia vera, hypercoagulability states associated with malignant tumors, pregnancy, bacterial infection, metastatic disease of the liver, and trauma. Sinusoidal obstruction syndrome or hepatic veno-occlusive disease is a variant of the Budd-Chiari syndrome seen most commonly in people treated with certain cancer chemotherapeutic drugs, hepatic irradiation, or bone marrow transplantation.

Intrahepatic causes of portal hypertension include conditions that cause obstruction of blood flow within the liver. In alcoholic cirrhosis, which is the major cause of portal hypertension, bands of fibrous tissue and fibrous nodules distort the architecture of the liver and increase the resistance to portal blood flow, which leads to portal hypertension.

Complications of portal hypertension arise from the increased pressure and dilation of the venous channels behind the obstruction (Fig. 46.14). In addition, collateral channels open that connect the portal circulation with the systemic circulation. The major complications of the increased portal vein pressure and the opening of collateral channels are ascites, splenomegaly, hepatic encephalopathy, and the formation of portosystemic shunts with bleeding from esophageal varices.

**KEY POINTS**

**PORTAL HYPERTENSION**

- Venous blood from the gastrointestinal tract empties into the portal vein and travels through the liver before moving into the general venous circulation.
- Obstruction of blood flow in the portal vein produces an increase in the hydrostatic pressure within the peritoneal capillaries, contributing to the development of ascites, splenomegaly, hepatic encephalopathy, and the formation of portosystemic shunts with bleeding from esophageal varices.

![FIGURE 46.14 • Mechanisms of disturbed liver function related to portal hypertension.](image-url)
Ascites. Ascites occurs when the amount of fluid in the peritoneal cavity is increased and is a late-stage manifestation of cirrhosis and portal hypertension.\textsuperscript{72} It is not uncommon for people with advanced cirrhosis to present with an accumulation of 15 L or more of ascitic fluid. These persons often experience abdominal discomfort, dyspnea, and insomnia. They may also have difficulty walking or living independently.

Although the mechanisms responsible for the development of ascites are not completely understood, several factors seem to contribute to fluid accumulation, including an increase in capillary pressure due to portal hypertension and obstruction of venous flow through the liver, salt and water retention by the kidney, and decreased colloidal osmotic pressure due to impaired synthesis of albumin by the liver. Diminished blood volume (i.e., underfill theory) and excessive blood volume (i.e., overfill theory) have been used to explain the increased salt and water retention by the kidney. According to the underfill theory, a contraction in the effective blood volume constitutes an afferent signal that causes the kidney to retain salt and water. The effective blood volume may be reduced because of loss of fluid into the peritoneal cavity or because of vasodilatation caused by the presence of circulating vasodilating substances. The overfill theory proposes that the initial event in the development of ascites is renal retention of salt and water caused by disturbances in the liver itself. These disturbances include failure of the liver to metabolize aldosterone, causing an increase in salt and water retention by the kidney. Another likely contributing factor in the pathogenesis of ascites is a decreased colloidal osmotic pressure, which limits reabsorption of fluid from the peritoneal cavity.

Treatment of ascites usually focuses on dietary restriction of sodium and administration of diuretics. Water intake also may need to be restricted. Because of the many limitations in sodium restriction, the use of diuretics has become the mainstay of treatment for ascites. Two classes of diuretics are used: a diuretic that acts in the distal part of the nephron to inhibit aldosterone-dependent sodium reabsorption and a loop diuretic such as furosemide. Oral potassium supplements often are given to prevent hypokalemia. The upright position is associated with the activation of the renin–angiotensin–aldosterone system; therefore, bed rest may be recommended in persons with a large amount of ascites.\textsuperscript{73} Large-volume paracentesis (removal of 5 L or more of ascitic fluid) may be done in persons with massive ascites and pulmonary compromise. Because the removal of fluid produces a decrease in vascular volume along with increased plasma renin activity and aldosterone-mediated sodium and water reabsorption by the kidneys, a volume expander such as albumin usually is administered to maintain the effective circulating volume.\textsuperscript{74} A transjugular intrahepatic portosystemic shunt (TIPS) may be inserted in persons with refractory ascites.\textsuperscript{74}

Spontaneous bacterial peritonitis is a complication in people with both cirrhosis and ascites. The infection is serious and carries a high mortality rate even when treated with antibiotics. Presumably, the peritoneal fluid is seeded with bacteria from the blood or lymph or from passage of bacteria through the bowel wall. Symptoms include fever, altered mental status, and abdominal pain. Other symptoms include worsening of hepatic encephalopathy, diarrhea, hypothermia, and shock. It is diagnosed by a neutrophil count of 250/mm\textsuperscript{3} or higher.\textsuperscript{75}

Splenomegaly. The spleen enlarges progressively in portal hypertension because of shunting of blood into the splenic vein. The enlarged spleen often gives rise to sequestering of significant numbers of blood elements and development of a syndrome known as hypersplenism. Hypersplenism is characterized by a decrease in the lifespan of all the formed elements of the blood and a subsequent decrease in their numbers, leading to anemia, thrombocytopenia, and leukopenia.\textsuperscript{75} The decreased lifespan of the blood elements is thought to result from an increased rate of removal because of the prolonged transit time through the enlarged spleen.

Portosystemic Shunts. With the gradual obstruction of venous blood flow in the liver, the pressure in the portal vein increases, and large collateral channels develop between the portal and systemic veins that supply the lower rectum and esophagus and the umbilical veins of the falciform ligament that attaches to the anterior wall of the abdomen. The collaterals between the inferior and internal iliac veins may give rise to hemorrhoids. In some persons, the fetal umbilical vein is not totally obliterated; it forms a channel on the anterior abdominal wall. Dilated veins around the umbilicus are called caput medusae.\textsuperscript{76} Portopulmonary shunts also may develop and cause blood to bypass the pulmonary capillaries, interfering with blood oxygenation and producing cyanosis.

Clinically, the most important collateral channels are those connecting the portal and coronary veins that lead to reversal of flow and formation of thin-walled varicosities in the submucosa of the esophagus\textsuperscript{77} (Fig. 46.15). These thin-walled esophageal varices are subject to rupture, producing massive and sometimes fatal hemorrhage. Impaired hepatic synthesis of coagulation factors and decreased platelet levels (i.e., thrombocytopenia) due to splenomegaly may further complicate the control of esophageal bleeding. Esophageal varices develop in 5% to 15% of people with cirrhosis, and approximately 33% will have bleeding varices.\textsuperscript{77}

Treatment of portal hypertension and esophageal varices is directed at prevention of initial hemorrhage, management of acute hemorrhage, and prevention of recurrent hemorrhage. Pharmacologic therapy is used to lower portal venous pressure and prevent initial hemorrhage. \β-Adrenergic-blocking drugs (e.g., propranolol) commonly are used for this purpose. These agents reduce portal venous pressure by decreasing splanchic blood flow and thereby decreasing blood flow in collateral channels.

Several methods are used to control acute hemorrhage, including administration of octreotide or vasopressin, balloon tamponade, endoscopic injection sclerotherapy, vessel ligation, or esophageal transection. Octreotide, a long-acting synthetic analog of somatostatin, reduces splanchic and hepatic blood flow and portal pressures in persons with cirrhosis.
Vasopressin, a hormone from the posterior pituitary, is a nonselective vasoconstrictor, which can potentially produce unwanted side effects and therefore has limited the use of the drug. Because octreotide has fewer side effects and appears to be more effective than vasopressin, it has become the drug of choice for pharmacologic management of acute variceal bleeding. Balloon tamponade provides compression of the varices and is accomplished through the insertion of a tube with inflatable gastric and esophageal balloons. After the tube has been inserted, the balloons are inflated; the esophageal balloon compresses the bleeding esophageal veins, and the gastric balloon helps to maintain the position of the tube. During endoscopic sclerotherapy, the varices are injected with a sclerosing solution that obliterates the vessel lumen.

Prevention of recurrent hemorrhage focuses on lowering portal venous pressure and diverting blood flow away from the easily ruptured collateral channels. Two procedures may be used for this purpose: the surgical creation of a portosystemic shunt or a TIPS. **Surgical portosystemic shunt** procedures involve the creation of an opening between the portal vein and a systemic vein. These shunts have a considerable complication rate, and TIPS has evolved as the preferred treatment for refractory portal hypertension. The TIPS procedure involves insertion of an expandable metal stent between a branch of the hepatic vein and the portal vein using a catheter inserted through the internal jugular vein. A limitation of the procedure is that stenosis and thrombosis of the stent occur in most cases over time, with consequent risk of rebleeding. A complication that is associated with the creation of a portosystemic shunt is hepatic encephalopathy, which is thought to result when ammonia and other neurotoxic substances from the gut pass directly into the systemic circulation without going through the liver.

**Liver Failure**

The most severe clinical consequence of liver disease is hepatic failure. It may result from sudden and massive liver destruction, as in fulminant hepatitis, or be the result of progressive damage to the liver, as occurs in alcoholic cirrhosis. Whatever the cause, 80% to 90% of hepatic functional capacity must be lost before liver failure occurs. In many cases, the progressive decompensating effects of the disease are hastened by intercurrent conditions such as gastrointestinal bleeding, systemic infection, electrolyte disturbances, or superimposed diseases such as heart failure.

**Clinical Manifestations.** The manifestations of liver failure reflect the various synthesis, storage, metabolic, and elimination functions of the liver (Fig. 46.16). **Fetor hepaticus** refers to a characteristic musty, sweetish odor of the breath in the person in advanced liver failure, resulting from the metabolic by-products of the intestinal bacteria.

**Hematologic Disorders.** Liver failure can cause anemia, thrombocytopenia, coagulation defects, and leukopenia. Anemia may be caused by blood loss, excessive red blood cell destruction, and impaired formation of red blood cells. A folic acid deficiency may lead to severe megaloblastic anemia. Changes in the lipid composition of the red blood cell membrane increase hemolysis. Because factors V, VII, IX, and X, prothrombin, and fibrinogen are synthesized by the liver, their decline in liver disease contributes to bleeding disorders. Malabsorption of the fat-soluble vitamin K contributes further to the impaired synthesis of these clotting factors. Thrombocytopenia often occurs as the result of splenomegaly. The person with liver failure is subject to purpura, easy bruising, hematuria, and abnormal menstrual bleeding and is vulnerable to bleeding from the esophagus and other segments of the gastrointestinal tract.

**Endocrine Disorders.** The liver metabolizes the steroid hormones. Endocrine disorders, particularly disturbances in gonadal (sex hormone) function, are common accompaniments of cirrhosis and liver failure. Women may have menstrual irregularities (usually amenorrhea), loss of libido, and sterility. In men, testosterone levels usually fall; the testes atrophy; and loss of libido, impotence, and gynecomastia occur. A decrease in aldosterone metabolism may contribute to salt and water retention by the kidney, along with a lowering of serum potassium resulting from increased elimination of potassium.

**Skin Disorders.** Liver failure brings on numerous skin disorders. These lesions, called variously *vascular spiders*, telangiectases, *spider angiomas*, and *spider nevi*, are seen...
most often in the upper half of the body. They consist of a central pulsating arteriole from which smaller vessels radiate. Palmar erythema is redness of the palms, probably caused by increased blood flow from higher cardiac output. Clubbing of the fingers may be seen in people with cirrhosis. Jaundice usually is a late manifestation of liver failure.

**Hepatorenal Syndrome.** The hepatorenal syndrome refers to a functional renal failure sometimes seen during the terminal stages of liver failure when no functional causes of renal disease exist. It is characterized by progressive azotemia, increased serum creatinine levels, and oliguria. Although the basic cause is unknown, a decrease in renal blood flow is believed to play a part. Ultimately, when renal failure is superimposed on liver failure, azotemia and elevated levels of blood ammonia occur; this condition is thought to contribute to hepatic encephalopathy and coma.

**Hepatic Encephalopathy.** Hepatic encephalopathy refers to the totality of central nervous system manifestations of liver failure. It is characterized by neural disturbances ranging from a lack of mental alertness to confusion, coma, and convulsions. A very early sign of hepatic encephalopathy is a flapping tremor called asterixis. Various degrees of memory loss may occur, coupled with personality changes such as euphoria, irritability, anxiety, and lack of concern about personal appearance and self. Speech may be impaired, and the patient may be unable to perform certain purposeful movements. The encephalopathy may progress to decerebrate rigidity and then to a terminal deep coma.

Although the cause of hepatic encephalopathy is unknown, the accumulation of neurotoxins, which appear in the blood because the liver has lost its detoxifying capacity, is believed to be a factor.

One of the suspected neurotoxins is ammonia. A particularly important function of the liver is the conversion of ammonia, a by-product of protein and amino acid metabolism, to urea. The ammonium ion is produced in abundance in the intestinal tract, particularly in the colon, by the bacterial degradation of luminal proteins and amino acids. Normally, these ammonium ions diffuse into the portal blood and are transported to the liver, where they are converted to urea before entering the general circulation. When the blood from the intestine bypasses the liver or the liver is unable to convert ammonia to urea, ammonia moves directly into the general circulation and from there to the cerebral circulation. Hepatic encephalopathy may become worse after a large protein meal or gastrointestinal tract bleeding. Narcotics and tranquilizers are poorly metabolized by the liver, and administration of these drugs may cause central nervous system depression and precipitate hepatic encephalopathy.

A nonabsorbable antibiotic, such as neomycin, may be given to eradicate bacteria from the bowel and thus prevent ammonia production. Another drug that may be given...
is lactulose. It is not absorbed from the small intestine but moves directly to the large intestine, where it is catabolized by colonic bacteria to small organic acids that cause production of large, loose stools with a low pH. The low pH favors the conversion of ammonia to ammonium ions, which are not absorbed by the blood. The acid pH also inhibits the intestinal degradation of amino acids, proteins, and blood.

Treatment. The treatment of liver failure is directed toward eliminating alcohol intake when the condition is caused by alcoholic cirrhosis; preventing infections; providing sufficient carbohydrates and calories to prevent protein breakdown; correcting fluid and electrolyte imbalances, particularly hypokalemia; and decreasing ammonia production in the gastrointestinal tract by controlling protein intake.

In many cases, liver transplantation remains the only effective treatment. Liver transplantation rapidly is becoming a realistic form of treatment for many people with irreversible chronic liver disease, fulminant liver failure, primary biliary cirrhosis, chronic active hepatitis, sclerosing cholangitis, and certain metabolic disorders that result in end-stage liver disease. The 5-year survival rate in 2009 for the United States was 74% and 79% for people receiving livers from deceased and live donors.78 In addition to longer survival, many liver recipients are now experiencing improved quality of life, including return to active employment. Unfortunately, the shortage of donor organs severely limits the number of transplantations that are done, and many people die each year while waiting for a transplant. There are presently 16,000 people on the waiting list to receive a liver transplant.80 During the past several years, a number of innovative methods have been developed to deal with the shortage, including split liver transplantation, in which a cadaver liver is split into two pieces and transplanted into two recipients, and living donor transplantation, in which a segment or lobe from the liver from a living donor is resected and grafted into a recipient.81

Cancer of the Liver
Primary Liver Cancers

There are two major types of primary liver cancer: hepatocellular carcinoma, which arises from the liver cells, and cholangiocarcinoma, which is a primary cancer of bile duct cells.10

Hepatocellular Carcinoma. Hepatocellular cancer accounted for 19,000 of new cases liver cancer in the United States in 2010, making it the most common form of liver cancer.85 In areas with greater resources such as Europe, Australia, and the United States, the incidence is between 2.5 and 5 cases per 100,000.83 Rates as high as 40 cases per 100,000 have been found in Thailand, Korea, Japan, and China.83 There has also been increased incidence in developed countries as a consequence of chronic HCV infection.84 The incidence in the United States has increased from 1.4 cases per 100,000 between 1976 and 1980 to 2.4 cases between 1990 and 1995.83 Although primary tumors of the liver are relatively rare in developed countries of the world, the liver shares with the lung the distinction of being the most common site of metastatic tumors.

Among the factors identified as etiologic agents in liver cancer are chronic viral hepatitis (i.e., HBV, HCV, HDV), cirrhosis, long-term exposure to environmental agents such as aflatoxin, and drinking water contaminated with arsenic. Just how these etiologic agents contribute to the development of liver cancer is still unclear. With HBV and HCV, both of which become integrated into the host DNA, repeated cycles of cell death and regeneration afford the potential for development of cancer-producing mutations. Aflatoxins, produced by food spoilage molds, such as Aspergillus flavus and Aspergillus parasiticus, in certain areas endemic for hepatocellular carcinoma, are particularly potent carcinogenic agents.83 They are activated by hepatocytes and their products incorporated into the host DNA with the potential for developing cancer-producing mutations. A particularly susceptible site for aflatoxin mutation is the TP53 tumor suppressor gene.85

Clinical Manifestations and Diagnosis. The manifestations of hepatocellular cancer often are insidious in onset and masked by those related to cirrhosis or chronic hepatitis. The initial symptoms include weakness, anorexia, weight loss, fatigue, abdominal swelling, a sensation of abdominal fullness, and a dull, aching abdominal pain.85,86 Ascites, which often obscures weight loss, is common. Jaundice, if present, usually is mild. There may be a rapid increase in liver size and worsening of ascites in people with preexisting cirrhosis. Usually, the liver is enlarged when these symptoms appear. Various paraneoplastic syndromes (e.g., disturbances due to ectopic hormone or growth factor production by the tumor) have been associated with hepatocellular cancer, including erythrocytosis (erythropoietin), hypoglycemia (insulin-like growth factor), and hypercalcemia (parathyroid-related protein). Serum α-fetoprotein is present during fetal life but barely detectable in the serum after the age of 2 years.86 When high levels of α-fetoprotein are found in adults, it is usually indicative of hepatocellular carcinoma, although not all primary liver cancers produce α-fetoprotein. Therefore, additional methods, such as ultrasonography, CT scans, and MRI, are recommended for diagnosis.86 Liver biopsy may be used to confirm the diagnosis.

Treatment. Primary cancers of the liver usually are far advanced at the time of diagnosis. The treatment of choice is subtotal hepatectomy, if conditions permit. Chemotherapy and radiation therapy are largely palliative. Although liver transplantation may be an option for people with well-compensated cirrhosis and small tumors, it often is impractical because of the shortage of donor organs.

Cholangiocarcinoma. Cholangiocarcinoma, with an incidence of 1.2 to 0.5 per 100,000 in North America, occurs much less frequently than hepatocellular carcinoma.10 The etiology,
Clinical features, and prognosis vary considerably with the part of the biliary tree that is the site of origin. Cholangiocarcinoma is not associated with the same risk factors as hepatocellular carcinoma. Instead, most of the risk factors revolve around long-standing inflammation and injury of the bile duct epithelium. Cholangiocarcinoma often presents with pain, weight loss, anorexia, and abdominal swelling or awareness of a mass in the right hypochondrium. Tumors affecting the central or distal bile ducts may present with jaundice.

**Metastatic Tumors**

Metastatic tumors of the liver are much more common than primary tumors. Common sources include colorectal cancer and those spread from breast, colon, lung, or urogenital cancer. In addition, tumors of neuroendocrine origin spread to the liver. It often is difficult to distinguish primary from metastatic tumors with the use of CT scans, MRI, or ultrasonography. Usually the diagnosis is confirmed by biopsy.

**IN SUMMARY**

The liver is subject to most of the disease processes that affect other body structures, such as vascular disorders, inflammation, metabolic diseases, toxic injury, and neoplasms. As the major drug-metabolizing and detoxifying organ in the body, the liver is subject to potential damage from the enormous array of pharmaceutical and environmental chemicals. Drugs and chemicals can exert their effects by causing hepatocyte injury and death or by cholestatic liver damage due to injury of biliary drainage structures. Drug reactions can be predictable based on the drug’s chemical structure and metabolites or unpredictable (idiosyncratic) based on individual characteristics of the person receiving the drug. Early identification of drug-induced liver disease is important because withdrawal of the drug is curative in most cases.

Hepatitis is characterized by inflammation of the liver. Acute viral hepatitis is caused by hepatitis viruses A, B, C, D, and E. Although all these viruses cause acute hepatitis, they differ in terms of mode of transmission, incubation period, mechanism, degree and chronicity of liver damage, and the ability to evolve to a carrier state. HBV, HCV, and HDV infections have the potential for progression to the carrier state, chronic hepatitis, and hepatocellular carcinoma.

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Among the causes of intrahepatic biliary diseases are primary biliary cirrhosis, primary sclerosing cholangitis, and secondary biliary cirrhosis. Because alcohol competes for use of intracellular cofactors normally needed by the liver for other metabolic processes, it tends to disrupt the metabolic functions of the liver. The spectrum of alcoholic liver disease includes fatty liver disease, alcoholic hepatitis, and cirrhosis.

Cirrhosis represents the end stage of chronic liver disease in which much of the functional liver tissue has been replaced by fibrous tissue. The fibrous tissue replaces normally functioning liver tissue and forms constrictive bands that disrupt flow in the vascular channels and biliary duct systems of the liver. The disruption of vascular channels predisposes to portal hypertension and its complications, loss of liver cells, and eventual liver failure. Portal hypertension is characterized by increased resistance to flow and increased pressure in the portal venous system; the pathologic consequences of the disorder include ascites, the formation of collateral bypass channels (e.g., esophageal varices) from the portosystemic circulation, and splenomegaly. Liver failure represents the end stage of a number of liver diseases and occurs when less than 10% to 20% of liver tissue is functional. The manifestations of liver failure reflect the various functions of the liver, including hematologic disorders, disruption of endocrine function, skin disorders, hepatorenal syndrome, and hepatic encephalopathy.

There are two types of primary cancers of the liver: hepatocellular (the most common form, derived from hepatocytes and their precursors) and cholangiocarcinoma ( bile duct cancer, arising from biliary epithelium). Hepatocellular carcinoma, which is associated with HBV and HCV hepatitis, alcoholic cirrhosis, and food contaminants (e.g., aflatoxins), is the fifth most common cancer and third leading cause of cancer-related mortality worldwide. Cholangiocarcinoma occurs primarily in older adults with a history of chronic disorders of the bile ducts. Although primary tumors of the liver are relatively rare in developed countries of the world, the liver shares with the lung the distinction of being the most common site of metastatic tumors.

**DISORDERS OF THE GALLBLADDER AND EXOCRINE PANCREAS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the function of the gallbladder in regulating the flow of bile into the duodenum and relate to the formation of cholelithiasis (gallstones).
- Describe the clinical manifestations of acute and chronic cholecystitis.
- Cite the possible causes and describe the manifestations and treatment of acute and chronic pancreatitis.

**Disorders of the Gallbladder and Extrahepatic Bile Ducts**

The hepatobiliary system consists of the gallbladder; the left and right hepatic ducts, which come together to form the common hepatic duct; the cystic duct, which extends to the...
gallbladder; and the common bile duct, which is formed by the union of the common hepatic duct and the cystic duct (Fig. 46.17). The common bile duct descends posteriorly to the first part of the duodenum, where it comes in contact with the main pancreatic duct. These ducts unite to form the hepatopancreatic ampulla. The circular muscle around the distal end of the bile duct is thickened to form the sphincter of the bile duct.

The gallbladder is a distensible, pear-shaped muscular sac located on the ventral surface of the liver. It has an outer serous peritoneal layer, a middle smooth muscle layer, and an inner mucosal layer that is continuous with the linings of the bile duct. The function of the gallbladder is to store and concentrate bile. Bile contains bile salts, cholesterol, bilirubin, lecithin, fatty acids, and water and the electrolytes normally found in the plasma. The cholesterol found in bile has no known function. It is assumed to be a by-product of bile salt formation, and its presence is linked to the excretory function of bile. Normally insoluble in water, cholesterol is rendered soluble by the action of bile salts and lecithin, which combine with it to form micelles. In the gallbladder, water and electrolytes are absorbed from the liver bile, causing the bile to become more concentrated. Because neither lecithin nor bile salts are absorbed in the gallbladder, their concentration increases along with that of cholesterol; in this way, the solubility of cholesterol is maintained.

Entrance of food into the intestine causes the gallbladder to contract and the sphincter of the bile duct to relax, such that bile stored in the gallbladder moves into the duodenum. The stimulus for gallbladder contraction is primarily hormonal. Products of food digestion, particularly lipids, stimulate the release of a gastrointestinal hormone called cholecystokinin from the mucosa of the duodenum. Cholecystokinin provides a strong stimulus for gallbladder contraction. The role of other gastrointestinal hormones in bile release is less clearly understood.

Pressure in the common duct largely is responsible for regulating passage of bile into the intestine. Normally, the gallbladder regulates this pressure. It collects and stores bile as it relaxes and the pressure in the common bile duct decreases, and it empties bile into the intestine as the gallbladder contracts, producing an increase in common duct pressure. After gallbladder surgery, the pressure in the common duct changes, causing the common duct to dilate. The sphincters in the common duct then regulate the flow of bile.

Two common disorders of the biliary system are cholelithiasis (i.e., gallstones) and inflammation of the gallbladder (cholecystitis) or common bile duct (cholangitis). In adult Western populations, 15% of people have gallstones. In both circumstances, hypersecretion of biliary cholesterol appears to play a major role.

**Cholelithiasis**

Cholelithiasis or gallstones is caused by precipitation of substances contained in bile, mainly cholesterol and bilirubin. Approximately 80% of gallstones are composed primarily of cholesterol; the other 20% are black or brown pigment stones composed of mucin glycoproteins and calcium salts. Many stones have a mixed composition. Figure 46.18 shows a gallbladder with numerous cholesterol gallstones.
is usually located in the upper right quadrant or epigastric area and may be referred to the upper back, the right shoulder, or midscapular region. Typically the pain is abrupt in onset, increases steadily in intensity, persists for 30 minutes to 5 hours, and is followed by soreness in the upper right quadrant.

**Acute and Chronic Cholecystitis**

Acute cholecystitis is a diffuse inflammation of the gallbladder, usually secondary to obstruction of the gallbladder outlet. Most cases of acute cholecystitis (85% to 90%) are associated with the presence of gallstones (calculous cholecystitis). The remaining cases (acalculous cholecystitis) are associated with sepsis, severe trauma, or infection of the gallbladder. It has been theorized that obstruction of the cystic duct by a gallstone leads to the release of phospholipase from the epithelium of the gallbladder. In turn, this enzyme may hydrolyze lecithin and release lysolecithin, a membrane-active toxin. At the same time, disruption of the normally protective mucous lining of the epithelium renders the mucosal cells vulnerable to damage by the detergent action of concentrated bile salts. Acute acalculous cholecystitis occurs with no apparent cause in 50% of cases, trauma, burns, biliary sludge and vasculitis have been possible causative factors. Acute acalculous cholecystitis can rapidly progress to gangrene and perforation because the process appears to involve a transmural infarction, rather than inflammatory changes associated with stones.

Chronic cholecystitis results from repeated episodes of acute cholecystitis or chronic irritation of the gallbladder by stones. It is characterized by varying degrees of chronic inflammation. Gallstones almost always are present. Cholelithiasis with chronic cholecystitis may be associated with acute exacerbations of gallbladder inflammation, common duct stone, pancreatitis, and, rarely, carcinoma of the gallbladder.

**Clinical Manifestations.** People with acute cholecystitis usually experience an acute onset of upper right quadrant or epigastric pain, frequently associated with mild fever, anorexia, nausea, and vomiting. Whereas in biliary colic the cystic duct obstruction is transient, in acute cholecystitis it is persistent. People with calculous cholecystitis usually, but not always, have experienced previous episodes of biliary pain. The pain may appear with remarkable suddenness and constitute a surgical emergency. In the absence of medical attention, the attack usually subsides in 7 to 10 days. In people who recover, recurrence is common. The onset of acalculous cholecystitis tends to be more insidious because the manifestations are obscured by the underlying conditions precipitating the attack. In the severely ill person, early recognition is crucial because a delay in treatment can prove life-threatening. People with acute cholecystitis usually have an elevated white blood cell count, and many have mild elevations in AST, ALT, alkaline phosphatase, and bilirubin.

The manifestations of chronic cholecystitis are more vague than those of acute cholecystitis. There may be intolerance to fatty foods, belching, and other indications of discomfort. Often, there are episodes of colicky pain with obstruction.
Clinical Manifestations. The manifestations of choledocholithiasis are similar to those of gallstones and acute cholecystitis. There is a history of acute biliary colic and right upper abdominal pain, with chills, fever, and jaundice associated with episodes of abdominal pain. Bilirubinuria and an elevated serum bilirubin are present if the common duct is obstructed. Complications include acute suppurative cholangitis accompanied by purulent fluid in the common duct. It is characterized by the presence of an altered sensorium, lethargy, and septic shock. Acute suppurative cholangitis represents an endoscopic or surgical emergency. Common duct stones also can obstruct the outflow of the pancreatic duct, causing a secondary pancreatitis.

Diagnosis and Treatment. The methods used to diagnose gallbladder disease include ultrasonography, cholescintigraphy (nuclear scanning), and CT scans. Ultrasonography is widely used in diagnosing gallbladder disease and has largely replaced the oral cholecystogram in most medical centers. It can detect stones as small as 1 to 2 cm, and its overall accuracy in detecting gallbladder disease is high. In addition to stones, ultrasonography can detect wall thickening, which indicates inflammation. It also can rule out other causes of right upper quadrant pain such as tumors. Cholescintigraphy, also called a gallbladder scan, relies on the ability of the liver to extract a rapidly injected radionuclide, technetium-99m, bound to one of several iminodiacetic acids, that is excreted into the bile ducts. Serial scanning images are obtained within several minutes of the injection of the tracer and every 10 to 15 minutes during the next hour. The gallbladder scan is highly accurate in detecting acute cholecystitis. Although CT is not as accurate as ultrasonography in detecting gallstones, it can show thickening of the gallbladder wall or pericholecystic fluid associated with acute cholecystitis.

Gallbladder disease usually is treated by removing the gallbladder. The gallbladder stores and concentrates bile, and its removal usually does not interfere with digestion. Laparoscopic cholecystectomy has become the treatment of choice for symptomatic gallbladder disease. The procedure involves insertion of a laparoscope through a small incision near the umbilicus, and surgical instruments are inserted through several stab wounds in the upper abdomen. Although the procedure requires more time than the older open surgical procedure, it usually requires only one night in the hospital. A major advantage of the procedure is that people can return to work in 1 to 2 weeks, compared with 4 to 6 weeks after open cholecystectomy.

Choledocholithiasis and Cholangitis
Choledocholithiasis refers to stones in the common duct and cholangitis to inflammation of the common duct. Common duct stones usually originate in the gallbladder, but can form spontaneously in the common duct.

Disorders of the Exocrine Pancreas
The pancreas lies transversely in the posterior part of the upper abdomen (see Fig. 46.1). The head of the pancreas is at the right of the abdomen; it rests against the curve of the duodenum in the area of the hepatopancreatic ampulla and its entrance into the duodenum. The body of the pancreas lies beneath the stomach. The tail touches the spleen. The pancreas is virtually hidden because of its posterior position; unlike many other organs, it cannot be palpated. Because of the position of the pancreas and its large functional reserve, symptoms from conditions such as cancer of the pancreas do not usually appear until the disorder is far advanced.

The pancreas is both an endocrine and exocrine organ. The exocrine pancreas is made up of lobules that consist of acinar cells, which secrete digestive enzymes into a system
of microscopic ducts. These ducts empty into the main pancreatic duct, which extends from left to right through the substance of the pancreas. The main pancreatic duct and the bile duct unite to form the hepatopancreatic ampulla, which empties into the duodenum. The sphincter of the pancreatic duct controls the flow of pancreatic secretions into duodenum (see Fig. 46.17).

The pancreatic secretions contain proteolytic enzymes that break down dietary proteins, including trypsin, chymotrypsin, carboxypeptidase, ribonuclease, and deoxyribonuclease. The pancreas also secretes pancreatic amylase, which breaks down starch, and lipases, which hydrolyze neutral fats into glycerol and fatty acids. The pancreatic enzymes are secreted in the inactive form and become activated in the intestine. This is important because the enzymes would digest the tissue of the pancreas itself if they were secreted in the active form. The acinar cells secrete a trypsin inhibitor, which prevents trypsin activation. Because trypsin activates other proteolytic enzymes, the trypsin inhibitor prevents subsequent activation of the other enzymes.

Two types of pancreatic disease are discussed in this chapter: acute and chronic pancreatitis and cancer of the pancreas.

**Acute Pancreatitis**

Acute pancreatitis represents a reversible inflammatory process of the pancreatic acini brought about by premature activation of pancreatic enzymes. Although the disease process may be limited to pancreatic tissue, it also can involve peripancreatic tissues or those of more distant organs. In the United States, up to 220,000 people are admitted to the hospital each year with acute pancreatitis.

The pathogenesis of acute pancreatitis involves the autodigestion of pancreatic tissue by inappropriately activated pancreatic enzymes. The process is thought to begin with the activation of trypsin. Once activated, trypsin can then activate a variety of digestive enzymes that cause pancreatic injury, resulting in an intense inflammatory response. The acute inflammatory response itself causes substantial tissue damage and may progress beyond the pancreas to produce a systemic inflammatory response syndrome and multiorgan failure. Although a number of factors are associated with the development of acute pancreatitis, most cases result from gallstones (stones in the common duct) or alcohol abuse. In the case of biliary tract obstruction due to gallstones, pancreatic duct obstruction or biliary reflux is believed to activate the enzymes in the pancreatic duct system. The precise mechanisms whereby alcohol exerts its action are largely unknown. The capacity for oxidative and nonoxidative metabolism of ethanol by the pancreas and the harmful by-products that result have been related to the disease process. A recent study, looking at specifically beer, has shown that pancreatic secretions may be stimulated by the nonalcoholic ingredients in the beverage. Acute pancreatitis also is associated with hyperlipidemia, hypercalcemia, infections (particularly viral), abdominal and surgical trauma, and drugs such as thiazide diuretics.

**Clinical Manifestations.** The manifestations of acute pancreatitis can range from mild with minimal organ dysfunction to severe and life threatening. Overall, about 20% of people with acute pancreatitis have a severe course. Abdominal pain is a cardinal manifestation of acute pancreatitis. The pain is usually located in the epigastric or periumbilical region and may radiate to the back, chest, or flank areas. Physical examination findings are variable and include fever, tachycardia, hypotension, severe abdominal tenderness, respiratory distress, and abdominal distention. Recognized markers of severe disease include laboratory values that measure the inflammatory response (e.g., C-reactive protein), scoring systems that assess inflammation or organ failure, and findings on imaging studies. Clinical findings such as thirst, poor urine output, progressive tachycardia, tachypnea, hypoxemia, agitation, confusion, a rising hematocrit level, and lack of improvement in symptoms within the first 48 hours are warning signs of impending severe disease. Complications include the systemic inflammatory response, acute respiratory distress syndrome, acute tubular necrosis, and organ failure. An important disturbance related to acute pancreatitis is the loss of a large volume of fluid into the retroperitoneal and peripancreatic spaces and the abdominal cavity.

**Diagnosis and Treatment.** Serum amylase and lipase are the laboratory markers most commonly used to establish a diagnosis of acute pancreatitis. The serum lipase may remain elevated slightly longer than amylase. However, the level of elevation of the serum amylase or lipase does not correlate with the severity of the disorder. The white blood cell count may be increased, and hyperglycemia and an elevated serum bilirubin level may be present. Determination of the cause is important in guiding the immediate management and preventing recurrence. Abdominal ultrasonography is usually performed to assess for gallstones. CT scans and dynamic contrast-enhanced CT of the pancreas are used to detect necrosis and fluid accumulation. Recent research has focused on potential biomarkers for predicting the severity and prognosis of pancreatitis. One study has examined trypsinogen-2 and pancreatic proteases, enzymes involved in the autodigestive processes. Other investigational serologic markers include tumor necrosis factor, C-reactive protein, procalletonin, phospholipase A2, and the cytokines interleukin-8 and interleukin-10.

Treatment measures depend on the severity of the disease. People who present with persistent or severe pain, vomiting, dehydration, or signs of impending severe acute pancreatitis require hospitalization. Treatment measures are directed at pain relief, “putting the pancreas to rest” by withholding oral foods and fluids, and restoration of lost plasma volume. Meperidine rather than morphine usually is given for pain relief because it causes fewer spasms of the sphincter of the pancreatic duct. Gastric suction is instituted to treat distention of the bowel and prevent further stimulation of the secretion of pancreatic enzymes. Intravenous fluids and electrolytes are administered to replace those lost from the circulation and to
Because of the frequent episodes of pain, narcotic addiction is a potential problem in people with chronic pancreatitis. Surgical intervention sometimes is needed to relieve the pain and usually focuses on relieving any obstruction that may be present. In advanced cases, a subtotal or total pancreatectomy may be necessary.98

Complications. Sequelae in people surviving an episode of severe acute pancreatitis include fluid collections and infection.98 In people with acute necrotizing pancreatitis, the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary canal, further complicating the condition.101 Fluid collections with a high level of pancreatic enzymes are usually associated with pancreatic duct disruptions and may eventually form pseudocysts (a collection of pancreatic fluid enclosed in a layer of inflammatory tissue). A pseudocyst most often is connected to a pancreatic duct, so that it continues to increase in mass. The symptoms depend on its location; for example, jaundice may occur when a cyst develops near the head of the pancreas, close to the common duct. Pseudocysts may resolve or, if they persist, may require surgical intervention.

Chronic Pancreatitis

Chronic pancreatitis is characterized by progressive destruction of the exocrine pancreas, by fibrosis, and, in the later stages, by destruction of the endocrine pancreas. Most factors that cause acute pancreatitis can also cause chronic pancreatitis. However, the chief distinction between the two conditions is the irreversibility of pancreatic function that is characteristic of chronic pancreatitis.102 By far the most common cause of chronic pancreatitis in Western countries is long-term alcohol abuse.98 Less common causes are long-standing obstruction of the pancreatic duct by pseudocysts, calculi, or neoplasms; autoimmune chronic pancreatitis, which occurs in association with autoimmune disorders such as Sjögren syndrome, primary sclerosing cholangitis, and inflammatory bowel disease; idiopathic chronic pancreatitis, associated with cystic fibrosis; and hereditary pancreatitis, a rare autosomal dominant disorder that is associated with both acute and chronic pancreatitis.

Clinical Manifestations. Chronic pancreatitis is manifested in episodes that are similar, albeit of lesser severity, to those of acute pancreatitis. People with chronic pancreatitis have persistent, recurring episodes of epigastric and upper left quadrant pain; the attacks often are precipitated by alcohol abuse or overeating. Anorexia, nausea, vomiting, constipation, and flatulence are common. Eventually, the disease progresses to the extent that endocrine and exocrine pancreatic functions become deficient. At this point, signs of diabetes mellitus and the malabsorption syndrome (e.g., weight loss, fatty stools [steatorrhea]) become apparent.

Treatment. Treatment consists of measures to treat coexisting biliary tract disease. A low-fat diet usually is prescribed. The signs of malabsorption may be treated with pancreatic enzymes. When diabetes is present, it is treated with insulin. Alcohol is forbidden because it frequently precipitates attacks. Because of the frequent episodes of pain, narcotic addiction

Cancer of the Pancreas

Pancreatic cancer remains the fourth leading cause of death from cancer in the United States, with more than 44,000 new cases diagnosed each year.103 Considered to be one of the most deadly malignancies, pancreatic cancer is associated with a 5-year survival rate of only 4%.104 The incidence of pancreatic cancer seems to be increasing in all countries studied and has tripled in the United States over the past 50 years.95

Etiology. The cause of pancreatic cancer is unknown. Age, smoking, and chronic pancreatitis have been found to be risk factors.98 Pancreatic cancer rarely occurs in people younger than 50 years of age, and the risk increases with age. The most significant and reproducible environmental risk factor is cigarette smoking.95 The incidence of pancreatic cancer is twice as high among smokers than nonsmokers. Diabetes and chronic pancreatitis also are associated with pancreatic cancer, although neither the nature nor the sequence of the possible cause-and-effect relation has been established. Hereditary pancreatitis and familial atypical mole multiple melanoma syndrome are two other causes linked to pancreatic cancer.98

Clinical Manifestations. Almost all pancreatic cancers are adenocarcinomas of the ductal epithelium, and symptoms are primarily caused by mass effect rather than disruption of exocrine or endocrine function. The clinical manifestations depend on the size and location of the tumor as well as its metastasis. Pain, jaundice, and weight loss constitute the classic presentation of the disease. The most common pain is a dull epigastric pain often accompanied by back pain, often worse in the supine position, and relieved by sitting forward. Although the tumor can arise anywhere in the pancreas, the most frequent site is the head (60%), followed by the body (10%), and tail (5%). The pancreas is diffusely involved in the remaining 25%.99 Because of the proximity of the pancreas to the common duct and the hepatopancreatic ampulla, cancer of the head of the pancreas tends to obstruct bile flow. Jaundice frequently is the presenting symptom of a person with cancer of the head of the pancreas, and it usually is accompanied by complaints of pain and pruritus.105 Cancer of the body of the pancreas usually impinges on the celiac ganglion, causing pain. The pain usually worsens with ingestion of food or assumption of the supine position. Cancer of the tail of the pancreas usually has metastasized before symptoms appear.

Migratory thrombophlebitis (deep vein thrombosis) develops in about 10% of people with pancreatic cancer, particularly when the tumor involves the body or tail of the pancreas.98 Thrombi develop in multiple veins, including the deep veins of the legs, the subclavian vein, the inferior and superior mesenteric veins, and even the vena cava. It is not uncommon...
are not diagnostic. The serum cancer antigen (CA) 19-9, a marker that may suggest the presence of pancreatic cancer, but only occurs in 10% to 15% of people with end-stage pancreatic cancer.105 Therefore, this test does not confirm the diagnosis.105

Diagnosis and Treatment. Patient history, physical examination, and elevated serum bilirubin and alkaline phosphate levels may suggest the presence of pancreatic cancer, but are not diagnostic.105 The serum cancer antigen (CA) 19-9, a Lewis blood group antigen, may help confirm the diagnosis in symptomatic patients and may help predict prognosis and recurrence after resection. However, CA 19-9 has a sensitivity and specificity of 80% to 90%, so it does not confirm the diagnosis.105

Ultrasonography and CT scanning are the most frequently used diagnostic methods to confirm the disease. Intravenous and oral contrast-enhanced spiral CT is the preferred method for imaging the pancreas. Percutaneous fine-needle aspiration cytology of the pancreas has been one of the major advances in the diagnosis of pancreatic cancer. Unfortunately, the smaller and more curable tumors are more likely to be missed by this procedure. ERCP may be used for evaluation of people with suspected pancreatic cancer and obstructive jaundice.

Surgical resection of the tumor is done when the tumor is localized. However, this only occurs in 10% to 15% of people because most cancers of the pancreas have metastasized by the time of diagnosis.106 Otherwise, surgical resection is reserved for palliative measures. Radiation therapy may be useful when the disease is not resectable but appears to be localized. The use of irradiation and chemotherapy for pancreatic cancer continues to be investigated. Pain control is one of the most important aspects in the management of persons with end-stage pancreatic cancer.

IN SUMMARY

The biliary tract serves as a passageway for the delivery of bile from the liver to the intestine. This tract consists of the bile ducts and gallbladder. The most common causes of biliary tract disease are cholelithiasis and cholecystitis. Three factors contribute to the development of cholelithiasis: abnormalities in the composition of bile, stasis of bile, and inflammation of the gallbladder. Cholelithiasis predisposes to obstruction of bile flow, causing biliary colic and acute or chronic cholecystitis. Cancer of the gallbladder, which has a poor 5-year survival rate, occurs in 2% of people with biliary tract disease.

The pancreas is an endocrine and exocrine organ. The exocrine pancreas produces digestive enzymes that are secreted in an inactive form and transported to the small intestine through the main pancreatic duct, which usually empties into the hepatopancreatic ampulla and then into the duodenum through the sphincter of the pancreatic duct. The most common diseases of the exocrine pancreas are acute and chronic forms of pancreatitis, and cancer. Acute and chronic pancreatitis are associated with biliary reflux and chronic alcoholism. Acute pancreatitis is an inflammatory condition of the pancreas due to inappropriate activation of pancreatic enzymes, with manifestations that can range from mild to severe and life-threatening. Chronic pancreatitis causes progressive destruction of the endocrine and exocrine pancreas. It is characterized by episodes of pain and epigastric distress that are similar to but less severe than those that occur with acute pancreatitis. Cancer of the pancreas is the fourth leading cause of cancer death in the United States. It usually is far advanced at the time of diagnosis, and the 5-year survival rate is 4%.

REVIEW EXERCISES

1. A 24-year-old woman reports to her health care professional with complaints of a yellow discoloration of her skin, loss of appetite, and a feeling of upper gastric discomfort. She denies use of intravenous drugs and has not received blood products. She cannot recall eating uncooked shellfish or drinking water that might have been contaminated. She has a daughter who attends day care.
   A. What tests could be done to confirm a diagnosis of hepatitis A?
   B. What is the most common mode of transmission for hepatitis A? It is suggested that the source might be through the day care center that her daughter attends. Explain.
   C. What methods could be used to protect other family members from getting the disease?

2. A 56-year-old man with a history of heavy alcohol consumption and a previous diagnosis of alcoholic cirrhosis and portal hypertension is admitted to the emergency department with acute gastrointestinal bleeding due to a tentative diagnosis of bleeding esophageal varices and signs of circulatory shock.
   A. Relate the development of esophageal varices to portal hypertension in people with cirrhosis of the liver.
   B. Many people with esophageal varices have blood coagulation problems. Explain.
   C. What are the possible treatment measures for this man, in terms of both controlling the current bleeding episode and preventing further bleeding episodes?

3. A 40-year-old woman presents in the emergency department with a sudden episode of vomiting and severe right epigastric pain that developed after eating a fatty evening meal. Although there is no evidence of jaundice in her skin, the sclera of her
eyes is noted to have a yellowish discoloration. Palpation reveals tenderness of the upper right quadrant with muscle splitting and rebound pain. Right upper quadrant abdominal ultrasonography confirms the presence of gallstones. The woman is treated conservatively with pain and antiemetic medications. She is subsequently scheduled for a laparoscopic cholecystectomy.

A. Relate this woman’s signs and symptoms to gallstones and their effect on gallbladder function.

B. Explain the initial appearance of jaundice in the eyes as opposed to the skin. Which of the two laboratory tests for bilirubin would you expect to be elevated—direct (conjugated) or indirect (unconjugated or free)?

C. What effect will removal of the gallbladder have on the storage and release of bile into the intestine, particularly as it relates to meals?

Alterations in Nutritional Status

Nutritional status describes the condition of the body with respect to the availability and use of nutrients. Nutrients that are taken into the body can be used to provide the energy needed to perform various body functions, or they can be stored for future use. The stability and composition of body weight over time require that a person’s energy intake be balanced with energy expenditure. When a person is overfed, and nutrient intake consistently exceeds expenditure, most of the nutrients are stored and body weight increases. Conversely, when energy expenditure exceeds nutrient intake, energy stores are lost and body weight decreases.

Also, because different foods contain different amounts of proteins, fats, carbohydrates, vitamins, and minerals, appropriate amounts of these dietary elements must be maintained to ensure that all parts of the body’s metabolic systems can be supplied with requisite materials. This chapter discusses the regulation of energy expenditure and storage, nutritional needs, overnutrition and obesity, and undernutrition and eating disorders.
the nutrients are infused directly into the circulatory system. Once inside the body, nutrients are used for energy or as the building blocks for tissue growth and repair. When excess nutrients are available, they frequently are stored for future use. If the required nutrients are unavailable, the body adapts by conserving and using its nutrient stores.

**Energy Metabolism**

Energy is measured in heat units called calories. A calorie, spelled with a small c and also called a gram calorie, is the amount of heat or energy required to raise the temperature of 1 g of water by 1°C. A kilocalorie (kcal) or large Calorie, which is equivalent to 1000 calories, is the amount of energy needed to raise the temperature of 1 kg of water by 1°C. Because a gram calorie is so small, the kilocalorie or large Calorie, spelled with a capitol “C,” is often used when discussing energy metabolism. The oxidation of proteins provides 4 kcal/g; fats, 9 kcal/g; carbohydrates, 4 kcal/g; and alcohol, 7 kcal/g.

Metabolism is the organized process through which nutrients such as carbohydrates, fats, and proteins are broken down, transformed, or otherwise converted into cellular energy. The process of metabolism is unique in that it enables the continual release of energy, and it couples this energy with physiologic functioning. For example, the energy used for muscle contraction is derived largely from energy sources that are stored in muscle cells and then released as the muscle contracts. Because most of our energy sources come from the nutrients in the food that is eaten, the ability to store energy and control its release is important.

**Anabolism and Catabolism**

There are two phases of metabolism: anabolism and catabolism. Anabolism is the phase of metabolic storage and synthesis of cell constituents. Anabolism does not provide energy for the body; it requires energy. Catabolism involves the breakdown of complex molecules into substances that can be used in the production of energy. The chemical intermediates for anabolism and catabolism are called metabolites (e.g., lactic acid is a metabolite formed when glucose is broken down in the absence of oxygen). Both anabolism and catabolism are catalyzed by enzyme systems located in body cells. A substrate is a substance on which an enzyme acts. Enzyme systems selectively transform fuel substrates into cellular energy and facilitate the use of energy in the process of assembling molecules to form energy substrates and storage forms of energy.

Because body energy cannot be stored as heat, the cellular oxidative processes that release energy are low-temperature reactions that convert food components to chemical energy that can be stored or dissipated. The body transforms carbohydrates, fats, and proteins into the intermediary compound, adenosine triphosphate (ATP). ATP is called the energy currency of the cell because almost all body cells store and use ATP as their energy source. The metabolic events involved in ATP formation allow cellular energy to be stored, used, and replenished. However, under some circumstances, decreasing metabolic efficiency can increase energy expenditure; an uncoupling of ATP synthesis within the mitochondria results in a loss of energy as released heat. This process may have relevance to obesity (the more energy “wasted” as heat loss, the less weight gain), but is also important in maintaining body warmth in newborns. This is because the increased proportion of brown fat found in neonates is much less efficient at generating ATP than white fat, resulting in increased heat production.

**Energy Storage**

**Adipose Tissue**

More than 90% of body energy is stored in the adipose tissues of the body. Adipocytes, or fat cells, occur singly or in small groups in loose connective tissue. In many parts of the body, they cushion body organs such as the kidneys. In addition to isolated groups of fat cells, entire regions of fat tissue are committed to fat storage. Collectively, fat cells constitute a large body organ that is metabolically active in the uptake, synthesis, storage, and mobilization of lipids, which are the main source of stored fuel for the body. Some tissues, such as liver cells, are able to store small amounts of lipids, but when these lipids accumulate (so-called ectopic deposition, as occurs in fatty liver), they begin to interfere with normal cell function. Adipose tissue not only serves as a storage site for body fuels, but also provides insulation for the body, fills body crevices, and protects body organs.

Studies of adipocytes in the laboratory have shown that fully differentiated cells do not divide. However, such cells have a long lifespan, and anyone born with large numbers of adipocytes runs the risk of becoming obese. Some immature adipocytes (termed preadipocytes) capable of division are present in postnatal life. Fat deposition can result from proliferation of these existing immature adipocytes. Some medications can also have an important effect on fat cell numbers. The thiazolidinedione class of antidiabetic drugs can also stimulate the formation of new fat cells from preadipocytes, allowing increased uptake of glucose into these cells (and storage as fat) and resulting in the desired reduction in serum glucose levels, but with unwanted weight gain. In contrast, some drugs can cause loss of fat cells, resulting in lipodystrophy. This occurs in human immunodeficiency virus (HIV)-associated lipodystrophy in people treated with highly active antiretroviral therapy (HAART). The mechanism of fat loss is unknown. However, it may be due to increased programmed cell death of the adipocytes (i.e., increased apoptosis).

There are two types of adipose tissue: white fat and brown fat. White fat, which despite its name is cream-colored or yellow, is the prevalent form of adipose tissue in postnatal life. It constitutes 10% to 20% of body weight in adult men and 15% to 25% in adult women. At body temperature, the lipid content of fat cells exists as oil. It consists of triglycerides, which are three molecules of fatty acids esterified to a glycerol molecule. Triglycerides, which contain no water, have the highest caloric content of all nutrients and are an efficient form of energy storage. Fat cells synthesize triglycerides, the
major fat storage form, from dietary fats and carbohydrates. Insulin is required for transport of glucose into fat cells. When calorie intake is restricted for any reason, fat cell triglycerides are broken down, and the resultant fatty acids and glycerol are released as energy sources.

Brown fat differs from white fat in terms of its thermogenic capacity or ability to produce heat. Brown fat is found primarily in early neonatal life in humans and in animals that hibernate. The major function of brown fat is to generate heat in animals or humans that do not shiver, and it contains a higher concentration of specialized mitochondria, which enable this process. In humans, brown fat decreases with age but is still detectable in the sixth decade. This small amount of brown fat has a minimal effect on energy expenditure.

**Adipose Tissue as an Endocrine Organ**

Adipose tissue is now recognized as an endocrine and paracrine organ that secretes a number of important factors. These factors are termed adipokines and include leptin, certain cytokines (e.g., tumor necrosis factor-α [TNF-α]), growth factors, and adiponectin (important in insulin resistance). Figure 47.1 identifies many of the substances produced by adipose tissue. The discovery of leptin (from the Greek meaning “thin”), a peptide released from adipocytes, has led to renewed interest in adipose tissue and its role in energy homeostasis. Recent studies suggest that leptin acts at the level of the hypothalamus to decrease food intake and increase energy expenditure through an increase in thermogenesis and sympathetic nervous system activity. Leptin is also involved in glucose metabolism and normal sexual maturation and reproduction and has interactions with the hypothalamic–pituitary–adrenal, thyroid, and growth hormones axes.

Leptin acts by binding, and activating, specific leptin receptors found in several peripheral tissues and in many areas of the brain, including specific regions of the hypothalamus. Receptors in these hypothalamic regions are known to be involved in appetite, food intake, sympathetic nervous system activity, temperature regulation, and insulin release by the pancreatic beta cells. Leptin levels tend to rise after food intake and fall during fasting. Adipose tissue signals the brain via leptin that sufficient storage of calories has been achieved, and increased food intake is not necessary. Leptin resistance or a failure to respond to the high levels of leptin may result in obesity.

**Energy Expenditure**

The expenditure of body energy results from five mechanisms of heat production (i.e., thermogenesis): basal metabolic rate or resting energy equivalent, diet-induced thermogenesis, exercise-induced thermogenesis, nonexercise activity thermogenesis, and thermogenesis in response to changes in environmental conditions. The amount of energy used varies with age, body size, rate of growth, and state of health.

**Basal Metabolic Rate**

The basal metabolic rate (BMR) refers to the chemical reactions occurring when the body is at rest. These reactions are necessary to provide energy for maintenance of normal body functions, such as cardiovascular and respiratory function, muscle tone, and other essential activities of tissues and cells in the resting body. The BMR constitutes 50% to 70% of body energy needs. The BMR is measured using an instrument called an indirect calorimeter that measures the rate of oxygen use. Oxygen consumption is measured under basal conditions: after a full night’s sleep, after at least 12 hours without food, after no strenuous activity for 1 hour, and while the person is awake and at rest in a warm and comfortable room. The BMR is then calculated in terms of calories per hour and normally averages approximately 65 to 70 cal/hour in an average 70-kg man. Women in general have a 5% to 10% lower BMR than men because of their higher percentage of adipose tissue. Although much of the BMR is accounted for by essential activities of the central nervous system, kidneys, and other body organs, the variations in BMR among different people are related largely to skeletal muscle mass and body size. Under normal resting conditions, skeletal muscle accounts for 20% to 30% of the BMR. For this reason, the BMR is commonly corrected for body size by expressing it as calories per hour per square meter of body surface area. Factors that affect the BMR are age, sex, physical state, and pregnancy. A progressive decline in the normal BMR occurs with aging and is likely related to loss of muscle mass and replacement with adipose tissue. The BMR can be used to predict the calorie needs for maintenance of nutrition.
The resting energy equivalent (REE) is used for predicting energy expenditure. The most accurate way to determine REE is by indirect calorimetry. However, this is expensive and requires trained personnel. Multiplying the REE by a factor of 1.2 usually adequately predicts the caloric needs for maintenance of nutrition when the person is in a state of health. A factor of 1.5 usually provides the needed nutrients during repletion and during illnesses such as pneumonia, long bone fractures, cancer, peritonitis, and recovery from most types of surgery.

Diet- and Exercise-Induced Thermogenesis

Diet-induced thermogenesis, or thermic effect of food, describes the energy used by the body for the digestion, absorption, and assimilation of food after its ingestion. It is energy expended over and above the caloric value of the food and accounts for approximately 8% of the total calories expended. When food is eaten, the metabolic rate rises and then returns to normal within a few hours. The ingestion of a high-protein meal increases the normal metabolic rate more significantly, by up to 30%, and lasts 3 to 12 hours. This is called the specific dynamic action of protein.1

The type of activity performed, the length of participation, and the person’s weight and physical fitness determine the amount of energy expended for physical activity. The most significant increases in metabolic rate come from strenuous activity.

Nonexercise Activity Thermogenesis

Energy expenditure can also be affected by increasing non-exercise activity thermogenesis (NEAT). NEAT includes the energy expended in maintaining posture and in activities such as fidgeting.3 Normally, NEAT accounts for 7% of daily energy expended in maintaining posture and in activities other than the most vigorous exercise activity thermogenesis (NEAT). NEAT includes the energy expended for physical activity. The most significant increases in metabolic rate come from strenuous activity.

Environmentally Related Thermogenesis

Shivering in response to cold also produces heat through increased muscle activity. Nonshivering thermogenesis occurs in response to cold stress as well, caused by sympathetic nervous system activation, with the release of norepinephrine and epinephrine causing increased metabolic activity. Sympathetic stimulation also causes brown fat to generate heat.

Recent studies have shown that obese people with persistent excess caloric intake have increased sympathetic activity. While the exact mechanism is not known, this appears to be triggered in part by leptin and results in increased thermogenesis. This increase in energy production can help to limit the amount of weight gained. While clearly not enough to stop or reverse the weight gain process completely, it may contribute to the rate of weight gain or stabilization of overweight at a certain point.

IN SUMMARY

Nutritional status describes the condition of the body related to the availability and use of nutrients. Nutrients provide the energy and materials necessary for performing the activities of daily living and for the growth and repair of body tissues. Metabolism is the organized process whereby nutrients such as carbohydrates, fats, and proteins are broken down, transformed, or otherwise converted to cellular energy. Glucose, fats, and amino acids from proteins serve as fuel sources for cellular metabolism. These fuel sources are ingested during meals and stored for future use. Glucose is stored as glycogen or converted to triglycerides in fat cells for storage. Fats are stored in adipose tissue as triglycerides. Fat also functions as an endocrine organ in producing adipokines such as leptin and cytokines, which affect weight gain. Amino acids are the building blocks of proteins, and most of the stored amino acids are contained in body proteins and as fuel sources for cellular metabolism. Energy is measured in heat units called calories.

The expenditure of body energy results from heat production (i.e., thermogenesis) associated with the BMR or basal energy equivalent, diet-induced thermogenesis, exercise-induced thermogenesis, NEAT, and thermogenesis in response to changes in environmental conditions.

NUTRITIONAL NEEDS

After completing this section of the chapter, you should be able to meet the following objectives:

- Discuss the different dietary standards that are utilized to formulate uniform diet guidelines for calories, proteins, fats, carbohydrates, fiber, vitamins, and minerals.
- Differentiate between hunger, appetite, and satiety.
- State the interactions between neurohormones in both short-term and long-term mechanisms to control food intake.

Dietary Reference Intakes

The dietary reference intakes (DRIs) include a set of nutrient-based reference values—the recommended dietary allowance (RDA), the adequate intake (AI), the estimated average requirement, the tolerable upper intake level, and the acceptable macronutrient distribution range (AMDR), each of which has specific uses.5 The DRIs, which are periodically updated, are published by the National Academy of Sciences. The DRIs are used to advise people about the level of nutrient intake they need to decrease the risk of chronic disease. The current recommended DRIs for selected nutrients, vitamins, and...
minerals are available on the U.S. Department of Agriculture’s (USDA) Food and Nutrition Information Center website at: http://fnic.nal.usda.gov/fnic/interactiveDRI/. This site contains an interactive tool that calculates a person’s current nutritional needs based on gender, height, weight, age, and activity levels.  

The RDA defines the intakes that meet the nutrient needs of almost all healthy people in a specific age and sex group. The most recent guidelines have established RDA levels for carbohydrates, but not for fats. Recommended fat intake is outlined in the AMDR and expressed as percentage of overall daily dietary intake, rather than a set level.  

The AI is set when there is not enough scientific evidence to estimate an average requirement. The AI is derived from experimental or observational data that show a mean intake that appears to sustain a desired indicator of health. An estimated average requirement is the intake that meets the estimated nutrient need of half of the people in a specific group. This figure is used as the basis for developing the RDA. Nutrition policy makers use this when evaluating the adequacy of a nutrient for a specific group and for planning how much of the nutrient the group should consume. The tolerable upper intake level is the maximum intake that is judged unlikely to pose a health risk in almost all healthy people in a specified group. It refers to the total intakes from food, fortified food, and nutrient supplements. This value is not intended to be a recommended level of intake, and there are no established benefits for people who consume nutrients at the RDA or AI levels.  

Food and supplement labels use daily values (DVs), which are set by the U.S. Food and Drug Administration (FDA). However, the DVs are based on data that are older than the data used to determine the DRIs. Percent daily value (%DV) tells the consumer what percentages of the DV one serving of a food or supplement supplies.

**Nutritional Needs**

Proteins, fats, carbohydrates, vitamins and minerals, and fiber each have their own function in providing the body with what it needs to maintain life and health.

**Calories**

Energy requirements are greater during growth periods. A person requires approximately 115 kcal/kg of body weight at birth, 105 kcal/kg at 1 year of age, and 80 kcal/kg from 1 to 10 years of age. During adolescence, boys require 45 kcal/kg of body weight and girls require 38 kcal/kg. During pregnancy, a woman needs an extra 300 kcal/day above her usual requirement, and during the first 3 months of breast-feeding she requires an additional 500 kcal.  

**Proteins**

Proteins are required for growth and maintenance of body tissues, enzymes and antibody formation, fluid and electrolyte balance, and nutrient transport. Proteins are composed of amino acids, nine of which are essential to the body (i.e., these amino acids cannot be synthesized by the body and must be derived from dietary sources). These are leucine, isoleucine, methionine, phenylalanine, threonine, tryptophan, valine, lysine, and histidine. Complete protein foods are those that provide these essential amino acids in adequate amounts. Complete proteins most often are derived from animal sources and include milk, eggs, meat, fish, and poultry. However, there are a few vegetable-derived complete protein sources, including soy and quinoa. Other vegetable proteins, including dried peas and beans, nuts, seeds, and grains, contain all the essential amino acids but in less than adequate proportions. These proteins need to be combined with each other to meet the amino acid requirements for protein synthesis (though combining them at one meal is not necessary). The average daily protein requirement is 30 to 50 g, provided the protein is of good quality, and the diet contains adequate carbohydrates and fats. Diets that are adequate in calories, but inadequate in protein can result in kwashiorkor. If both calories and protein are inadequate, protein–calorie malnutrition occurs (see the section, Protein–Energy Malnutrition).

**Fats**

Fat is the most concentrated source of energy. The Food and Nutrition Board has set an AMDR for fat of 25% to 35% of daily caloric intake in adults, 25% to 35% in children between 4 and 18 years of age, and 30% to 40% in children between 1 and 3 years of age. The daily dietary recommendation for cholesterol is less than 300 mg. Cholesterol is a waxy lipid contained in every body cell, which is produced in the liver. It is necessary for numerous body functions, including hormone production, metabolism of many vitamins, nerve function, and cell permeability. Cholesterol is transmitted throughout the body by lipoproteins; low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglycerides. Excess cholesterol in the body can cause significant harm to the cardiovascular system and increase risk of serious cardiac disease. Careful monitoring of blood levels and reduction of dietary intake of cholesterol help to keep cholesterol levels in balance.

Dietary fats are composed primarily of triglycerides (i.e., a mixture of fatty acids and glycerol). The fatty acids are saturated (SFA), monounsaturated (MUFA), or polyunsaturated (PUFA). The SFAs elevate blood cholesterol, whereas the monounsaturated and polyunsaturated fats lower blood cholesterol. Saturated fats usually are from animal sources and remain solid at room temperature. With the exception of coconut and palm oils (which are saturated), unsaturated fats are found in plant oils and usually are liquid at room temperature. Trans fatty acids (TFAs) are produced when unsaturated oils are partially hydrogenated and are called artificial trans fats. They are found primarily in vegetable shortenings, some margarines, and in foods containing either of these. Natural sources of TFAs include dairy products, some meats, and other animal-based foods. TFAs increase LDL cholesterol (“bad cholesterol”) and decrease HDL cholesterol (“good cholesterol”). However, the naturally occurring trans fats may have a beneficial effect. Dietary fats provide energy, function as carriers for the fat-soluble vitamins, serve as precursors of prostaglandins, and are a source of fatty acids.
PUFAs, including linoleic acid (an omega-6 fatty acid) and alpha-linolenic acid (an omega-3 fatty acid), are examples of essential fatty acids. This means that they are not synthesized in the body and must be included in the diet. An AI has been set for both linoleic and alpha-linolenic acids. Because certain vegetable oils are rich sources of alpha-linolenic and linoleic acid, the AI can be met by including two teaspoons per day of vegetable oil in the diet. Deficiency of linoleic acid results in dermatitis and deficiency of alpha-linolenic acid can result in neurological abnormalities and poor growth.

Omega-3 and omega-6 fatty acids have been found to contribute to both formation and treatment of many disease states. Gamma linolenic acid, a derivative of linoleic acid, may promote inflammation, while alpha-linolenic acid has been effective in treating some disease states with inflammatory states, but not in others. Much is still unknown about the effects of this group of nutrients. Omega-3 acids are primarily found in cold water fish, walnuts, and flaxseeds. Omega-6 fatty acids are found in seeds and nuts. In general, omega-6 fatty acids promote inflammation, blood clotting, and cell proliferation, while omega-3 fatty acids decrease these functions. A diet with a balanced intake of both is often recommended.

**Carbohydrates**

Dietary carbohydrates are composed of simple sugars, complex carbohydrates, and indigestible carbohydrates (i.e., fiber). Because of their vitamin, mineral, and fiber content, it is recommended that the bulk of the carbohydrate content in the diet be in the complex form rather than as simple sugars that contain few nutrients.

There is no specific dietary requirement for carbohydrates. All of the energy requirements of the body can be met by dietary fats and proteins. Although some tissues, such as the nervous system, require glucose as an energy source, this need can be met through the conversion of amino acids and the glycerol part of the triglyceride molecule to glucose. The fatty acids from triglycerides are converted to ketones and used for energy by other body tissues. A carbohydrate-deficient diet usually results in the loss of tissue proteins and the development of ketosis. Because protein and fat metabolism increase the production of osmotically active metabolic wastes that must be eliminated through the kidneys, there is a danger of dehydration and electrolyte imbalances. The amount of carbohydrate needed to prevent tissue wasting and ketosis is 50 to 100 g/day.

In practice, carbohydrates should supply most of the daily energy requirement because many protein sources also are high in fat and more expensive. The AMDR indicates that carbohydrate intake should consist of 45% to 65% of the daily calories in the diet.

Carbohydrates should be in the form of whole grains, vegetables, and fruits, which have higher fiber content compared to refined flour and sugar products.

**Vitamins and Minerals**

**Vitamins.** Vitamins are a group of organic compounds that act as catalysts in various chemical reactions. A compound cannot be classified as a vitamin unless it is shown that a deficiency of it causes disease. Contrary to popular belief, vitamins do not provide energy directly. As catalysts, they are part of the enzyme systems required for the release of energy from protein, fat, and carbohydrates. Vitamins also are necessary for the formation of red blood cells, hormones, genetic materials, and the nervous system. They are essential for normal growth and development.

There are two types of vitamins: fat soluble and water soluble. The four fat-soluble vitamins are vitamins A, D, E, and K. The nine required water-soluble vitamins are thiamine, riboflavin, niacin, pyridoxine (vitamin B₆), pantothenic acid, vitamin B₁₂, folic acid, biotin, and vitamin C. Fat-soluble vitamins are stored in the body and may reach toxic levels if ingested in amounts greater than what is required by the body. Because the water-soluble vitamins are excreted in the urine, they are less likely to accumulate in the body to toxic levels. Table 47.1 lists major food sources of vitamins.

**Minerals.** Minerals serve many functions. They are involved in acid–base balance and in the maintenance of osmotic pressure in body compartments. Minerals are components of vitamins, hormones, and enzymes. They maintain normal hemoglobin levels, play a role in nervous system function, and are involved in muscle contraction and skeletal development and maintenance. Minerals that are present in relatively large amounts in the body are called macrominerals. These include calcium, phosphorus, sodium, chloride, potassium, magnesium, and sulfur. Other minerals are classified as trace minerals and include iron, manganese, copper, iodine, zinc, cobalt, fluorine, and selenium. Over- or underinjection of recommended levels of minerals can result in illness or toxicity. Table 47.2 provides a list of mineral sources and their functions.

**Fiber**

Dietary fiber, the nondigestible carbohydrates found in plants such as fruits, vegetables, beans, nuts, and whole grains, and functional fiber, isolated nondigestible carbohydrates that have beneficial physiological benefits, together form total fiber. Functional fibers are synthetic or extracted from plant sources and added to food. Examples include psyllium and methylcellulose, and they are commonly found in processed foods. Dietary fiber provides increased bulk, viscosity, and fermentation. Bulking slows gastric emptying, therefore increasing satiety, and increases the rate of transport through the gastrointestinal tract, thereby increasing stool bulk and facilitating normal bowel movements. Viscosity thickens the lining of the intestinal track, helps moderate blood glucose levels, and lowers cholesterol levels. Fermentation contributes to growth of healthy intestinal bacteria and to immune system functioning. More studies are needed to establish whether fiber prevents colon cancer and promotes weight loss. In 2002, the Food and Nutrition Board gave its first recommended intake for fiber. Current recommendations for men and women who are young adults are 34 and 28 g, respectively, of fiber daily, whereas those older than 50 years should have 28 and 22 g, respectively, each day.
### TABLE 47.1 MAJOR FOOD SOURCES OF VITAMINS

<table>
<thead>
<tr>
<th>VITAMIN</th>
<th>MAJOR FOOD SOURCES</th>

Regulation of Food Intake and Energy Storage

Stability of body weight and composition over time requires that energy intake matches energy utilization. Environmental, cultural, genetic, and psychological factors all influence food intake and energy expenditure. In addition, body weight is tightly controlled by various physiologic feedback control systems that contribute to the regulation of hunger, food intake, and energy expenditure.1

Hunger, Appetite, and Control Mechanisms of Food Intake

The sensation of hunger is associated with several sensory perceptions, such as the rhythmic contractions of the stomach and that “empty feeling” in the stomach that stimulates a person to seek food. A person’s appetite is the desire for a particular type of food. It is useful in helping the person determine the type of food that is eaten. Satiety is the feeling of fullness or decreased desire for food.

Two centers in the brain interact with various hormones and neurotransmitters to help control food intake and energy output. The arcuate nucleus of the hypothalamus has been identified as the center for hunger and satiety. However, current research indicates that other centers in the brainstem also contribute to the mechanisms.8 These centers receive neural input from the gastrointestinal tract that provides information about stomach filling; chemical signals from nutrients (glucose, amino acids, and fatty acids) in the blood; and input from the cerebral cortex regarding the smell, sight, and taste of the food. Centers in the hypothalamus also control the secretion of several hormones (e.g., thyroid and adrenocortical hormones) that regulate energy balance and metabolism.

The control of food intake is subject to short-term regulation, which is concerned with the amount of food that is consumed at a meal or snack, and intermediate- and long-term regulation, which is concerned with the maintenance of energy stores over time.1

The short-term regulation of food intake from neurohormones, which either increase feeding considered to be orexigenic or decrease feeding classified as anorexigenic,1 Figure 47.2 lists several of these neural messengers and the overall effects they promote. Over 30 gastrointestinal hormone genes have been identified that play a role in regulating hunger and satiety.9 Research is providing additional insights into the complex system; however, much is still unknown.9,10

Three main short-term messengers that promote orexigenic effects include ghrelin, produced mainly in the stomach, and neuropeptide Y (NPY) and agouti-related protein (AGRP), both produced in the hypothalamus. Many of the other gut hormones have anorexigenic effects by signaling satiety to the neural centers. Among these are cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), peptide tyrosine tyrosine (PYY), and oxyntomodulin (OXM), all produced in the small intestine. Pancreatic peptide (PP) is secreted in the pancreas, as are amylin and insulin, in response to the presence of food. All of these messengers send messages of satiety that ultimately help decrease food intake.8

The intermediate- and long-term regulation of food intake is determined by the amount of nutrients that are in the blood and in storage sites. It has long been known that a decrease in blood glucose causes hunger. In contrast, an increase in breakdown products of lipids such as ketocids produces a decrease in appetite. A ketogenic weight-loss diet (e.g., the Atkins diet) relies partly on the appetite-suppressant effects of ketones in the blood.

Adipocytes release leptin in proportion to the amount of fat stores. The stimulation of leptin receptors in the hypothalamus produces a decrease in appetite and food intake as well as an increase in metabolic rate and energy consumption. It also produces a decrease in insulin release from the beta cells, which decreases energy storage in fat cells.8

IN SUMMARY

The body requires more than 40 nutrients on a daily basis. Nutritional status reflects the continued daily intake of nutrients over time and the deposition and use of these nutrients in the body. The DRIs classify the amounts of essential nutrients considered to be adequate to meet the known nutritional needs of healthy people. The DRIs have 22 age and sex classifications and include recommendations...
for calories, proteins, fats, carbohydrates, vitamins, and minerals. Hunger and satiety are controlled by a complex group of neurohormones, many of which are produced in the gastrointestinal tract. These messengers function to either stimulate hunger or signal satiety to control both short- and long-term effects. While much information has been revealed through research in recent years, there is still much to be learned in order to effectively manage the complex process more effectively.

OVERWEIGHT AND OBESITY

After completing this section of the chapter, you should be able to meet the following objectives:

• Explain the use of body mass index (BMI) in evaluating body weight.
• Define and discuss the causes and types of obesity and health risks associated with obesity.
• Discuss the treatment of obesity in terms of diet, behavior modification, exercise, social support, pharmacotherapy, and surgical methods.

Obesity is defined as having excess body fat accumulation with multiple organ-specific pathologic consequences. Overweight and obesity have become global health problems. In 2008, 1.5 billion people were classified as overweight and more than 1 in 10 of the world’s population were ranked as obese.11 In the United States, more than 65% of adults are currently either overweight or obese, and more than 33% of the population is obese, with obesity having an even higher prevalence in minority groups such as non-Hispanic blacks and those of Hispanic ethnicity.12 The prevalence of overweight and obesity is even more alarming in children and adolescents. Approximately 17% of children between 2 and 19 years of age are obese—a percentage that has tripled since 1980.13

Body Mass Index

Clinically, obesity and overweight have been defined in terms of the BMI. The BMI is based on height and weight measurements (see Fig. 47.3) and has a correlation with body fat. It is now becoming clear that different ethnic groups have different percentages of body fat for the same BMI.14 In 1997, the World Health Organization (WHO) defined the various classifications of overweight (BMI ≥ 25) and obesity (BMI ≥ 30). The National Institutes of Health (NIH) subsequently adopted this classification.15 The use of a BMI cut-off of 25 as a measure of overweight raised some concern that the BMI of some men might be a function of muscle rather than fat weight. However, it has been shown that a BMI cut-off of 25 can sensitively detect most overweight people and does not erroneously detect overlean people.

The definition for obesity in children is a BMI at or above the sex- and age-specific 95th percentile, whereas a BMI between the 85th and 95th percentiles is defined as being overweight.15 These criteria have been selected because they correspond to adult BMIs of 30 and 25, respectively.

Causes of Obesity

The epidemic of obesity results from many causative factors, and research is adding to the body of knowledge almost daily.

While overweight and obesity ultimately result from an energy imbalance of eating too many calories and not getting enough physical activity, many factors contribute to both the development of obesity and the body’s response to attempts to control it. Commonly acknowledged contributing causes include genetics, metabolism, behavior, environment, culture, and socioeconomic status.12,16 Medical conditions such as thyroid disorder, Cushing syndrome, and polycystic ovarian syndrome can also contribute to weight gain and obesity, as do many medications.

The relationship between genetics and weight gain is complex and, as yet, not fully understood. The most recent update of the human obesity gene map, completed in 2005, suggests that there are 100 chromosomal locations relevant to obesity.17 Many of these relate to known brain-gut controls of hunger and satiety, metabolism, and the body’s storage mechanisms. Researchers believe these theories may help to explain differences in obesity levels found in various populations. Identification of these genetic influences may allow for more targeted treatment interventions in the future. It is yet unknown how genes and mutations may directly or indirectly interact with environmental causes of obesity. One description for the complex interaction between environment and genetics is attributed to George Bray, a noted expert on obesity, who stated “the genetic background loads the gun, but the environment pulls the trigger.”13

There is new evidence that behavior-based interventions may help keep genetic influence in check.10

Though genetic research gives new insight into the genesis of obesity, environmental influence remains the major contributor to this worldwide issue.17 Obesity rates have reached epidemic proportions in populations with high availability of calorie-rich foods and few opportunities for physical activity.15,17 Influences such as family eating patterns, time spent on the computer, watching television, reliance on the automobile for transportation, easy access to food, higher energy density of food, increased consumption of sugar-sweetened beverages,
and increasing portion sizes have all been cited as contributing factors to overweight trends. More recent epidemiologic studies indicate that while decreased physical activity plays a role in increasing rates of overweight and obesity, diet changes due to increased availability of cheap, tasty, highly promoted, obesogenic types of food appear to have caused a much more steep rise in obesity. 19

Psychological factors are another area of influence on behavior related to weight gain. Eating may be a way to cope with stress, boredom, or anxiety. However, the relationships of these behaviors to mental health and obesity are complex and poorly understood. 19,20 No specific personality traits characteristic of obese people have been identified. 20 While the causal relationship of psychological behaviors is not clear, binge-eating disorder (BED) behaviors, described as uncontrolled consumption of large quantities of food, have been found in 20% to 30% of obese people seeking weight-loss treatment. 20

Culture and socioeconomic status are also believed to be contributing factors in the increased rates of overweight and obesity. Increased rates of obesity are seen in African American, and Hispanic groups, particularly in women. Although many theories have been set forth, it is not yet clear what impact cultural food choices and accepted cultural behaviors have on these rates. 16 It is clear that interventions will need to be developed to address the needs of different cultures, as well as to address the socioeconomic barriers to improved dietary choices. 16 Much discussion and debate will continue related to causative factors, especially as effective means to treat and prevent obesity are sought.

Types of Obesity

Two types of obesity based on distribution of fat have been described: upper body and lower body obesity (see Fig. 47.4). Upper body obesity is also referred to as central, abdominal, visceral, or male (“android”) obesity. Lower body obesity is also known as peripheral, gluteal-femoral, or female (“gynoid”) obesity. Subjects with upper body obesity are often referred to as being shaped like an “apple,” compared with lower body obesity, which is more “pear” shaped. In general, men have more intra-abdominal fat and women more subcutaneous fat. As men age, the proportion of intra-abdominal fat to subcutaneous fat increases. After menopause, women tend to acquire more central fat distribution.

The obesity type is determined by dividing the waist by hip circumference. Comparison of the waist measurement and hip measurement can identify the type of obesity. A waist–hip ratio greater than 1.0 in men and 0.8 in women also indicates upper body or central obesity. Central obesity can be further differentiated into intra-abdominal adipose tissue (visceral fat) and subcutaneous abdominal adipose tissue by the use of computed tomography (CT) or magnetic resonance imaging (MRI) scans. 21 Waist-circumference, which is a measure of central fat distribution, measures both subcutaneous abdominal adipose tissue and intra-abdominal adipose tissue. One of the characteristics of visceral fat is the release of adipokines (such as TNF-α and adiponectin) and fatty acids directly to the liver before entering the systemic circulation, having a potentially greater impact on hepatic function (e.g., the increased fatty acids are deposited in the liver, causing fatty liver, resulting in insulin resistance in the liver). Higher levels of these adipokines and circulating free fatty acids in obese people, particularly those with upper body obesity, are thought to be associated with many of the adverse effects of obesity. 22

The presence of excess fat in the abdomen out of proportion to total body fat is an independent predictor of risk factors and mortality. Both BMI and waist circumference are positively correlated with total body adipose tissue, but waist circumference is a better predictor of abdominal visceral fat content than BMI. 13,14 A waist circumference 88 cm (35 inches) or greater in women and 102 cm (40 inches) or greater in men has been associated with increased health risk 13 (see Table 47.3).

Weight loss causes a preferential loss of visceral fat (due to higher turnover of visceral fat cells than subcutaneous) and can result in improvements in metabolic and hormonal abnormalities. Although peripheral obesity is associated with varicose veins in the legs and mechanical problems, it is not as strongly associated with cardiometabolic risk. In terms of weight reduction, some studies have shown that people with upper body obesity are easier to treat than those with lower body obesity. Other studies have shown no difference in terms of success with weight reduction programs between the two types of obesity.

Health Risks Associated with Obesity

The excess body fat of obesity often significantly impairs health. As a result, obesity is the second leading cause of preventable death in the United States in adults under age 70, and the third leading cause in all ages, following smoking and hypertension. 23 It has been predicted that the health effects of obesity will result in a shorter life expectancy for today’s youth. 13 Obese people
have a 50% to 100% increased risk of premature death from all causes compared to people with a healthy weight.\(^{24}\)

Obesity affects nearly every body system (see Fig. 47.5). Cardiac disease is increased, as well as hypertension, hypertriglyceridemia, and decreased HDL cholesterol. Significant weight gain increases the risk of developing type 2 diabetes, obstructive sleep apnea, gastric reflux, urinary stress incontinence, and gallbladder disease. Limited mobility and increased joint disorders are functional results of increased weight on the body’s skeletal system. In women, obesity can contribute to infertility, higher risk pregnancy, gestational diabetes, maternal hypertension, and difficulty in labor and delivery. Infants who are born to obese mothers are more likely to be high birth weight, contributing to an increased rate of cesarean section delivery. Several types of cancer are seen in higher frequency in people who are obese, including endometrial, colon, gallbladder, prostate, kidney, and postmenopausal breast cancer. Obesity also causes nonalcoholic steatohepatitis and fatty liver disease.\(^{11,12,14}\)

In the United States as well as in other countries, there are many negative stereotypes associated with obesity.\(^{25,26}\) People, especially women, are expected to be thin, and obesity may be seen as a sign of lack of self-control. Obesity may negatively affect employment and educational opportunities, as well as marital status.\(^{26}\) Obesity may also play a role in a person’s treatment by health professionals.\(^{25,27}\) Although nurses, physicians, and other health professionals are aware of the low success rate and difficulty in treating weight problems, they still may place the blame on the obese person.\(^{25,27}\)

### Prevention and Treatment of Obesity

#### Prevention

Obesity in epidemic proportions has led to much discussion on methods of prevention; yet few effective approaches have resulted.\(^{17}\) More research is now being focused on prevention efforts directed at children and adolescents. Most interventions involve modification of lifestyle behaviors to promote healthy food choices and more physical activity. Public debate is also focused on policy methods to regulate availability of less desirable food choices, such as high-calorie snacks and sweetened drinks. However, evidence on the effectiveness of these methods is limited.\(^{17}\)

Major public education and policy efforts are now being undertaken by federal agencies. *We Can! is a national educational program developed by the NIH to help children between 8 and 13 years old achieve or stay at a healthy weight by encouraging healthy eating, increasing physical activity, and reducing screen time for the family as a whole. Another pro-

**BMI, body mass index.**

Dietary Therapy. The two major components of all diet therapy are caloric restriction and diet composition. While diet modification and caloric restriction are important components of weight-loss therapy, no one method has been shown to be most effective. Therefore, dietary therapy should be individually prescribed based on the person’s overweight status and risk profile. The diet should be a personalized plan with realistic goals.

Caloric restriction may vary from low-calorie diets (LCDs) to very-low-calorie diets (VLCDs). LCDs typically restrict caloric intake to 1200 kcal/day. This results in a variable reduction, depending on the initial dietary intake of the individual. VLCDs restrict calories to approximately 450 kcal/day, primarily made up of protein. This diet has higher risks, including abnormal heart rhythms and cholelithiasis. Anyone on this diet should be under direct supervision of a medical professional.

A more conservative dietary approach is to reduce the current dietary intake by 500 to 1000 kcal/day. Total caloric intake should be distributed in four or five meals or snacks throughout the day. Portion control is an effective technique to help achieve calorie reduction. Many overweight people have not practiced or monitored portion size. Keeping daily diet logs of all food ingested helps to increase awareness of both content and frequency. Meal replacements, such as protein shakes with vitamins and minerals, may also be used as a substitute for solid food meals.

After caloric restriction is determined, diet composition should be addressed. There are many methods of altering dietary content, including low-fat diets, and low-carbohydrate/high-protein diets. Low-fat diets strive to limit daily calories from fat to 10% to 15% of total calorie intake. This level may be difficult to achieve and often is less palatable. Low-carbohydrate/high-protein diets became popular in the 1960s and 1970s. Although effective for weight loss, especially in the initial stages, they can contribute to health risks. Higher protein diets can increase the risk of kidney stones, and the decrease in fiber can also increase risks of cancer and raise cholesterol levels.

Physical Activity. There is convincing evidence that increased physical activity decreases the risk of overweight and obesity. In addition, it reduces cardiovascular and diabetes risk beyond that achieved by weight loss alone. Although physical activity is an important part of weight-loss therapy and helps with maintaining weight loss, it does not independently lead to a significant weight loss. It may, however, help reduce abdominal fat, increase cardiopulmonary fitness, and prevent the decrease in muscle mass that often occurs with weight loss. Exercise should be started slowly with the duration and intensity increased independently of each other. The goal for adults should be a minimum of 150 to 300 minutes or more of moderate to vigorous activity per week to achieve and maintain a healthy weight.

Behavior Therapy. Lifestyle modification is an essential factor in treating weight loss. Strategies include helping participants learn to self-monitor eating habits, including where and when they eat, and identifying situations that trigger eating behavior. Techniques for changing behavior include stress management, stimulus control, problem solving, contingency management, cognitive restructuring, social support, and relapse prevention.

Another important aspect to behavior modification is helping the person to set realistic weight-loss goals. Weight loss from
diet therapy, exercise, and behavioral therapy typically is 10% below the initial baseline.\textsuperscript{17} In many cases, this level can lessen health risks, but often falls short of individual expectations.

**Pharmacotherapy.** Drugs approved by the U.S. FDA can be used as an adjunct to the aforementioned regimen in some people with a BMI of 30 or more with no other risk factors or diseases, and for people with a BMI of 27 or more with concomitant risk factors or diseases.\textsuperscript{28} The risk factors and diseases defined as warranting pharmacotherapy are coronary heart disease, type 2 diabetes, metabolic syndrome, gynecologic abnormalities, osteoarthritis, gallbladder disease, stress incontinence, and sleep apnea.

Medications that have been approved for the treatment of obesity generally fall into one of two categories:

1. Reduction of food intake via the central nervous system.
2. Action primarily outside the brain.

Medications that primarily act via the central nervous system either block or activate portions of the neurotransmitter systems that are involved in signaling hunger and satiety. Pathways, which may be affected, include norepinephrine, serotonin, dopamine, and histamine. The endocannabinoid system is also known to affect food intake and is the focus of research for effective weight reduction therapy. Many psychoactive drugs have been shown to produce weight loss or weight gain as a side effect of their desired treatment goal, further emphasizing that these complex pathways exist. Drug development in this category, while promising in early stages, has thus far resulted in no effective, safe long-term treatments. Several sympathomimetic drugs have been approved for short-term therapy of 12 weeks or less.

Drugs that act peripherally include those that cause the blockade of lipase absorption in the gastrointestinal tract (“fat-blockers”) and newer drugs that target areas in the pancreas and intestine as well as the brain to help reduce food intake, increase insulin secretion, and slow gastric emptying.

A growing area of research and drug utilization includes non-FDA–approved usage of medications approved for other indications. Examples include antidepressants such as bupropion and fluoxetine, antiepileptic drugs such as topiramate, and antidiabetic medications such as metformin, pramlintide, and exenatide. With all such applications, use should be carefully monitored for any untoward side effects, as well as for desired weight-loss effects.\textsuperscript{17}

**Weight-Loss (Bariatric) Surgery.** In people with clinically severe obesity (a BMI > 40) and in those with a BMI greater than 35 who have comorbid conditions who have failed medical attempts to control weight, surgical therapy is currently the most effective treatment of obesity. Weight-loss surgery provides medically significant weight loss sustained for 5 years in most people.\textsuperscript{28}

There are three types of weight-loss surgery: (1) restrictive procedures, which reduce the amount of food that can be taken in, (2) malabsorptive procedures, which bypass sections of the intestine and result in less nutrients being absorbed, and (3) combined restrictive and malabsorptive procedures. Restrictive procedures include the adjustable gastric band and the sleeve gastrectomy, while the malabsorptive procedures include the biliopancreatic diversion with duodenal switch. The Roux-en-Y gastric bypass is the combined restrictive and malabsorptive procedure. Each surgery has specific risks and potential complications and requires lifelong nutritional monitoring after surgery. The key to long-term success and maintenance of weight loss after these surgical procedures is participation in a program that provides guidance in nutrition, physical activity, behavioral therapy, and social support.

One major benefit of weight-loss surgery is resolution or remission of comorbid disease states. The significant improvement of type 2 diabetes symptoms in particular has prompted the International Diabetes Federation to endorse bariatric surgery eligibility for type 2 diabetics with BMIs greater than 35, and for people with BMIs greater than 30 who have not responded adequately to conventional therapy.\textsuperscript{29}

**IN SUMMARY**

Obesity is defined as having excess body fat accumulation with multiple organ-specific pathologic consequences. Genetic, socioeconomic, cultural, and environmental factors; psychological influences; and activity levels have been implicated as causative factors in the development of obesity. There are two types of obesity—upper body and lower body obesity. Upper body obesity is associated with a higher incidence of health risks. The health risks associated with obesity affect almost every body system. The treatment of obesity focuses on nutritionally adequate weight-loss diets, behavior modification, exercise, social support, and, in situations of marked obesity, pharmacotherapy and surgical methods.

**UNDERNUTRITION AND EATING DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- State the difference between protein–calorie starvation (i.e., marasmus) and protein malnutrition (i.e., kwashiorkor).
- Explain the effect of malnutrition on muscle mass, respiratory function, acid–base balance, wound healing, immune function, bone mineralization, the menstrual cycle, and testicular function.
- Compare the eating disorders of anorexia and bulimia nervosa (BN) and the complications associated with each.
Undernutrition continues to be a major health problem throughout the world. Globally, undernourished rates peaked sharply to an estimated 1.023 million people in 2009 following the worldwide food and economic crisis. Rates were expected to decline in 2010 by 9.6%, to an estimated 9.25 million. Developing countries have a prevalence of 16% undernourished populations and are responsible for 98% of the overall total. In developed countries, undernutrition is most commonly seen in the pediatric and older adult populations.

**Malnutrition and Starvation**

Malnutrition and starvation are conditions in which a person does not receive or is unable to use an adequate amount of nutrients for body function. An adequate diet should provide adequate energy in the form of carbohydrates, fats, and proteins; essential amino acids and fatty acids for use as building blocks for synthesis of structural and functional proteins and lipids; and vitamins and minerals, needed to function as coenzymes or hormones in vital metabolic processes, or, as in the case of calcium and phosphate, as important structural components of bone.

Among the many causes of malnutrition are poverty and ignorance, acute and chronic illness, and self-imposed dietary restriction. Homeless people, older adults, and children of the poor often demonstrate the effects of protein and energy malnutrition, as well as vitamin and mineral deficiencies. Even the affluent may fail to recognize that infants, adolescents, and pregnant women have increased nutritional needs. Some types of malnutrition are caused by acute and chronic illnesses, such as occurs in people with Crohn disease who are unable to absorb nutrients from their food. Anorexia nervosa and less overt eating disorders affect a large population of people who are concerned about body image or athletic performance.

**Protein–Energy Malnutrition**

Protein and energy (calorie) malnutrition represents a depletion of the body’s lean tissues caused by starvation or a combination of starvation and catabolic stress. The lean tissues are the fat-free, metabolically active tissues of the body, namely, the skeletal muscles, viscera, and cells of the blood and immune system. Because lean tissues are the largest body compartment, their rate of loss is the main determinant of total body weight in most cases of protein–energy malnutrition.

Much of the literature on malnutrition and starvation has dealt with infants and children in underdeveloped countries in which food deprivation results in an inadequate intake of protein and calories to meet the body’s energy needs. Protein–energy malnutrition in this population commonly is divided into two distinct conditions: marasmus (protein and calorie deficiency) and kwashiorkor (protein deficiency). The pathologic changes for both types of malnutrition include humoral and cellular immunodeficiencies resulting from protein deficiency and lack of immune mediators. There is impaired synthesis of pigments of the hair and skin (e.g., hair color may change and the skin may become hyperpigmented) because of a lack of substrate (tyrosine) and coenzymes.

**Marasmus** represents a progressive loss of muscle mass and fat stores due to inadequate food intake that is equally deficient in calories and protein. It results in a reduction in body weight adjusted for age and size. The child with marasmus has a wasted appearance, with loss of muscle mass, stunted growth, and loss of subcutaneous fat; a protuberant abdomen (from muscular hypotonia); wrinkled skin; sparse, dry, and dull hair; and depressed heart rate, blood pressure, and body temperature. Diarrhea is common. Because immune function is impaired, concurrent infections occur and place additional stress on an already weakened body. An important characteristic of marasmus is growth failure; if sufficient food is not provided, these children will not reach their full potential stature.

**Kwashiorkor** results from a deficiency in protein in diets relatively high in carbohydrates. The term kwashiorkor comes from an African word meaning “the disease suffered by the displaced child,” because the condition develops soon after a child is displaced from the breast after the arrival of a new infant and placed on a starchy gruel feeding. Kwashiorkor is a more severe form of malnutrition than marasmus. Unlike marasmus, severe protein deficiency is associated with extensive loss of the visceral protein compartment with a resultant hypalbuminemia that gives rise to generalized or dependent edema. The child with kwashiorkor usually presents with edema, desquamating skin, discolored hair, anorexia, and extreme apathy (Fig. 47.7). There are “flaky paint” lesions of the skin on the face, extremities, and perineum, and the hair becomes a sandy or reddish color, with linear depigmentation (flag sign). There is generalized growth failure and muscle wasting as in marasmus, but subcutaneous fat is normal because calorie intake is adequate. Other manifestations include skin lesions, hepatomegaly and distended abdomen, cold extremities, and decreased cardiac output and tachycardia.

**Marasmus–kwashiorkor** is an advanced protein–energy deficit coupled with increased protein requirement or loss. This results in a rapid decrease in anthropometric measurements, with obvious edema and wasting and loss of organ mass. One essential aspect of severe protein–energy malnutrition is fatty degeneration of such diverse organs as the heart and liver. This degeneration causes subclinical and overt cardiac dysfunction, especially when malnutrition is accompanied by edema. A second injurious aspect is the loss of subcutaneous fat, which markedly reduces the body’s capacity for temperature regulation and water storage. As a consequence, malnourished children become dehydrated and hypothermic more quickly and more severely than normally nourished children. Most children with severe protein–energy malnutrition have asymptomatic infections because their immune system fails to respond appropriately. Their immune system is so depressed that many are unable to produce the fever that is typical of an acute infection.

**Malnutrition in Trauma and Illness**

In industrialized societies, protein–energy malnutrition most often occurs secondary to trauma or illness. Kwashiorkor-like protein malnutrition occurs most commonly in association with hypermetabolic acute illnesses, such as trauma, burns, and
Disorders of Gastrointestinal Function

and respiratory function becomes compromised as muscle proteins are used as a fuel source. A reduction in respiratory function has many implications, especially for people with burns, trauma, infection, or chronic respiratory disease, and for people who are being mechanically ventilated because of respiratory failure.

In people who are hospitalized, malnutrition increases morbidity and mortality rates, incidence of complications, and length of stay. Malnutrition may present at the time of admission or develop during hospitalization. The hospitalized person often finds eating a healthful diet difficult and commonly has restrictions on food and water intake in preparation for tests and surgery. Pain, medications, special diets, and stress can decrease appetite. Even when the person is well enough to eat, being alone in a room where unpleasant treatments may be given is not conducive to eating. Although people who are hospitalized may appear to need fewer calories because they are on bed rest, their actual need for caloric intake may be higher because of other energy expenditures. For example, more calories are expended during fever, when the metabolic rate is increased. There also may be an increased need for protein to support tissue repair after trauma or surgery.

Diagnosis

No single diagnostic measure is sufficiently accurate to serve as a reliable test for malnutrition. Techniques of nutritional assessment include evaluation of dietary intake, anthropometric measurements, clinical examination, and laboratory tests. Evaluation of weight is particularly important. Body weight can be assessed in relation to height using the BMI. Evaluation of body composition can be performed by inspection or using anthropometric measurements such as skinfold thickness. Serum albumin and prealbumin are used in the diagnosis of protein–calorie malnutrition. Albumin, which has historically been used as a determinant of nutrition status, has a relatively large body pool and a half-life of 20 days and is less sensitive to changes in nutrition than prealbumin, which has a shorter half-life and a relatively small body pool.

Treatment

The treatment of severe protein–energy malnutrition involves the use of measures to correct fluid and electrolyte abnormalities and replenish proteins, calories, and micronutrients. Treatment is started with modest quantities of proteins and calories based on the person’s actual weight. Concurrent administration of vitamins and minerals is needed. Either the enteral or parenteral route can be used. The treatment should be undertaken slowly to avoid complications. The administration of water and sodium with carbohydrates can overload a heart that has been weakened by malnutrition and result in heart failure. Enteral feedings can result in malabsorptive symptoms due to abnormalities in the gastrointestinal tract. Refeeding edema is benign-dependent edema that results from renal sodium reabsorption and poor skin and blood vessel integrity. It is treated by elevation of the dependent area and modest sodium restrictions. Diuretics are ineffective and may aggravate electrolyte deficiencies.

FIGURE 47.7 • Clinical manifestations of kwashiorkor.
Eating Disorders
Eating disorders affect an estimated 24 million Americans of all ages and genders.4 These illnesses, which include anorexia nervosa, bulimia nervosa, and binge-eating disorder and their variants, incorporate serious disturbances in eating, such as restriction of intake and binging, with an excessive concern over body shape or body weight.35 Eating disorders manifest in both men and women, with occurrence in women at slightly higher rates. However, BED is more prevalent in men than AN and bulimia combined.35

Eating disorders are more prevalent in industrialized societies and occur in all socioeconomic and major ethnic groups. A combination of genetic, neurochemical, developmental, and sociocultural factors is thought to contribute to the development of the disorders.35 Criteria for the diagnosis of AN and BN have been established.36 BED and eating disorders not otherwise specified (EDNOS) also have been identified by specific diagnostic criteria. Although these criteria allow clinicians to make a diagnosis in people with a specific eating disorder, the symptoms often occur along a continuum between those of AN and BN. Preoccupation with weight and excessive self-evaluation of weight and shape are common to all disorders, and people with eating disorders may demonstrate a mixture of symptoms from the disorders.35 People with eating disorders may require concomitant evaluation for psychiatric illness because eating disorders often are accompanied by mood, anxiety, and personality disorders.

Anorexia Nervosa
AN is an eating disorder that usually begins in adolescence and is characterized by determined dieting, often accompanied by compulsive exercise and, in a subgroup of people, purging behavior with or without binge eating, resulting in sustained low weight. Other features include a disturbed body image, a pervasive fear of becoming obese, and an obsession with severely restricted caloric intake and frequently with excessive physical exercise. AN is more prevalent among young women compared to men.34,35

The causes of anorexia appear to be multifactorial, with determinants that include genetic influence; personality traits of perfectionism and compulsiveness; anxiety disorders; family history of depression and obesity; and peer, familial, and cultural pressures with respect to appearance. Diagnostic criteria for AN are: (1) a refusal to maintain a minimally normal body weight for age and height (e.g., at least 85% of minimal expected weight or BMI ≥ 17.5); (2) an intense fear of gaining weight or becoming fat; (3) a disturbance in the way one’s body size, weight, or shape is perceived; and (4) amenorrhea (in girls and women after menarche).35 Other psychiatric disorders often coexist with AN, including major depression or dysthymia, and obsessive-compulsive disorder. Alcohol and substance abuse may also be present, more often among those with binge-purging type of AN.35

Many organ systems are affected by the malnutrition that accompanies AN. The severity of the abnormalities tends to be related to the degree of malnutrition and is reversed by refeeding. The most frequent complication of anorexia is amenorrhea and loss of secondary sex characteristics with decreased levels of estrogen, which can eventually lead to osteoporosis. Bone loss can occur, and symptomatic compression fractures and kyphosis have been reported.35 Constipation, cold intolerance, and failure to shiver when cold, bradycardia, hypertension, decreased heart size, electrocardiographic changes, blood and electrolyte abnormalities, and increased growth of lanugo (i.e., fine hair) are common. Abnormalities in cognitive function may also occur. The brain loses both white and gray matter during severe weight loss; weight restoration results in return of white matter, but some loss of gray matter persists.35 Unexpected sudden deaths have been reported; the risk appears to increase as weight drops to less than 35% to 40% of ideal weight. It is believed that these deaths are caused by myocardial degeneration and heart failure rather than arrhythmias.

One of the most challenging aspects of the treatment of anorexia is the inability of the person with anorexia to recognize that there is a problem. People with the disorder are usually willing to talk about their preoccupation with weight loss, food refusal and rituals about food, and excessive exercise routines; purging and laxative use; and withdrawal from activities and relationships, but have difficulty recognizing this behavior as pathological.35 Because anorexia is a form of starvation, it can lead to death if left untreated. A multidisciplinary approach appears to be the most effective method of treating people with the disorder.35,36 The goals of treatment are eating and weight gain; resolution of issues with the family; healing of pain from the past; and efforts to work on psychological, relationship, and emotional issues. Specialized eating disorder treatment programs may include in-patient hospitalization, partial hospitalization, or intensive outpatient specialty eating disorder programs, depending on the level of weight loss, medical complications, and availability of family support.

Bulimia Nervosa
BN is defined by recurrent binge eating and activities such as vomiting; fasting; excessive exercise; and use of diuretics, laxatives, or enemas to compensate for that behavior. The criteria for BN are: (1) recurrent binge eating (at least two times per week for 3 months); (2) inappropriate compensatory behaviors such as self-induced vomiting, abuse of laxatives or diuretics, fasting, or excessive exercise that follow the binge-eating episode; (3) self-evaluation that is unduly influenced by body shape and weight; and (4) a determination that the eating disorder does not occur exclusively during episodes of AN.34,37 In contrast to AN, which is characterized by a weight that is less than 85% of the normal value, most people with BN are of normal weight. The diagnostic criteria for BN now include subtypes to distinguish people who compensate by purging (e.g., vomiting or abuse of laxatives or diuretics) and those who use nonpurging behaviors (e.g., fasting or excessive exercise). The disorder may be associated with other psychiatric disorders such as anxiety disorder or depression. There is also an association with substance abuse and risky and self-destructive behaviors.35

The complications of BN include those resulting from overeating, self-induced vomiting, and cathartic and diuretic
Antidepressants such as serotonin reuptake inhibitors have been found to be useful in treating bulimia and BEDs and one, fluoxetine, has received U.S. FDA approval for treatment.35

**Eating Disorder Not Otherwise Specified**

EDNOS is a diagnostic category for patients who have eating disorder symptoms but do not meet the full criteria for either AN or BN. Within this group is the subgroup, BED.

**Binge-Eating Disorder.** Binge eating is characterized by recurrent episodes of binge eating at least 2 days per week for 6 months and at least three of the following: (1) eating rapidly; (2) eating until becoming uncomfortably full; (3) eating large amounts when not hungry; (4) eating alone because of embarrassment; and (5) disgust, depression, or guilt because of eating episodes. The great majority of people with BED are overweight, and, in turn, obese people have a higher prevalence of BED than the nonobese population.34,35,38

The primary goal of therapy for BED is to establish a regular, healthful eating pattern. People with BED who have been successfully treated for their eating disorder have reported that making meal plans, eating a balanced diet of three regular meals a day, avoiding high-sugar foods and other binge foods, recording food intake and binge-eating episodes, exercising regularly, finding alternative activities, and avoiding alcohol and drugs are helpful in maintaining their more healthful eating behaviors after treatment.

Undernutrition can range from a selective deficiency of a single nutrient to starvation, in which there is deprivation of all nutrients. Malnutrition and starvation are among the most widespread causes of morbidity and mortality in the world. Protein–energy malnutrition in this population commonly is divided into two distinct conditions: marasmus (protein and calorie deficiency) and kwashiorkor (protein deficiency). Malnutrition is common during illness, recovery from trauma, and hospitalization. The effects of malnutrition and starvation on body function are widespread. They include loss of muscle mass, impaired wound healing, impaired immunologic function, decreased appetite, loss of calcium and phosphate from bone, anovulation and amenorrhea in women, and decreased testicular function in men.

AN and BN are eating disorders that result in malnutrition. In AN, distorted attitudes about eating lead to determined dieting, weight loss to below 85% of normal body weight, and malnutrition. BN is characterized by secretive episodes or binges of eating large quantities of easily consumed, high-calorie foods, followed by compensatory behaviors such as fasting, self-induced vomiting, or abuse of laxatives or diuretics. EDNOS is a new diagnostic category for patients who have eating disorders such as BED, but do not meet the full criteria for either AN or BN.

**REVIEW EXERCISES**

1. A 25-year-old woman is 65 inches (165 cm) tall and weighs 300 lb (136 kg). She works as a receptionist in an office, brings her lunch to work with her, spends her evenings watching television, and gets very little exercise. She reports that she has been fat ever since she was a little girl, has tried “every diet under the sun,” and when she diets she loses some weight, but gains it all back again.
   A. Calculate her BMI
   B. How would you classify her obesity?
   C. What are her risk factors for obesity?
   D. What would be one of the first steps in helping her develop a plan to lose weight?

2. A 16-year-old high school student is brought into the physician’s office by her mother, who is worried because her daughter insists on dieting because she thinks she is too fat. The daughter is 67 inches (170 cm) tall and weighs 96 lb (43.5 kg). Her history reveals that she is a straight-A student, plays in the orchestra, and is on the track team. Although she had been having regular
menstrual periods, she has not had a period in 4 months. She is given a tentative diagnosis of AN.

A. What are the criteria for a diagnosis of AN?
B. What is the physiologic reason for her amenorrhea?
C. What are some of the physiologic manifestations associated with malnutrition and severe weight loss?

Chapter 47 Alterations in Nutritional Status

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
Emily Toronto, 7 years old, has been feeling nauseous for the last few days, and her mother states she has been very thirsty and urinating frequently over the last 2 months. Today she has vomited three times and is lethargic. Her mother says her breath smells “fruity,” and she seems slightly confused. Emily’s past medical history is unremarkable, but her grandfather has type 1 diabetes mellitus. She is admitted to the pediatric unit. Arterial blood gas analysis indicates that she is in metabolic acidosis (arterial pH, 7.29; PaCO₂, 42 mm Hg [normal, 35 to 45 mm Hg]). Blood chemistry test results include the following: bicarbonate (HCO₃⁻), 10 mEq/L; glucose, 650 mg/dL; calcium, 10.4 mg/dL; magnesium, 1.1 mg/dL; phosphate, 3.2 mg/dL (normal, 2.7 to 4.5 mg/dL); blood urea nitrogen (BUN), 44 mg/dL; and creatinine, 2.4 mg/dL. Urinalysis reveals the presence of small amounts (1+) of ketones. Her CBC with differential is unremarkable, but her glycosylated hemoglobin level (hemoglobin A1c) is 10% (normal, 4% to 7%). Her vital signs are as follows: temperature, 98.3°F; pulse, 126/minute and normal sinus rhythm; and blood pressure, 118/76 mm Hg. Her respiratory rate is fast (46/minute) and irregular. She is diagnosed with diabetic ketoacidosis and type 1 diabetes mellitus. The pathophysiology of Emily’s disorder is discussed in greater detail in Chapters 48 and 50 (see Appendix A to compare Emily’s blood test results with the normal values).
The endocrine system is involved in all of the integrative aspects of life, including growth, sex differentiation, metabolism, and adaptation to an ever-changing environment. This chapter focuses on the general aspects of endocrine function, organization of the endocrine system, hormone receptors and hormone actions, and regulation of hormone levels.

The endocrine system uses chemical substances called hormones as a means of regulating and integrating body functions. The endocrine system participates in the regulation of digestion and the usage and storage of nutrients, growth and development, electrolyte and water metabolism, and reproductive functions. The endocrine network of organs and mediators does not work in isolation. It is closely integrated with the central and peripheral nervous systems as well as with the immune systems, leading to currently used terminology such as “neuroendocrine” or “neuroendocrine-immune” systems for describing their interactions.

Hormones

Hormones generally are thought of as chemical messengers that are transported in body fluids. They are highly specialized organic molecules produced by endocrine organs that exert their action on specific target cells. Hormones do not initiate
Hormones can be released from the endocrine glands; the brain; and other organs such as the heart, liver, and adipose tissue. Most hormones are present in body fluids at all times, but in greater or lesser amounts depending on the needs of the body.

A characteristic of hormones is that a single hormone can exert various effects in different tissues or, conversely, several different hormones can regulate a single function. For example, the heart is the principal source of atrial natriuretic peptide, which acts to induce natriuresis in a distant target organ—the kidney. Erythropoietin, a traditional circulating hormone, is made in the kidney and stimulates erythropoiesis in the bone marrow. Lipolysis, which is the release of free fatty acids from adipose tissue, is an example of a single function that is regulated by several hormones, including the catecholamines, insulin, and glucagon, but also by the cytokine, tumor necrosis factor-α.

Table 48.1 lists the major actions and sources of body hormones.

### Hormone Effects and Actions

Depending on where the biologic effect of a hormone is elicited in relation to where it is released, the effects can be grouped in one of four ways—endocrine, paracrine, autocrine, or intracrine (Table 48.2). The effect is called endocrine when a hormone released into the circulation and then travels in the bloodstream to produce a biologic effect on distant target cells. Usually, synthesis involves the production of a pre- or prohormone, which is modified by the addition of peptides or sugar units. These precursor hormones often contain extra peptide units that ensure proper folding of the molecule and insertion of essential linkages. If extra amino acids are present, as in insulin, the precursor hormone is called a prohormone. Stimulation of the endocrine cell causes the vesicles to move to the cell membrane and release their hormones. The vesicle-mediated pathway is also used for secretion of a number of nonpolypeptide hormones and neurotransmitters such as the catecholamines (dopamine, epinephrine, and norepinephrine). Hormones synthesized by non–vesicle-mediated pathways include the glucocorticoids, androgens, estrogens, and mineralocorticoids—all steroids derived from cholesterol.

### Structural Classification

Hormones, which have diverse structures ranging from single amino acids to complex proteins and lipids, are divided into three categories:

1. Amines and amino acids
2. Peptides and proteins
3. Steroids (Chart 48.1)

The first category, the amines, includes norepinephrine and epinephrine, which are derived from a single amino acid (i.e., tyrosine), and the thyroid hormones, which are derived from two-iodinated tyrosine amino acid residues. The second category, the peptides and proteins, constitute the majority of hormones and can be as small as thyrotropin-releasing hormone (TRH), which contains three amino acids, and as large and complex as growth hormone (GH), which has approximately 200 amino acids. Glycoproteins are large peptide hormones associated with a carbohydrate (e.g., follicle-stimulating hormone [FSH]). The third category consists of the steroid hormones, which are derivatives of cholesterol.

### Synthesis and Release

The mechanisms for hormone synthesis and release vary with hormone structure, and they are not fully understood. Hormones, such as protein, are synthesized and stored in vesicles in the cytoplasm of the endocrine cell until secretion is required. While others, such as steroids, are secreted upon synthesis. The protein hormones comprise the most prominent class of hormones whose synthesis and release is vesicle mediated. Usually, synthesis involves the production of a precursor hormone, which is modified by the addition of peptides or sugar units. These precursor hormones often contain extra peptide units that ensure proper folding of the molecule and insertion of essential linkages. If extra amino acids are present, as in insulin, the precursor hormone is called a prohormone. Stimulation of the endocrine cell causes the vesicles to move to the cell membrane and release their hormones. The vesicle-mediated pathway is also used for secretion of a number of nonpolypeptide hormones and neurotransmitters such as the catecholamines (dopamine, epinephrine, and norepinephrine).

Hormones synthesized by non–vesicle-mediated pathways include the glucocorticoids, androgens, estrogens, and mineralocorticoids—all steroids derived from cholesterol. These hormones are synthesized in the smooth endoplasmic reticulum, and steroid-secreting cells can be identified by their large amounts of smooth endoplasmic reticulum. Certain steroids serve as precursors for the production of other hormones. In the adrenal cortex, for example, progesterone and other steroid intermediates are enzymatically converted into aldosterone, cortisol, or androgens (see Chapter 41).

### Transport

Hormones that are released into the bloodstream circulate as either free or unbound molecules, or as hormones attached to transport carriers (Fig. 48.1). Peptide hormones and protein hormones usually circulate unbound in the blood.

</table>
Carrier proteins synthesized in the liver carry steroid hormones and thyroid hormone. The extent of carrier binding influences the rate at which hormones leave the blood and enter the cells. The half-life of a hormone—the time it takes for the body to reduce the concentration of the hormone by one half—is positively correlated with its percentage of protein binding. Thyroxine, which is more than 99% protein bound, has a half-life of 6 days. Aldosterone, which is only 15% bound, has a half-life of only 25 minutes. Drugs that compete with a hormone for binding with transport carrier molecules increase hormone action by increasing the availability of the active unbound hormone. For example, aspirin competes with thyroid hormone for binding to transport proteins. When this drug is administered to people with excessive levels of circulating thyroid hormone, such as during thyroid crisis, serious effects may occur due to the dissociation of free hormone from the binding proteins.

**Metabolism and Elimination**

Hormones secreted by endocrine cells must be inactivated continuously to prevent their accumulation. Intracellular and extracellular mechanisms participate in the termination of hormone function. Most peptide hormones and catecholamines are water soluble and circulate freely in the blood. They are usually degraded by enzymes in the blood or tissues and then excreted by the kidneys and liver. In general, peptide hormones also have a short lifespan in the circulation. Their major mechanism of degradation is through binding to

Mechanisms of Action

Hormones produce their effects through interaction with high-affinity receptors, which in turn are linked to one or more effector systems within the cell. These mechanisms involve many of the cell’s metabolic activities, ranging from ion transport at the cell surface to stimulation of nuclear transcription of complex molecules. The rate at which hormones react depends on their mechanism of action. The neurotransmitters, which control the opening of ion channels, have a reaction time of milliseconds. Thyroid hormone, which functions in the control of cell metabolism and synthesis of intracellular signaling molecules, requires days for its full effect to occur.

Receptors. Hormone receptors are complex molecular structures that are located either on the surface or inside target cells. The function of these receptors is to recognize a specific hormone and translate the hormonal signal into a cellular response. The structure of these receptors varies in a manner that allows target cells to respond to one hormone and not to others. For example, receptors in the thyroid are specific for thyroid-stimulating hormone (TSH), and receptors on the gonads respond to the gonadotrophic hormones.

The response of a target cell to a hormone varies with the number of receptors present and with the affinity of these receptors for hormone binding. A variety of factors influence the number of receptors that are present on target cells and their affinity for hormone binding.

There are approximately 2000 to 100,000 hormone receptor molecules per cell. The number of hormone receptors on a cell may be altered for any of several reasons. Antibodies may destroy or block the receptor proteins. Increased or decreased hormone levels often induce changes in the activity of the genes that regulate receptor synthesis. For example, decreased hormone levels often produce an increase in receptor numbers by means of a process called up-regulation. This increases the sensitivity of the body to existing hormone levels. Likewise, sustained levels of excess hormone often bring about a decrease in receptor numbers by down-regulation, producing a decrease in hormone sensitivity. In some instances, the reverse effect occurs, and an increase in hormone levels appears to recruit its own receptors, thereby increasing the sensitivity of the cell to the hormone. The process of up-regulation and down-regulation of receptors is regulated largely by inducing or repressing the expression of receptor genes.

Some hormone receptors are located on the surface of the cell and act through second-messenger mechanisms, and others are located within the cell, where they modulate the synthesis of enzymes, transport proteins, or structural proteins. Chart 48.2 lists examples of hormones that act through the two types of receptors.

Cell-Surface Receptors. Because of their low solubility in the lipid layer of cell membranes, peptide hormones and catecholamines cannot readily cross the cell membrane. Instead, these hormones interact with surface receptors in a manner that incites the generation of an intracellular signal or message. The intracellular signal system is termed the second messenger, and the hormone is considered to be the first messenger. For example, the first messenger glucagon binds to surface receptors on liver cells to incite glycogen breakdown by way of the second-messenger system.

Intracellular Receptors. A second type of receptor mechanism is involved in mediating the action of hormones such as the steroid and thyroid hormones. These hormones are lipid soluble and pass freely through the cell membrane. They then attach to intracellular receptors and form a hormone–receptor complex that travels to the cell nucleus. The hormone–messenger complex binds to hormone response elements (HREs) that then activate or suppress intracellular mechanisms such as gene activity, with the subsequent production or inhibition of messenger RNA (mRNA) and protein synthesis.

Control of Hormone Levels

Hormone secretion varies widely over a 24-hour period. Some hormones, such as GH and adrenocorticotropic hormone (ACTH), have diurnal fluctuations that vary with the sleep–wake cycle. Others, such as the female sex hormones, are secreted in a complicated cyclic manner. The levels of hormones such as insulin and antidiuretic hormone (ADH) are regulated by feedback mechanisms that monitor substances
Understanding Hormone Receptors

Hormones bring about their effects on cell activity by binding to specific cell receptors. There are two general types of receptors: (1) cell-surface receptors that exert their actions through cytoplasmic second-messenger systems and (2) intracellular nuclear receptors that modulate gene expression by binding to DNA or promoters of target genes.

Cell-Surface Receptors

Water-soluble peptide hormones, such as PTH and glucagon, which cannot penetrate the lipid layer of the cell plasma membrane, exert their effects through intracellular second messengers. They bind to a portion of a membrane receptor that protrudes through the surface of the cell. This produces a structural change in the receptor molecule itself, causing activation of a hormone-regulated signal system located on the inner aspect of the cell membrane. This system allows the cell to sense extracellular events and pass this information to the intracellular environment. There are several types of cell-surface receptors, including G-protein–coupled receptors, which mediate the actions of catecholamines, prostaglandins, TSH, and others. Binding of the hormone to the receptor activates a G protein, which in turn acts on an effector such as adenyl cyclase to generate a second messenger such as cyclic adenosine monophosphate (cAMP). The second messenger, in turn, activates other enzymes that participate in cellular secretion, gene activation, or other target cell responses.

Continued
Steroid hormones, vitamin D, thyroid hormones, and other lipid-soluble hormones diffuse across the cell membrane into the cytoplasm of the target cell. Once inside, they bind to an intracellular receptor that is activated by the interaction. The activated hormone–receptor complex then moves to the nucleus, where the hormone binds to an HRE in the promoters on a target gene or to another transcription factor. Attachment to the HRE results in transcription of a specific mRNA. The mRNA then moves into the cytoplasm, where the “transcribed message” is translated and used by cytoplasmic ribosomes to produce new cellular proteins or changes in the production of existing proteins. These proteins promote a specific cellular response or, in some cases, the synthesis of a structural protein that is exported from the cell.

### Hypothalamic–Pituitary Regulation

The hypothalamus and pituitary (i.e., hypophysis) form a unit that exerts control over many functions of several endocrine glands as well as a wide range of other physiologic functions. These two structures are connected by blood flow in the hypophysial portal system, which begins in the hypothalamus and drains into the anterior pituitary gland, and by the nerve axons that connect the supraoptic and paraventricular nuclei of the hypothalamus with the posterior pituitary gland (Fig. 48.2). The pituitary is enclosed in the bony sella turcica and is bridged over by the diaphragma sellae.

### Hypothalamic Hormones

The synthesis and release of anterior pituitary hormones are largely regulated by the action of releasing or inhibiting hormones from the hypothalamus, which is the coordinating center of the brain for endocrine, behavioral, and autonomic nervous system function. It is at the level of the hypothalamus that emotion, pain, body temperature, and other neural input are communicated to the endocrine system (see Fig. 48.4). The posterior pituitary hormones, ADH and oxytocin, are synthesized in the cell bodies of neurons in the hypothalamus that have axons that travel to the posterior pituitary.

The hypothalamic hormones that regulate the secretion of anterior pituitary hormones include GH-releasing hormone (GHRH), somatostatin, dopamine, TRH, corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). With the exception of GH and prolactin,
hypothalamic stimulatory hormones regulate most of the pituitary hormones. GH secretion is stimulated by GHRH; TSH by TRH; ACTH by CRH; and luteinizing hormone (LH) and FSH by GnRH.

The activity of the hypothalamus is regulated by both hormonally mediated signals (e.g., negative feedback signals) and by neuronal input from a number of sources. Neuronal signals are mediated by neurotransmitters such as acetylcholine, dopamine, norepinephrine, serotonin, \( \gamma \)-aminobutyric acid (GABA), and opioids. Cytokines that are involved in immune and inflammatory responses, such as the interleukins, also are involved in the regulation of hypothalamic function. This is particularly true of the hormones involved in the hypothalamic–pituitary–adrenal axis. Thus, the hypothalamus can be viewed as a bridge by which signals from multiple systems are relayed to the pituitary gland (Fig. 48.3).

**Feedback Regulation**

The level of many of the hormones in the body is regulated by negative feedback mechanisms. The function of this type of system is similar to that of the thermostat in a heating system. In the endocrine system, sensors detect a change in the hormone level and adjust hormone secretion so that body levels are maintained within an appropriate range. When the sensors detect a decrease in hormone levels, they initiate changes that cause an increase in hormone production. When hormone levels rise above the set point of the system, the sensors cause hormone production and release to decrease. For example, sensors in the hypothalamus or anterior pituitary gland detect an increase in thyroid hormone, and this causes a reduction in the secretion of TSH, with a subsequent decrease in the output of thyroid hormone from the thyroid gland. The feedback loops for the hypothalamic–pituitary feedback mechanisms are illustrated in Figure 48.4.

Positive feedback control also occurs but is not well understood. In positive feedback control, rising levels of a hormone cause another gland to release a hormone that is stimulating to the first. An example of such a system is that of estrogens for the hypothalamic releasing factors for Luteinizing Hormone-Releasing Hormone (LHRH) and FSH-Releasing Hormone (FSH-RH).
The possibility of error is always present and the quality of any endocrine test is only as good as the quality of the specimen presented for testing. Patient education regarding test preparation, timing, collection procedure, and storage are critical and will be discussed in relation to the specific test.

Several techniques are available for assessing endocrine function and hormone levels. One technique measures the effect of a hormone on body function. Measurement of blood glucose, for example, is an indirect method of assessing insulin availability. The most common method is to measure hormone levels directly.

**Diagnostic Tests**

The field of endocrinology is one of the most laboratory-dependent specialties in health care. However, a few guiding principles should be considered when approaching endocrine studies and disorders. No endocrine test is a substitute for a good physical examination and medical history. The person must be seen as a whole person, which includes many complex factors. One vital component to endocrine testing of any kind is strict adherence to all procedure and test requirements.

The possibility of error is always present and the quality of any endocrine test is only as good as the quality of the specimen presented for testing. Patient education regarding test preparation, timing, collection procedure, and storage are critical and will be discussed in relation to the specific test.

Several techniques are available for assessing endocrine function and hormone levels. One technique measures the effect of a hormone on body function. Measurement of blood glucose, for example, is an indirect method of assessing insulin availability. The most common method is to measure hormone levels directly.

**Blood Tests**

Blood tests for endocrine disorders are vast and encompass a wide variety of strategies to assess endocrine function. Hormones can be measured directly or, very commonly, as physiologic indicators of hormone function. Blood hormone
levels provide information about hormone levels at a specific time. For example, blood insulin levels can be measured along with blood glucose after administration of a challenge dose of glucose to measure the time course of change in blood insulin levels. More detailed descriptions of specific testing will be discussed related to the endocrine system being evaluated.

Emily, the young girl who was introduced at the beginning of this unit, presented with a blood glucose of 650 mg/dL, which is far above normal blood glucose levels (70 to 110 mg/dL). Her glycated hemoglobin test (hemoglobin A1c) was also very high at 10% when the normal range for people with diabetes is 6% to 7%.

Plasma hormone levels in plasma are measured using radioimmunoassay (RIA) methods based on the competitive binding of hormones. This method uses a radiolabeled form of the hormone and a hormone antibody that has been prepared by a purified form of the hormone. The unlabeled hormone in the sample being tested competes with the radiolabeled hormone for attachment to the binding sites of the antibody. Measurement of the radiolabeled hormone–antibody complex then provides a means of arriving at a measure of the hormone level in the sample. Because hormone binding is competitive, the amount of radiolabeled hormone–antibody complex that is formed decreases as the amount of unlabeled hormone in the sample is increased. The limitations of RIA include a lack of specificity due to cross-reactivity with more than one hormone along with limited shelf life of the radiolabeled hormone and the cost for the disposal of radioactive waste. Newer techniques of RIA have been introduced, including the immuno-radiometric assay (IRMA). IRMA uses the same principle of antibody recognition with two antibodies instead of one. These two antibodies are directed against two different parts of the molecule, and therefore IRMA assays are more specific. Other blood tests that are routinely measured in endocrine disorders include various autoantibodies. For example, anti-thyroid peroxidase (anti-TPO) antibodies are measured during the initial diagnostic work-up and subsequent follow-up of patients with Hashimoto thyroiditis. Other endocrine disorders that use autoantibody testing include type 1 diabetes, Graves disease, autoimmune hypoparathyroidism, and autoimmune Addison disease.

**Urine Tests**

Measurements of urinary hormone or hormone metabolite excretion often are done on a 24-hour urine sample and provide a better measure of hormone levels during that period compared to hormones measured in an isolated blood sample. The advantages of a urine test include the relative ease of obtaining urine samples and the fact that blood sampling is not required. The disadvantage is that reliably timed urine samples are not always practical.
collections often are difficult to obtain and rely on adequate renal function. For example, a person may be unable to urinate at specific timed intervals, and urine samples may be accidentally discarded or inaccurately preserved. Because many urine tests involve the measurement of a hormone metabolite rather than the hormone itself, drugs or disease states that alter hormone metabolism may interfere with the test result. Urine testing for hormones or metabolites underscores the need for a complete health history including medication use and specific adherence to test procedures.

**Stimulation and Suppression Tests**

Stimulation tests are used when hypofunction of an endocrine organ is suspected. A tropic or stimulating hormone can be administered to test the capacity of an endocrine organ to increase hormone production. The capacity of the target gland to respond is measured by an increase in the appropriate hormone. For example, the function of the hypothalamic–pituitary–thyroid system can be evaluated through stimulation tests using TRH and measuring TSH response. Failure to increase TSH levels after a TRH stimulation test suggests an inadequate capacity to produce TSH by the pituitary (i.e., the pituitary is dysfunctional in some way).

Suppression tests are used when hyperfunction of an endocrine organ is suspected. When an organ or tissue is functioning autonomously (i.e., it is not responding to the normal negative feedback control mechanisms and continues to secrete excessive amounts of hormone), a suppression test may be useful to confirm the situation. For example, when a GH-secreting tumor is suspected, the GH response to a glucose load is measured as part of the diagnostic work-up. Normally, a glucose load would suppress GH levels. However, in adults with GH-secreting tumors (a condition known as acromegaly), GH levels are not suppressed (and paradoxically increase in 50% of cases).

**Genetic Tests**

The diagnosis of genetic diseases using deoxyribonucleic acid (DNA) analysis is rapidly becoming a routine part of endocrine practice. Completion of the human genome sequence has revealed the presence of about 23,000 genes. Advances in proteomics (i.e., examination of the proteome, which is all of the proteins expressed by a cell or tissue type) have complemented the considerable interest in the field of genomics (i.e., examination of the DNA) and transcriptomics (i.e., examination of the mRNA). It is proposed that compared with the size of the genome, the proteome is far larger, with several hundred thousand to several million different protein forms possible. Analysis of the proteins produced by normal and abnormal endocrine cells, tissues, and organs will lead to a better understanding of the pathophysiologic processes of endocrine conditions. This may also lead to selective targeting for new drug development.

As the incidence of certain endocrine conditions, such as type 2 diabetes (DM2), have had such unprecedented growth, genetic discoveries in this field may lend critical support to treatment and prevention. Genetic studies of interrelated conditions such as DM2, metabolic syndrome, and obesity provide a complex study of genes in relation to race, ethnicity, socioeconomic conditions, and the evolution of mankind. Advances in genetic testing to evaluate the risk for, existence of, or treatment of endocrine disease is likely to expand greatly as the genetic factors of endocrine function are explored.

**Imaging**

Imaging studies are important in the diagnosis and follow-up of endocrine disorders. Imaging modalities related to endocrinology can be divided into isotopic and nonisotopic types. Isotopic imaging includes radioactive scanning of the thyroid (e.g., using radioiodine), parathyroids (e.g., using sestamibi), and adrenals. Nonisotopic imaging includes magnetic resonance imaging (MRI), which is the preferred choice for pituitary and hypothalamic imaging, and computed tomography (CT) scanning, which is preferred for adrenal lesions and abdominal endocrine lesions. Ultrasonographic scanning provides excellent and reproducible anatomic images for the thyroid, parathyroids, and neighboring structures. However, this is not considered definitive. Thyroid ultrasonography is recommended for managing thyroid nodules and can aid in visualization of the nodule for biopsy (fine-needle aspiration), which is necessary to help distinguish benign from malignant etiology. Dual-electron x-ray absorptiometry (DEXA) is used routinely for the diagnosis and monitoring of osteoporosis and metabolic bone diseases. Positron emission tomography (PET) scanning is being used more widely for evaluation of endocrine tumors. This PET scanning has expanded to PET/CT imaging in which both types of images are acquired almost simultaneously for enhanced detail and identification of previously difficult structures.

**IN SUMMARY**

The endocrine system acts as a communication system that uses chemical messengers, or hormones, for the transmission of information from cell to cell and from organ to organ. Hormones act by binding to receptors that are specific for the different types of hormones. Many of the endocrine glands are under the regulatory control of other parts of the endocrine system. The hypothalamus and the pituitary gland form a complex integrative network that joins the nervous system and the endocrine system; this central network controls the output from many of the other glands in the body.

Endocrine function can be assessed directly by measuring hormone levels or indirectly by assessing the effects that a hormone has on the body (e.g., assessment of insulin function through blood glucose). Imaging techniques are increasingly used to visualize endocrine structures, and genetic techniques are used to determine the presence of genes that contribute to the development of endocrine disorders.
Like many physiologic systems, the endocrine system is regulated by feedback mechanisms that enable the endocrine cells to change their rate of hormone secretion. Feedback can be negative or positive and may involve complex feedback loops involving hypothalamic–pituitary regulation.

**Negative Feedback**

With negative feedback, the most common mechanism of hormone control, some feature of hormone action directly or indirectly inhibits further hormone secretion so that the hormone level returns to an ideal level or set point. In the simple negative feedback loop, the amount of hormone or its effect on a physiologic mechanism regulates the response of the endocrine gland. After a meal, for example, a rise in blood glucose stimulates the pancreas to secrete insulin; insulin acts on target cells to take up the glucose, thus lowering blood glucose. The lowered glucose levels, in turn, suppress insulin release, causing blood glucose to rise.

**Hypothalamic–Pituitary Target Cell Feedback**

Hormones of the thyroid, adrenal cortex, and the gonads are regulated by more complex loops involving the hypothalamus and anterior pituitary gland. The hypothalamus produces a releasing hormone that stimulates the production of a tropic hormone by the anterior pituitary. The tropic hormone then stimulates the peripheral target gland to secrete its hormone, which acts on target cells to produce a physiologic response. A rise in blood levels of the target gland hormone also feeds back to the hypothalamus and anterior pituitary gland, resulting in a decrease in tropic hormone secretion and a subsequent reduction in hormone secretion by the target gland. As a result, blood levels of the hormone vary only within a narrow range.

*Continued*
REVIEW EXERCISES

1. Thyroid hormones are transported in the serum bound to transport proteins such as thyroid-binding globulin and albumin.
   A. Explain why free thyroxine (T₄) levels are usually used to assess thyroid function rather than total T₄ levels.

2. People who are being treated with exogenous forms of corticosteroid hormones often experience diminished levels of ACTH and exogenously produced cortisol.
   A. Explain, using information regarding the hypothalamic–pituitary feedback control of cortisol production by the adrenal cortex.

Positive Feedback

A small number of hormones are regulated by positive feedback. In this type of regulation, a hormone stimulates continued secretion until appropriate levels are reached. An example of positive feedback is the preovulatory surge in LH levels that trigger ovulation. At that time, an increase in estrogen levels exerts a positive feedback effect on the anterior pituitary secretion of LH.

The endocrine system affects all aspects of body function, including growth and development, energy metabolism, muscle and adipose tissue distribution, sexual development, fluid and electrolyte balance, and inflammation and immune responses. This chapter focuses on disorders of pituitary function, growth and growth hormone, thyroid function, and adrenal cortical function.

**GENERAL ASPECTS OF ALTERED ENDOCRINE FUNCTION**

- Hypofunction and Hyperfunction
- Primary, Secondary, and Tertiary Disorders

**PITUITARY AND GROWTH DISORDERS**

- Assessment of Hypothalamic–Pituitary Function
- Pituitary Tumors
- Hypopituitarism
- Growth and Growth Hormone Disorders
  - Growth Hormone
  - Growth Hormone Deficiency in Children
  - Growth Hormone Deficiency in Adults
  - Tall Stature in Children
  - Growth Hormone Excess in Children
  - Growth Hormone Excess in Adults
- Isosexual Precocious Puberty

**THYROID DISORDERS**

- Control of Thyroid Function
  - Actions of Thyroid Hormone
  - Tests of Thyroid Function
  - Alterations in Thyroid Function

**Hypothyroidism**

- Congenital Hypothyroidism
- Acquired Hypothyroidism and Myxedema
- Myxedematous Coma

**Hyperthyroidism**

- Etiology and Pathogenesis
- Clinical Manifestations
- Graves Disease
- Thyroid Storm

**DISORDERS OF ADRENAL CORTICAL FUNCTION**

- Control of Adrenal Cortical Function
  - Biosynthesis, Transport, and Metabolism
  - Adrenal Androgens
  - Mineralocorticoids
  - Glucocorticoids
  - Pharmacologic Suppression of Adrenal Function
  - Tests of Adrenal Function

**Congenital Adrenal Hyperplasia**

- Adrenal Cortical Insufficiency
  - Primary Adrenal Cortical Insufficiency
  - Secondary Adrenal Cortical Insufficiency
  - Acute Adrenal Crisis

**Glucocorticoid Hormone Excess (Cushing Syndrome)**

- Clinical Manifestations
- Diagnosis and Treatment
- Incidental Adrenal Mass

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the mechanisms of endocrine hypofunction and hyperfunction.
- Differentiate among primary, secondary, and tertiary endocrine disorders.
Hypofunction and Hyperfunction

Disturbances of endocrine function can usually be divided into two categories—hypofunction and hyperfunction. Hypofunction of an endocrine gland can occur for a variety of reasons such as with the absence or impaired development of a gland or due to a deficiency or lack of an enzyme that is needed for hormone synthesis. The gland may be destroyed by a disruption in blood flow, infection, inflammation, autoimmune responses, or neoplastic growth. There may be a decline in function with aging, or the gland may atrophy as a result of drug therapy or for unknown reasons. Some endocrine-deficient states are associated with receptor defects. Hormone receptors may be absent, the receptor binding of hormones may be defective, or the cellular responsiveness to the hormone may be impaired. It is suspected that in some cases a gland may produce a biologically inactive hormone or that circulating antibodies may destroy an active hormone before it can exert its action.

Hyperfunction usually is associated with excessive hormone production. This can result from excessive stimulation and hyperplasia of the endocrine gland or from a hormone-producing tumor. A tumor can produce hormones that are not normally secreted by the tissue from which the tumor is derived (ectopic hormone production). For example, certain bronchogenic tumors and other carcinomas produce hormones such as antidiuretic hormone (ADH) and adrenocorticotropic hormone (ACTH). A clinical example of this phenomenon is evidenced in the case of a woman with vaginal small cell carcinoma who also presented with Cushing syndrome. After testing, it was determined that the tumor was secreting ACTH.

Primary, Secondary, and Tertiary Disorders

Endocrine disorders in general can be divided into primary, secondary, and tertiary groups. Primary defects in endocrine function originate in the target gland responsible for producing the hormone. In secondary disorders of endocrine function, the target gland is essentially normal, but defective levels of stimulating hormones or releasing factors from the pituitary system alter its function. For example, total thyroidectomy produces a primary deficiency of thyroid hormones. Removal or destruction of the pituitary gland eliminates ACTH stimulation of the adrenal cortex and brings about a secondary deficiency. A tertiary disorder results from hypothalamic dysfunction (as may occur with craniohypophysealomas or cerebral irradiation). Thus, both the pituitary and target organ are understimulated.

IN SUMMARY

Endocrine disorders are the result of hypofunction or hyperfunction of an endocrine gland. They can occur as a primary defect in hormone production by a target gland or as a secondary or tertiary disorder resulting from a defect in the hypothalamic–pituitary system that controls a target gland’s function.

PITUITARY AND GROWTH DISORDERS

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the clinical features and causes of hypopituitarism.
- Analyze the effects of a deficiency in growth hormone.
- Relate the functions of growth hormone to the manifestations of acromegaly and adult-onset growth hormone deficiency.

The pituitary gland, or hypophysis, is a pea-sized gland located at the base of the brain, where it lies in a saddle-shaped depression in the sphenoid bone called the sella turcica. A short funnel-shaped stalk, the infundibulum, connects the pituitary gland with the hypothalamus. The pituitary gland has two components—a posterior lobe (neurohypophysis) and an anterior lobe (adenohypophysis) or glandular component.

The anterior lobe of the pituitary gland produces ACTH, thyroid-stimulating hormone (TSH), growth hormone (GH), the gonadotrophic hormones (follicle stimulating hormone [FSH] and luteinizing hormone [LH]), and prolactin. Four of these, ACTH, TSH, LH, and FSH, control the secretion of hormones from other endocrine glands:

- ACTH controls the release of cortisol from the adrenal gland.
- TSH controls the secretion of thyroid hormone from the thyroid gland.
- LH regulates sex hormones.
- FSH regulates fertility.

Assessment of Hypothalamic–Pituitary Function

The assessment of hypothalamic–pituitary function has been made possible by many newly developed imaging and radioimmunoassay methods. Assessment of the baseline status of the hypothalamic–pituitary target cell hormones involves measuring the following (ideally the laboratory specimens are obtained before 8:00 AM):

- Serum cortisol
- Serum prolactin
- Serum thyroxine and TSH
- Serum testosterone (male)/serum estrogen (female) and serum LH/FSH
- Serum GH/insulin-like growth factor-1 (IGF)
- Plasma osmolality and urine osmolality

Imaging studies (e.g., magnetic resonance imaging [MRI]) of the hypothalamus/pituitary should also be performed...
as required. When further information regarding pituitary function is required, combined hypothalamic–pituitary function tests are undertaken. These tests consist mainly of hormone stimulation tests (e.g., rapid ACTH stimulation test) or suppression tests (e.g., GH suppression test).

It is often important to test pituitary function, especially if pituitary adenomas are discovered and surgery or radiation treatment is being considered. Diagnostic methods include both static and dynamic testing, and radiologic assessment as required. Any of the systems discussed previously may be affected by either deficiency or excess of the usual hormones secreted.

**Pituitary Tumors**

Pituitary tumors can be divided into primary or secondary tumors (i.e., metastatic lesions). Tumors of the pituitary can be further divided into functional tumors that secrete pituitary hormones and nonfunctional tumors that do not secrete hormones. They can range in size from small lesions that do not enlarge the gland (microadenomas, <10 mm) to large, expansive tumors (macroadenomas, >10 mm) that erode the sella turcica and impinge on surrounding cranial structures. Small, non-functioning tumors are found in up to 20% of adult autopsies. Benign adenomas account for most of the functioning anterior pituitary tumors. Carcinomas of the pituitary are less common tumors. Functional adenomas can be subdivided according to cell type and the type of hormone secreted (Table 49.1).

**Hypopituitarism**

Hypopituitarism, which is characterized by a decreased secretion of pituitary hormones, is a condition that affects many of the other endocrine systems. The cause may be congenital or may result from a variety of acquired abnormalities (Chart 49.1). Hypopituitarism is associated with increased morbidity and mortality.

| TABLE 49.1 FREQUENCY OF ADENOMAS OF THE ANTERIOR PITUITARY |
|-----------------|------------------|-----------|
| CELL TYPE       | HORMONE          | FREQUENCY (%) |
| Lactotrope      | Prolactin (PRL)  | 32        |
| Somatotrope     | Growth hormone (GH) | 21      |
| Lactotrope/somatotrope | Mixed PRL/GH | 6         |
| Corticotrope    | Adrenocorticotropic hormone (ACTH) | 13     |
| Gonadotrope     | Follicle-stimulating hormone (FSH) | <4     |
| Thyrotrope      | Thyroid-stimulating hormone (TSH) |       |
| Nonfunctional tumors |                     | 25       |

Typically, 70% to 90% of the anterior pituitary must be destroyed before hypopituitarism becomes clinically evident. The clinical manifestations of hypopituitarism usually occur gradually, but it can present as an acute and life-threatening condition. People usually complain of being chronically unwell, with weakness, fatigue, loss of appetite, impairment of sexual function, and cold intolerance. However, ACTH deficiency (secondary adrenal insufficiency) is the most serious endocrine deficiency, leading to weakness, nausea, anorexia, fever, and postural hypotension.

Anterior pituitary hormone loss tends to follow a typical sequence, especially with progressive loss of pituitary reserve due to tumors or previous pituitary radiation therapy. The sequence of loss of pituitary hormones can be remembered by the mnemonic “Go Look For The Adenoma:”

- GH (GH secretion typically is first to be lost).
- LH (results in sex hormone deficiency).
- FSH (causes infertility).
- TSH (leads to secondary hypothyroidism).
- ACTH (usually the last to become deficient, results in secondary adrenal insufficiency).

Treatment of hypopituitarism includes treating any identified underlying cause. Hormone deficiencies should be treated as dictated by baseline hormone levels, and more sophisticated pituitary testing where appropriate. Cortisol replacement is started when ACTH deficiency is present; thyroid replacement when TSH deficiency is detected; and sex hormone replacement when LH and FSH are deficient. GH replacement is indicated for pediatric GH deficiency, and is increasingly being used to treat GH deficiency in adults.
Growth and Growth Hormone Disorders

Several hormones are essential for normal body growth and maturation, including GH, insulin, thyroid hormone, and androgens. In addition to its actions on carbohydrate and fat metabolism, insulin plays an essential role in growth processes. Children with diabetes, particularly those who have difficulty with balancing blood sugar, often fail to grow normally even though GH levels are normal. When levels of thyroid hormone are lower than normal, bone growth and epiphyseal closure are delayed. Androgens such as testosterone and dihydrotestosterone exert anabolic growth effects through their actions on protein synthesis. Glucocorticoids at excessive levels inhibit growth, apparently because of their antagonistic effect on GH secretion.

Growth Hormone

Growth hormone (GH), also called somatotropin, is a 191-amino-acid polypeptide hormone synthesized and secreted by special cells in the anterior pituitary called somatotropes. It has been a common belief that GH was produced primarily during periods of growth. However, this has proved incorrect since the rate of GH production in adults is almost as great as it is in children. GH is necessary for growth and contributes to the regulation of metabolic functions (Fig. 49.1). GH stimulates all aspects of cartilage growth. One of the most obvious effects of GH is on linear bone growth, resulting from its action on the epiphyseal growth plates of long bones. The width of bone increases because of enhanced periosteal growth. Visceral and endocrine organs, skeletal and cardiac muscle, skin, and connective tissue all undergo increased growth in response to GH.

Additionally, GH facilitates the rate of protein synthesis in the body. It enhances fatty acid mobilization and increases the use of fatty acids for fuel and maintains or increases blood glucose levels by decreasing the use of glucose for fuel. GH has an initial effect of increasing insulin levels. However, the predominant effect of prolonged GH excess is to increase glucose levels despite an insulin increase. This is because GH induces a resistance to insulin in the peripheral tissues, inhibiting the uptake of glucose by muscle and adipose tissues.

Many of the effects of GH depend on insulin-like growth factors (IGFs), also called somatomedins, which are produced mainly by the liver. GH cannot directly cause bone growth. Instead, it acts indirectly by causing the liver to produce IGF. These IGF peptides act on cartilage and bone to promote their growth. At least four IGFs have been identified. Of these, IGF-1 (somatomedin C) appears to be the more important in terms of growth. It is also the most frequently measured IGF in laboratory tests. The IGFs have been sequenced and have structures similar to those of proinsulin. This explains the
insulin-like activity of the IGFs and the weak action of insulin on growth. IGF levels are themselves influenced by a family of six binding factors called IGF-binding proteins (IGFBPs). GH is carried unbound in the plasma and has a half-life of approximately 20 to 50 minutes. Two hypothalamic hormones regulate the secretion of GH:

- GH-releasing hormone (GHRH), which increases GH release.
- Somatostatin, which inhibits GH release.

A third hormone, the recently identified ghrelin, also has an important role, which is to increase our appetite by stimulating the hypothalamus and also increase lipid accumulation in visceral fatty tissue in the abdomen.

Neural, metabolic, and hormonal factors tightly regulate these hypothalamic influences (i.e., GHRH and somatostatin). For example, a study conducted on obese people found decreased levels of ghrelin since it was absorbed in the adipose tissue of the abdomen and not measurable in the serum. Therefore, increased morbidity and mortality were observed for these obese people. The two most common comorbidities that obese people had were hypertension and type 2 diabetes mellitus.

The secretion of GH fluctuates over a 24-hour period, with peak levels occurring 1 to 4 hours after onset of sleep (i.e., during sleep stages 3 and 4). GH secretion is stimulated by hypoglycemia, fasting, starvation, increased blood levels of amino acids (particularly arginine), and stress conditions such as trauma, excitement, emotional stress, and heavy exercise. GH is inhibited by increased glucose levels, free fatty acid release, cortisol, and obesity.

### Key Points

#### Growth Hormone

- Growth hormone (GH), which is produced by somatotropes in the anterior pituitary, is necessary for linear bone growth in children. It also increases the rate at which cells transport amino acids across their cell membranes, and it increases the rate at which they utilize fatty acids and decreases the rate at which they use carbohydrates.
- The effects of GH on linear growth manifest with IGFs, which are produced mainly by the liver.

#### Short Stature in Children

Short stature is a condition in which the attained height is well below the third percentile or linear growth is below normal for age and sex. Short stature, or growth retardation, has a variety of causes, including chromosomal abnormalities such as Turner syndrome, GH deficiency, hypothyroidism, and panhypopituitarism (i.e., deficiency of all pituitary-derived hormones). Other conditions known to cause short stature include protein–calorie malnutrition, chronic diseases such as chronic kidney disease and poorly controlled diabetes mellitus, malabsorption syndromes, and certain therapies such as excessive glucocorticoid administration. Emotional disturbances can lead to functional endocrine disorders, causing psychosocial dwarfism. The causes of short stature are summarized in Chart 49.2.

Accurate measurement of height is an important part of the physical examination of children. Completion of the developmental history and growth charts is essential. Growth curves and growth velocity studies are also needed. Diagnosis of short stature is not made on a single measurement, but is based on sequential height measurements and on velocity of growth and parental height.
The diagnostic procedures for short stature include tests to exclude nonendocrine causes. If the cause is hormonal, extensive hormonal testing procedures are initiated. Usually, GH and IGF-1 levels are determined. Tests can be performed using insulin (to induce hypoglycemia), GHRH, levodopa, and arginine, all of which stimulate GH secretion so that GH reserve can be evaluated. Because administration of pharmacologic agents can result in false-negative responses, two or more tests are usually performed to ensure accuracy. If a prompt rise in GH is realized, the child is considered normal. Physiologic tests of GH reserve (e.g., GH response to exercise) can also be performed. Levels of IGF-1 usually reflect those of GH and may be used to indicate GH deficiency. Radiologic films are used to assess bone age, which most often is delayed. MRI of the hypothalamic–pituitary area is recommended if a lesion is clinically suspected.

After the cause of short stature has been determined, treatment can be initiated. *Catch-up growth* is a term used to describe an abnormally high growth rate that occurs as a child approaches normal height for age. It occurs after the initiation of therapy for GH deficiency and hypothyroidism and the correction of chronic diseases.

**Genetic and Constitutional Short Stature.** Two forms of short stature, genetic short stature and constitutional short stature, are not disease states but variations from population norms. Genetically short children tend to be well proportioned and to have a height close to the midparental height of their parents. Ninety-five percent of normal children are within 8 cm (i.e., ±2 standard deviations) of the midparental height.

Constitutional short stature is a term used to describe children (particularly boys) who have moderately short stature, thin build, delayed skeletal and sexual maturation, and absence of other causes of decreased growth.

**Psychosocial Dwarfism.** Psychosocial dwarfism involves a functional hypopituitarism and is seen in some emotionally deprived children. These children usually present with poor growth, potbelly, and poor eating and drinking habits. Typically, there is a history of disturbed family relationships in which the child has been severely neglected or disciplined. Often, the neglect is confined to one child in the family. GH function usually returns to normal after the child is removed from the constraining environment. The prognosis depends on improvement in behavior and catch-up growth.

**Growth Hormone Deficiency in Children**

There are several forms of GH deficiency that present in childhood. Children with idiopathic GH deficiency lack the hypothalamic GHRH but have adequate somatotropes, whereas children with pituitary tumors or agenesis of the pituitary lack somatotropes. The term panhypopituitarism refers to conditions that cause a deficiency of all of the anterior pituitary hormones. In a rare condition called Laron-type dwarfism, GH levels are normal or elevated, but there is a hereditary defect in IGF production that can be treated directly with IGF-1 replacement.

Congenital GH deficiency is associated with decreased birth length, followed by a decrease in growth rate that can be identified by careful measurement during the first year and that becomes obvious by 1 to 2 years of age. Persons with classic GH deficiency have normal intelligence, short stature, obesity with immature facial features, and some delay in skeletal maturation. Puberty is often delayed, and males with the disorder may have microphallus (abnormally small penis), especially if the condition is accompanied by gonadotropin-releasing hormone (GnRH) deficiency. In the neonate, GH deficiency can lead to hypoglycemia and seizures. If ACTH deficiency also is present, the hypoglycemia often is more severe. Acquired GH deficiency develops in later childhood. It may be caused by a hypothalamic–pituitary tumor, particularly if it is accompanied by other pituitary hormone deficiencies.

When short stature is caused by a GH deficiency, GH replacement therapy is the treatment of choice. GH is species specific, and only human GH is effective in humans. GH was previously obtained from human cadaver pituitaries, but is now produced by recombinant DNA technology and is available in adequate supply. GH is administered by daily subcutaneous injection during the period of active growth, and can be continued into adulthood.

Children with short stature due to Turner syndrome and chronic renal insufficiency are also treated with GH. GH therapy may be considered for children with short stature but without GH deficiency. Evidence suggests that short-term treatment with GH increases the rate of growth in these children. Although the effect of GH on adult height is not great, it can result in improved psychological well-being. There are concerns about misuse of the drug to produce additional growth in children with normal GH function who are of near-normal height. Guidelines for use of the hormone continue to be established.

**Growth Hormone Deficiency in Adults**

There are two categories of GH deficiency in adults:

1. GH deficiency that was present in childhood.
2. GH deficiency that developed during adulthood, mainly as the result of hypopituitarism resulting from a pituitary tumor or its treatment.

Growth hormone (GH) levels can also decline with aging, and there has been interest in the effects of declining GH levels in the elderly (described as somatopause). GH replacement is obviously important in the growing child. However, the role in adults (especially for somatopause) is being assessed. Some of the differences between childhood and adult-onset GH deficiency are described in Table 49.2.

Evidence shows that cardiovascular mortality increases in GH-deficient adults. A higher prevalence of atherosclerotic plaques and endothelial dysfunction has been reported in both childhood and adult GH deficiency. The GH deficiency syndrome is associated with a cluster of cardiovascular risk
Tall Stature in Children

Just as there are children who are short for their age and sex, there are also children who are tall for their age and sex. Height that is greater than the 95th percentile is considered tall stature. Normal variants of tall stature include genetic tall stature and constitutional tall stature. Children with exceptionally tall parents tend to be taller than children with shorter parents. The term constitutional tall stature is used to describe a child who is taller than his or her peers and is growing at a velocity that is within the normal range for bone age. Other causes of tall stature are genetic or chromosomal disorders such as Marfan syndrome or XYY syndrome.

Exceptionally tall children (i.e., genetic tall stature and constitutional tall stature) can be treated with sex hormones—estrogens in girls and testosterone in boys—to effect early epiphyseal closure. Such treatment is undertaken only after full consideration of the risks involved. To be effective, such treatment must be instituted 3 to 4 years before expected epiphyseal fusion.

**Growth Hormone Excess in Children**

Growth hormone (GH) excess occurring before puberty and the fusion of the epiphyses of the long bones results in gigantism. Excessive secretion of GH by somatotrope adenomas causes gigantism in the prepubertal child. It occurs when the epiphyses are not fused and high levels of IGF-1 stimulate excessive skeletal growth. Fortunately, the condition is rare because of early recognition and treatment of the adenoma.

**Growth Hormone Excess in Adults**

When GH excess occurs in adulthood or after the epiphyses of the long bones have fused, the condition is referred to as acromegaly. The annual incidence of acromegaly is 3 to 4 cases per 1 million people, with a mean age of 40 to 45 years at the time of diagnosis.

**Etiology and Pathogenesis.** Acromegaly results from excess levels of GH that stimulate the hepatic secretion of IGF-1, which causes most of the clinical manifestations of acromegaly. The most common cause (95%) of acromegaly is a somatotrope adenoma. Approximately 75% of persons with acromegaly have a somatotrope macroadenoma at the time of diagnosis, and most of the remainder have microadenomas. The other causes of acromegaly (<5%) are excess secretion of GHRH by hypothalamic tumors, ectopic GHRH secretion by nonendocrine tumors such as carcinoid tumors or small cell lung cancers, and ectopic secretion of GH by nonendocrine tumors.

**Clinical Manifestations.** The disorder usually has an insidious onset, and symptoms are often present for a considerable period before a diagnosis is made. When the production of excessive GH occurs after the epiphyses of the long bones have closed, as in the adult, the person cannot grow taller, but the soft tissues continue to grow. Enlargement of the small bones of the hands and feet and of the membranous bones of the face and skull results in a pronounced enlargement of the hands and feet, a broad and bulbous nose, a protruding lower jaw, and a slanting forehead (Fig. 49.2). The teeth become splayed, causing a disturbed bite and difficulty in chewing.

factors, including central adiposity (associated with increased visceral fat), insulin resistance, and dyslipidemia. These features are also associated with the metabolic syndrome. In addition to these so-called traditional cardiovascular risk factors, nontraditional cardiovascular risk factors (e.g., elevated high-sensitivity C-reactive protein [hsCRP], which is a marker of the inflammatory pathway) tend to be present. GH therapy can limit the potential impact of many of these risk factors.

The diagnosis of GH deficiency in adults is made by finding subnormal serum GH responses to provocative stimuli. A low IGF-1 level in the presence of known pituitary disease may also indicate GH deficiency. Measurements of the basal GH levels do not distinguish reliably between normal and subnormal GH secretion in adults. Insulin-induced hypoglycemia is the gold standard test for GH reserve. The arginine plus GHRH test is probably the next best test. Other stimulation tests involve the use of arginine, l-dopa, clonidine (an α-adrenergic agonist), glucagon, or GHRH alone.

GH replacement therapy may lead to increased lean body mass and decreased fat mass, increased bone mineral density, increased glomerular filtration rate, decreased lipid levels, increased exercise capacity, and improved sense of well-being in GH-deficient adults. The most common side effects of GH treatment in adults with hypopituitarism are peripheral edema, arthralgias and myalgias, carpal tunnel syndrome, paresthesias, and decreased glucose tolerance. Side effects appear to be more common in people who are older, heavier, and are overtreated, as judged by a high serum IGF-1 concentration during therapy.

1 NL, normal.
UNIT XII Disorders of Endocrine Function

on carbohydrate metabolism, including decreased glucose uptake by tissues such as skeletal muscle and adipose tissue, increased glucose production by the liver, and increased insulin secretion. Each of these changes results in GH-induced insulin resistance. This leads to glucose intolerance, which stimulates the beta cells of the pancreas to produce additional insulin. Long-term elevation of GH results in overstimulation of the beta cells, causing them literally to “burn out.” Impaired glucose tolerance occurs in as much as 50% to 70% of people with acromegaly. Overt diabetes mellitus can result subsequently.\(^2,14\)

The pituitary gland is located in the pituitary fossa of the sphenoid bone (i.e., sella turcica), which lies directly below the optic nerve. Enlargement of the pituitary gland eventually causes erosion of the surrounding bone, and because of its location, this can lead to headaches, visual field defects resulting from compression of the optic nerve (classically, bitemporal hemianopia), and palsies of cranial nerves III, IV, and VI. Compression of other pituitary structures can cause secondary hypothyroidism, hypogonadism, and adrenal insufficiency. Hypogonadism can result from direct damage to the hypothalamic or pituitary system or indirectly because of hyperprolactinemia due to prevention of the prolactin inhibitory factor (dopamine) from reaching pituitary lactotropes (cells that secrete prolactin) because of damage by the pituitary tumor.\(^2\)

Other manifestations include excessive sweating with an unpleasant odor, oily skin, heat intolerance, moderate weight gain, muscle weakness and fatigue, menstrual irregularities, and decreased libido. Hypertension is relatively common. Sleep apnea syndrome is present in up to 90% of people. The pathogenesis of sleep apnea syndrome is obstructive in the majority of people due to increased pharyngeal soft tissue accumulation. Paresthesias may develop because of nerve entrapment and compression caused by excess soft tissue and accumulation of subcutaneous fluid (especially carpal tunnel syndrome). Acromegaly is also associated with an increased risk of colonic polyps and colorectal cancer. The mortality rate of people with acromegaly is two to three times the expected rate, mostly from cardiovascular diseases and cancer. The cardiovascular disease results from the combination of cardiomyopathy, hypertension, insulin resistance and hyperinsulinemia, and hyperlipidemia.\(^14\)

**Diagnosis.** Acromegaly often develops insidiously, and only a small number of people seek medical care because of changes in appearance. The diagnosis of acromegaly is facilitated by the typical features of the disorder—enlargement of the hands and feet and coarsening of facial features.\(^3\) Laboratory tests to detect elevated levels of GH not suppressed by a glucose load are used to confirm the diagnosis. MRI scans can detect and localize the pituitary lesions. Because most of the effects of GH are mediated by IGF-1, IGF-1 levels may provide information about disease activity.

**Treatment.** Treatment for acromegaly focuses on the correction of metabolic abnormalities; normalization of IGF-1...
levels to age- and sex-matched control levels; removal or reduction of the tumor mass; relieving the central pressure effects; and improvement of adverse clinical features.2 Pituitary tumors can be removed surgically using the transsphenoidal approach. Medical therapy is usually given in an adjunctive role.2 Somatostatin analogs produce feedback inhibition of GH, and are effective in the medical management of acromegaly.14 Dopamine agonists reduce GH levels and have been used in the medical management of acromegaly. GH receptor antagonists are analogs of human GH that have been structurally altered. GH receptor antagonists bind to GH receptors on the cell surfaces, where they block the binding of endogenous GH and thus interfere with GH signal transduction.

**Isosexual Precocious Puberty**

Isosexual precocious puberty is defined as early activation of the hypothalamic–pituitary–gonadal axis, resulting in the development of appropriate sexual characteristics and fertility.2,16 Precocious puberty is now defined as the appearance of secondary sexual development before the age of 7 years in white girls and 6 years in African American girls.2 In boys of both races, the lower age limit remains 9 years. However, it is recognized that puberty can develop earlier in boys with obesity.2 Precocious sexual development may be idiopathic or may be caused by gonadal, adrenal, or hypothalamic disease.2 Benign and malignant tumors of the central nervous system (CNS) can cause precocious puberty. These tumors are thought to remove the inhibitory influences normally exerted on the hypothalamus during childhood.

Diagnosis of precocious puberty is based on physical findings of early thelarche (i.e., beginning of breast development), adrenarche (i.e., beginning of augmented adrenal androgen production), and menarche (i.e., beginning of menstrual function) in girls. The most common sign in boys is early genital enlargement. Radiologic findings may indicate advanced bone age. People with precocious puberty are usually tall for their age as children but short as adults because of the early closure of the epiphyses. MRI or CT should be used to exclude intracranial lesions.16

Depending on the cause of precocious puberty, the treatment may involve surgery, medication, or no treatment.16 Administration of a long-acting GnRH agonist results in a decrease in pituitary responsiveness to GnRH, leading to decreased secretion of gonadotropin hormones and sex steroids (i.e., due to down-regulation of GnRH receptors).

**IN SUMMARY**

Pituitary tumors can result in deficiencies or excesses of pituitary hormones. Hypopituitarism, which is characterized by a decreased secretion of pituitary hormones, is a condition that affects many of the other endocrine systems. Depending on the extent of the disorder, it can result in decreased levels of GH, thyroid hormones, adrenal corticosteroid hormones, and testosterone in the male and estrogens and progesterone in the female.

A number of hormones are essential for normal body growth and maturation, including GH, insulin, thyroid hormone, and androgens. GH exerts its growth effects through IGF-1. GH also exerts an effect on metabolism and is produced in the adult and in the child. Its metabolic effects include a decrease in peripheral use of carbohydrates and an increased mobilization and use of fatty acids.

In children, alterations in growth include short stature, isosexual precocious puberty, and tall stature. Short stature is a condition in which the attained height is well below the third percentile or the linear growth velocity is below normal for a child’s age or sex. Short stature can occur as a variant of normal growth (i.e., genetic short stature or constitutional short stature) or as the result of endocrine disorders, chronic illness, malnutrition, emotional disturbances, or chromosomal disorders. Short stature resulting from GH deficiency can be treated with human GH preparations. In adults, GH deficiency represents a deficiency carried over from childhood or one that develops during adulthood as the result of a pituitary tumor or its treatment. GH levels also can decline with aging, and there has been interest in the effects of declining GH levels in the elderly (described as somatopause).

Tall stature refers to the condition in which children are tall for their age and gender. It can occur as a variant of normal growth (i.e., genetic tall stature or constitutional tall stature) or as the result of a chromosomal abnormality or GH excess. GH excess in adults results in acromegaly, which involves proliferation of bone, cartilage, and soft tissue along with the metabolic effects of excessive hormone levels. Isosexual precocious puberty defines a condition of early activation of the hypothalamic–pituitary–gonadal axis, resulting in the development of appropriate sexual characteristics and fertility. It causes tall stature during childhood but results in short stature in adulthood because of the early closure of the epiphyses.

**THYROID DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the synthesis, transport, and regulation of thyroid hormone.
- Describe tests in the diagnosis and management of thyroid disorders.
Control of Thyroid Function

The thyroid gland is a shield-shaped structure located immediately below the larynx in the anterior middle portion of the neck (Fig. 49.3A). It is composed of a large number of tiny, saclike structures called follicles (see Fig. 49.3B). These are the functional units of the thyroid. Each follicle is formed by a single layer of epithelial (follicular) cells and is filled with a secretory substance called colloid, which consists largely of a glycoprotein–iodine complex called thyroglobulin.²

The thyroglobulin that fills the thyroid follicles is a large glycoprotein molecule that contains 140 tyrosine amino acids. In the process of thyroid synthesis, iodine is attached to these tyrosine molecules. Both thyroglobulin and iodide are secreted into the colloid of the follicle by the follicular cells.²

The thyroid is remarkably efficient in its use of iodide. A daily absorption of approximately 50 mg of ingested iodine or about 1 mg/week is necessary to form normal quantities of thyroid hormone.³ In the process of removing it from the blood and storing it for future use, iodide is pumped into the follicular cells against a concentration gradient. Iodide (I⁻) is transported across the basement membrane of the thyroid cells by an intrinsic membrane protein called the Na⁺/I⁻ symporter (NIS).⁴ At the apical border, a second I⁻ transport protein called pendrin moves iodine into the colloid, where it is involved in hormonogenesis.⁴ The NIS derives its energy from Na⁺/K⁺-ATPase, which drives the process. As a result, the concentration of iodide in the normal thyroid gland is approximately 40 times that in the blood.²

The NIS is stimulated by both TSH and the TSH receptor–stimulating antibody found in Graves disease. Pendrin, encoded by the Pendred syndrome gene (PDS), is a transporter of chloride and iodide. Mutations in the PDS gene have been found in patients with goiter and congenital deafness.²

FIGURE 49.3 • (A) The thyroid gland. (B) Microscopic structure of thyroid follicles. (C) Cellular mechanisms for transport of iodide (I⁻), oxidation of I⁻ by thyroperoxidase (TPO), coupling of oxidized I⁻ with thyroglobulin to form thyroid hormones, and movement of T₃ and T₄ into the follicular cell by pinocytosis and release into the blood.
Once inside the follicle, most of the iodide is oxidized by the enzyme thyroid peroxidase (TPO) in a reaction that facilitates combination with a tyrosine molecule to form monoiodotyrosine (MIT) and then diiodotyrosine (DIT). Two DIT residues are coupled to form thyroxine (T₄), or a MIT and a DIT are coupled to form triiodothyronine (T₃). Only T₄ (90%) and T₃ (10%) are released into the circulation (see Fig. 49.3C). There is evidence that T₃ is the active form of the hormone and that T₄ is converted to T₃ before it can act physiologically.

Thyroid hormones are bound to thyroxine-binding globulin (TBG) and other plasma proteins for transport in the blood. Only the free hormone enters cells and regulates the pituitary feedback mechanism. Protein-bound thyroid hormone forms a large reservoir that is slowly drawn on as free thyroid hormone is needed. There are three major thyroid-binding proteins: TBG, transthyretin (formerly known as thyroxine-binding prealbumin [TBPA]), and albumin. More than 99% of T₄ and T₃ is carried in the bound form. TBG carries approximately 70% of T₄ and T₃; transthyretin binds approximately 10% of circulating T₄ and lesser amounts of T₃; and albumin binds approximately 15% of circulating T₄ and T₃.

A number of disease conditions and pharmacologic agents can decrease the amount of binding protein in the plasma or influence the binding of hormone. Congenital TBG deficiency is an X-linked trait that occurs in 1 of every 5000 live births. Premature sick infants need to be screened with a comprehensive thyroid serum profile in order to prevent missing primary hypothyroidism on infants. Glucocorticoid medications and systemic disease conditions such as protein malnutrition, nephrotic syndrome, and cirrhosis decrease TBG concentrations. Medications such as phenytoin, salicylates, and diazepam can affect the binding of thyroid hormone to normal concentrations of binding proteins.

The secretion of thyroid hormone is regulated by the hypothalamic–pituitary–thyroid feedback axis (Fig. 49.4). In this system, thyrotropin-releasing hormone (TRH), which is produced by the hypothalamus, controls the release of TSH from the anterior pituitary gland. TSH increases the overall activity of the thyroid gland by increasing thyroglobulin breakdown and the release of thyroid hormone from follicles into the bloodstream, activating the iodide pump (by increasing NIS activity), increasing the oxidation of iodide and the coupling of iodide to tyrosine, and increasing the number and the size of the follicle cells. The effect of TSH on the release of thyroid hormones occurs within approximately 30 minutes, but the other effects require days or weeks.

Increased levels of thyroid hormone act in the feedback inhibition of TRH or TSH. High levels of iodide also cause a temporary decrease in thyroid activity that lasts for several weeks, probably through a direct inhibition of TSH on the thyroid. Cold exposure is one of the strongest stimuli for increased thyroid hormone production and probably is mediated through TRH from the hypothalamus. Various emotional reactions can also affect the output of TRH and TSH.

FIGURE 49.4 • The hypothalamic–pituitary–thyroid feedback axis.

### Actions of Thyroid Hormone

Altered levels of thyroid hormone affect all the major organs in the body. Thyroid hormone has two major functions—it increases metabolism and protein synthesis, and it is necessary for growth and development in children, including mental development and attainment of sexual maturity. These actions are mainly mediated by T₃. In the cell, T₃ binds to a nuclear receptor, resulting in transcription of specific thyroid hormone response genes.

#### Metabolic Rate.

Thyroid hormone increases the metabolism of all body tissues except the retinas, spleen, testes, and lungs. The basal metabolic rate can increase by 60% to 100% above normal when large amounts of T₄ are present. As a result of this higher metabolism, the rate of glucose, fat, and protein use increases. Lipids are mobilized from adipose tissue, and the catabolism of cholesterol by the liver is increased. Blood levels of cholesterol are decreased in hyperthyroidism and increased in hypothyroidism. Muscle proteins are broken down and used as fuel, probably accounting for some of the muscle fatigue that occurs with hyperthyroidism. The absorption of glucose from the gastrointestinal tract is increased.

#### Cardiovascular Function.

Cardiovascular and respiratory functions are strongly affected by thyroid function. With an increase in metabolism, there is a rise in oxygen consumption and production of metabolic end products, with an accompanying increase in vasodilation. Blood flow to the skin, in particular, is augmented as a means of dissipating the body heat that results from the higher metabolic rate. Blood volume,
cardiac output, and ventilation are all increased as a means of maintaining blood flow and oxygen delivery to body tissues. Heart rate and cardiac contractility are enhanced as a means of maintaining the needed cardiac output. Blood pressure is likely to change little because the increase in vasodilation tends to offset the increase in cardiac output.

**Gastrointestinal Function.** Thyroid hormone enhances gastrointestinal function, causing an increase in motility and production of gastrointestinal secretions that often results in diarrhea. An increase in appetite and food intake accompanies the higher metabolic rate that occurs with increased thyroid hormone levels. At the same time, weight loss occurs because of the increased use of calories.

**Neuromuscular Effects.** Thyroid hormone has marked effects on neural control of muscle function and tone. Slight elevations in hormone levels cause skeletal muscles to react more vigorously, and a drop in hormone levels causes muscles to react more sluggishly. In the hyperthyroid state, a fine muscle tremor is present. The cause of this tremor is unknown, but it may represent an increased sensitivity of the neural synapses in the spinal cord that control muscle tone. In the infant, thyroid hormone is necessary for normal brain development. The hormone enhances cerebration; in the hyperthyroid state, it causes extreme nervousness, anxiety, and difficulty in sleeping.

Evidence suggests a strong interaction between thyroid hormone and the sympathetic nervous system. Many of the signs and symptoms of hyperthyroidism suggest overactivity of the sympathetic division of the autonomic nervous system, such as tachycardia, palpitations, and sweating. Tremor, restlessness, anxiety, and diarrhea may also reflect autonomic nervous system imbalances. Drugs that block sympathetic activity have proved to be valuable adjuncts in the treatment of hyperthyroidism because of their ability to relieve some of these undesirable symptoms.

**Tests of Thyroid Function**

Various tests aid in the diagnosis of thyroid disorders. Measures of T₃, T₄, and TSH have been made available through immunoassay methods. The free T₄ test measures the unbound portion of T₄ that is free to enter cells to produce its effects and is most often the first laboratory value obtained. TSH levels are used to differentiate between primary and secondary thyroid disorders. T₃, T₄, and free T₄ levels are low in primary hypothyroidism, and the TSH level is elevated (see Fig. 49.4). The assessment of thyroid autoantibodies (e.g., anti-TPO antibodies in Hashimoto thyroiditis) is important in the diagnostic workup and consequent follow-up of people with thyroid disorders.

The radioiodine (¹³¹I) uptake test measures the ability of the thyroid gland to concentrate and retain iodine from the blood. Thyroid scans (¹³¹I, ⁹⁹ᵐTc-pertechnetate) can be used to detect thyroid nodules and determine the functional activity of the thyroid gland. Ultrasonography can be used to differentiate cystic from solid thyroid lesions, and CT and MRI scans are used to demonstrate tracheal compression or impingement on other neighboring structures. Fine-needle aspiration biopsy of a thyroid nodule has proved to be the best method for differentiation of benign from malignant thyroid disease.

**Alterations in Thyroid Function**

An alteration in thyroid function can represent a hypofunctional or a hyperfunctional state. The manifestations of these two altered states are summarized in Table 49.3. Disorders of the thyroid may be due to a congenital defect in thyroid development, or they may develop later in life, with a gradual or sudden onset.

Goiter is an increase in the size of the thyroid gland (Fig. 49.5). It can occur in hypothyroid, euthyroid, and hyperthyroid states. Goiters may be diffuse, involving the entire gland without evidence of nodularity, or they may contain nodules. Diffuse goiters usually become nodular. Goiters may be toxic, producing signs of extreme hyperthyroidism, or thyrotoxicosis, or they may be nontoxic. Diffuse nontoxic and multinodular goiters are the result of compensatory hypertrophy and hyperplasia of follicular epithelium from some derangement that impairs thyroid hormone output.

The degree of thyroid enlargement is usually proportional to the extent and duration of thyroid deficiency. Multinodular goiters produce the largest thyroid enlargements. When sufficiently enlarged, they may compress the esophagus and trachea, causing difficulty in swallowing, a choking sensation, and inspiratory stridor. Such lesions may also compress the superior vena cava, producing distention of the veins of the neck and upper extremities, edema of the eyelids and conjunctiva, and syncope with coughing.

**Hypothyroidism**

Hypothyroidism can occur as a congenital or an acquired defect. Congenital hypothyroidism develops prenatally and is present at birth. Acquired hypothyroidism develops because

Goiter

FIGURE 49.5 • Goiter illustrates an enlarged thyroid gland. (From Rubin R., Strayer D. (2012). Pathology: Clinicopathologic Foundations of Medicine, (6th ed., p. 1047, Figure 21.11A). Philadelphia, PA: Lippincott Williams & Wilkins.)

of primary disease of the thyroid gland or secondary to disorders of hypothalamic or pituitary origin.

**Congenital Hypothyroidism**

Congenital hypothyroidism is a common cause of preventable mental retardation. It affects approximately 1 in 4000 infants. Hypothyroidism in the infant may result from a congenital lack of the thyroid gland or from abnormal biosynthesis of thyroid hormone or deficient TSH secretion. With congenital lack of the thyroid gland, the infant usually appears normal and functions normally at birth because hormones have been supplied in utero by the mother.

Thyroid hormone is essential for normal growth and brain development, almost half of which occurs during the first 6 months of life. If untreated, congenital hypothyroidism causes mental retardation and impairs physical growth. The manifestations of untreated congenital hypothyroidism are referred to as cretinism. However, the term does not apply to the normally developing infant in whom replacement thyroid hormone therapy was instituted shortly after birth.

Fortunately, neonatal screening tests have been instituted to detect congenital hypothyroidism during early infancy. Screening is usually done in the hospital nursery. In this test, a drop of blood is taken from the infant’s heel and analyzed for T₃ and TSH.

Transient congenital hypothyroidism has been recognized more frequently since the introduction of neonatal screening. High TSH levels and low or normal thyroid hormone levels characterize it. The fetal and infant thyroids are
sensitive to iodine excess. Iodine crosses the placenta and mammary glands and is readily absorbed by infant skin. Transient hypothyroidism may be caused by maternal or infant exposure to substances such as povidone–iodine used as a disinfectant (i.e., vaginal douche or skin disinfectant in the nursery). Antithyroid drugs such as propylthiouracil and methimazole can cross the placenta and block fetal thyroid function.

Congenital hypothyroidism is treated by hormone replacement. Evidence indicates that it is important to normalize T₄ levels as rapidly as possible because a delay is accompanied by poor psychomotor and mental development. Dosage levels are adjusted as the child grows. When early and adequate treatment regimens are followed, the risk of mental retardation in infants detected by screening programs is essentially nonexistent.

**Acquired Hypothyroidism and Myxedema**

Hypothyroidism in older children and adults causes a general slowing down of metabolic processes and myxedema. Myxedema implies the presence of a nonpitting mucus type of edema caused by an accumulation of a hydrophilic mucopolysaccharide substance in the connective tissues throughout the body. The hypothyroid state may be mild, with only a few signs and symptoms, or it may progress to a life-threatening condition with angioedema.

**Etiology and Pathogenesis.** Acquired hypothyroidism can result from destruction or dysfunction of the thyroid gland (i.e., primary hypothyroidism), or it can be a secondary disorder caused by impaired pituitary function or as a tertiary disorder caused by a hypothalamic dysfunction.

Primary hypothyroidism is much more common than secondary (and tertiary) hypothyroidism. It may result from thyroidectomy (i.e., surgical removal) or ablation of the gland with radiation. Certain goitrogenic agents, such as lithium carbonate (used in the treatment of manic-depressive states), and the antithyroid drugs propylthiouracil and methimazole in continuous dosage can block hormone synthesis and produce hypothyroidism with goiter. Large amounts of iodine (i.e., ingestion of kelp tablets or iodide-containing cough syrups, or administration of iodide-containing radiographic contrast media or the cardiac antiarrhythmic class III drug amiodarone, which contains 75 mg of iodine per 200-mg tablet) can also block thyroid hormone production and cause goiter, particularly in persons with autoimmune thyroid disease. Iodine deficiency, which can cause goiter and hypothyroidism, is uncommon in the United States because of the widespread use of iodized salt and other iodide sources. However, iodine deficiency affects an estimated 100 million people worldwide.

The most common cause of hypothyroidism is Hashimoto thyroiditis, an autoimmune disorder in which the thyroid gland may be totally destroyed by an immunologic process. It is the major cause of goiter and hypothyroidism in children and adults. Hashimoto thyroiditis is predominantly a disease of women. The course of the disease varies. At the onset, only a goiter may be present. In time, hypothyroidism usually becomes evident. Although the disorder usually causes hypothyroidism, a hyperthyroid state may develop midcourse in the disease. The transient hyperthyroid state is caused by leakage of preformed thyroid hormone from damaged cells of the gland. Subacute thyroiditis, which can occur in postpartum (postpartum thyroiditis), can also result in hypothyroidism.

**Clinical Manifestations.** Hypothyroidism may affect almost all body functions. The manifestations of the disorder are related largely to two factors: the hypometabolic state resulting from thyroid hormone deficiency and myxedematous involvement of body tissues. The hypometabolic state associated with hypothyroidism is characterized by a gradual onset of weakness and fatigue, a tendency to gain weight despite a loss of appetite, and cold intolerance (Fig. 49.6).
As the condition progresses, the skin becomes dry and rough and the hair becomes coarse and brittle. The face becomes puffy with edematous eyelids, and there is thinning of the outer third of the eyebrows. Gastrointestinal motility is decreased, producing constipation, flatulence, and abdominal distention. Delayed relaxation of deep tendon reflexes and bradycardia are sometimes noted. CNS involvement is manifested in mental dullness, lethargy, and impaired memory.

Although the myxedemous fluid is usually most obvious in the face, it can collect in the interstitial spaces of almost any body structure and is responsible for many of the manifestations of the severe hypothyroid state. The tongue is often enlarged, and the voice becomes hoarse and husky. Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. Mucopolysaccharide deposits in the heart cause generalized cardiac dilation, bradycardia, and other signs of altered cardiac function. The signs and symptoms of hypothyroidism are summarized in Table 49.3.

Diagnosis and Treatment. Diagnosis of hypothyroidism is based on history, physical examination, and laboratory tests. A low serum T4 and elevated TSH levels are characteristic of primary hypothyroidism. The tests for antithyroid antibodies should be done when Hashimoto thyroiditis is suspected (anti-TPO antibody titers are tested frequently).

Hypothyroidism is treated by replacement therapy with synthetic preparations of T4 or T3. Most people are treated with T4. Serum TSH levels are used to estimate the adequacy of T4 replacement therapy. When the TSH level is normalized, the T4 dosage is considered satisfactory (for primary hypothyroidism only). A "go low and go slow" approach should be considered in the treatment of elderly with hypothyroidism because of the risk of inducing acute coronary syndromes in the susceptible individual. It is also important that people consistently take the form of T4 prescribed so that their laboratory values are the most representative of their thyroid state. So people should remain on brand names of T4 they should stay on the same drug.

Myxedematous Coma
Myxedematous coma is a life-threatening, end-stage expression of hypothyroidism. It is characterized by coma, hypothermia, cardiovascular collapse, hypoventilation, and severe metabolic disorders that include hyponatremia, hypoglycemia, and lactic acidosis. The pathophysiology of myxedema coma involves three major aspects: (1) carbon dioxide retention and hypoxia, (2) fluid and electrolyte imbalance, and (3) hypothermia. The severely hypothyroid person is unable to metabolize sedatives, analgesics, and anesthetic drugs, and buildup of these agents may precipitate coma.

Treatment includes aggressive management of precipitating factors; supportive therapy such as management of cardiovascular status, hyponatremia, and hypoglycemia; and thyroid replacement therapy. If hypothermia is present, active rewarming of the body is contraindicated because it may induce vasodilation and vascular collapse. Prevention is preferable to treatment and entails special attention to high-risk populations, such as women with a history of Hashimoto thyroiditis. These persons should be informed about the signs and symptoms of severe hypothyroidism and the need for early medical treatment.

Hyperthyroidism
Thyrotoxicosis is the clinical syndrome that results when tissues are exposed to high levels of circulating thyroid hormone.

Etiology and Pathogenesis
In most instances, thyrotoxicosis is due to hyperactivity of the thyroid gland, or hyperthyroidism. The most common cause of hyperthyroidism is Graves disease, which is accompanied by ophthalmopathy (or dermopathy) and diffuse goiter. Other causes of hyperthyroidism are multinodular goiter, adenoma of the thyroid, and thyroiditis. Iodine-containing agents can induce hyperthyroidism as well as hypothyroidism. Thyroid crisis, or storm, is an acutely exaggerated manifestation of the thyrotoxic state.

Clinical Manifestations
Many of the manifestations of hyperthyroidism are related to the increase in oxygen consumption and use of metabolic fuels associated with the hypermetabolic state, as well as to the increase in sympathetic nervous system activity that occurs.

The fact that many of the signs and symptoms of hyperthyroidism resemble those of excessive sympathetic nervous system activity suggests that thyroid hormone may heighten the sensitivity of the body to the catecholamines or that it may act as a pseudocatecholamine. With the hypermetabolic state, there are frequent complaints of nervousness, irritability, and fatigability. The person appears restless and has a fine muscle tremor. Even in people without exophthalmos (i.e., bulging of the eyeballs seen in ophthalmopathy), there is an abnormal retraction of the eyelids and infrequent blinking such that they appear to be staring. The hair and skin are usually thin and have a silky appearance. About 15% of older adults with new-onset atrial fibrillation have thyrotoxicosis. The signs and symptoms of hyperthyroidism are summarized in Table 49.3.

The treatment of hyperthyroidism is directed toward reducing the level of thyroid hormone. This can be accomplished with eradication of the thyroid gland with radioactive iodine, through surgical removal of part or all of the gland, or the use of drugs that decrease thyroid function and thereby the effect of thyroid hormone on the peripheral
tissues. Eradication of the thyroid with radioactive iodine is more frequently undertaken than surgery. The β-adrenergic blocking drugs (propranolol, metoprolol, atenolol, and nadolol are preferred) are administered to block the effects of the hyperthyroid state on sympathetic nervous system function. They are given in conjunction with antithyroid drugs such as propylthiouracil and methimazole. These drugs prevent the thyroid gland from converting iodine to its organic (hormonal) form and block the conversion of T₄ to T₃ in the tissues (propylthiouracil only).^{22}

Graves Disease

Graves disease is a state of hyperthyroidism, goiter, and ophthalmopathy. Onset is usually between the ages of 20 and 40 years. It affects approximately 0.5% to 1% of the population under 40 years of age.^{23} Graves disease is an autoimmune disorder characterized by abnormal stimulation of the thyroid gland by thyroid-stimulating antibodies (TSH receptor antibodies) that act through the normal TSH receptors. It may be associated with other autoimmune disorders such as myasthenia gravis. The disease is associated with a major histocompatibility complex class 1 chain–related gene A (MICA), with genotypes MICA A5 correlated with Graves disease and MICA A6/A9 being preventive for Graves disease.^{23}

The ophthalmopathy, which occurs in up to one third of people with Graves disease, is thought to result from accumulation of T lymphocytes sensitized to antigens along thyroid follicular cells and orbital fibroblasts that secrete cytokines.^{23} The ophthalmopathy of Graves disease can cause severe eye problems, including tethering of the extraocular muscles resulting in diplopia; involvement of the optic nerve, with some visual loss; and corneal ulceration because the lids do not close over the protruding eyeball (due to the exophthalmos).^{22} The ophthalmopathy usually tends to stabilize after treatment of the hyperthyroidism. However, ophthalmopathy can worsen acutely after radiiodine treatment. Some physicians prescribe glucocorticoids for several weeks surrounding the radiiodine treatment if the person had signs of ophthalmopathy.^{22} Ophthalmopathy can also be aggravated by smoking, which should be strongly discouraged. Figure 49.8 shows a woman with Graves disease.
Thyroid Storm

Thyroid storm, or thyrotoxic crisis, is an extreme and life-threatening form of thyrotoxicosis rarely seen today because of improved diagnosis and treatment methods.\(^2^4\) When it occurs, it is seen most often in undiagnosed cases or in people with hyperthyroidism who have not been adequately treated. It is often precipitated by stress, such as an infection, by physical or emotional trauma, or by manipulation of a hyperactive thyroid gland during thyroidectomy.\(^2^4\) Thyroid storm is manifested by a very high fever, extreme cardiovascular effects (i.e., tachycardia, congestive failure, and angina), and severe CNS effects (i.e., agitation, restlessness, and delirium).\(^2^4\) The mortality rate is high.

Thyroid storm requires rapid diagnosis and implementation of treatment. Initially the person must be hemodynamically stabilized. The thyroid hormones can be removed by plasma pheresis, dialysis, or hemoperfusion adsorption.\(^2^4\) Peripheral cooling is initiated with cold packs and a cooling mattress. For cooling to be effective, the shivering response must be prevented. General supportive measures to replace fluids, glucose, and electrolytes are essential during the hypermetabolic state. A \(\beta\)-adrenergic blocking drug, such as propranolol, is given to block the undesirable effects of \(T_3\) on cardiovascular function. Glucocorticoids are used to correct the relative adrenal insufficiency resulting from the stress imposed by the hyperthyroid state and to inhibit the peripheral conversion of \(T_3\) to \(T_4\). Propylthiouracil or methimazole may be given to block thyroid synthesis.\(^2^4\) Aspirin increases the level of free thyroid hormones by displacing the hormones from their protein carriers, and should not be used during thyroid storm.

IN SUMMARY

Thyroid hormones play a role in the metabolic process of almost all body cells and are necessary for normal physical and mental growth in the infant and young child. Alterations in thyroid function can manifest as a hypothyroid or a hyperthyroid state. Hypothyroidism can occur as a congenital or an acquired defect. Congenital hypothyroidism leads to mental retardation and impaired physical growth unless treatment is initiated during the first months of life. Acquired hypothyroidism leads to a decrease in metabolic rate and an accumulation of a mucopolysaccharide substance in the intercellular spaces; this substance attracts water and causes a mucous type of edema called myxedema. Hyperthyroidism causes an increase in metabolic rate and alterations in body function similar to those produced by enhanced sympathetic nervous system activity. Graves disease is characterized by the triad of hyperthyroidism, goiter, and ophthalmopathy.

**Figure 49.9**

(A) The adrenal gland, showing the medulla and the three layers of the cortex. The outer layer of the cortex (zona glomerulosa) is primarily responsible for mineralocorticoid production, and the middle layer (zona fasciculata) and the inner layer (zona reticularis) produce the glucocorticoids and the adrenal androgens. (B) Predominant biosynthetic pathways of the adrenal cortex. Critical enzymes in the biosynthetic process include 11-\(\beta\)-hydroxylase and 21-hydroxylase. A deficiency in one of these enzymes blocks the synthesis of hormones dependent on that enzyme and routes the precursors into alternative pathways.
forms the bulk of the adrenal gland (approximately 80%) and is responsible for secreting three types of hormones—the glucocorticoids, the mineralocorticoids, and the adrenal androgens. Because the sympathetic nervous system also secretes epinephrine and norepinephrine, adrenal medullary function is not essential for life, but adrenal cortical function is. The total loss of adrenal cortical function is fatal in a few days to a few weeks if untreated. This section of the chapter describes the synthesis and function of the adrenal cortical hormones and the effects of adrenal cortical insufficiency and excess.

Biosynthesis, Transport, and Metabolism

More than 30 hormones are produced by the adrenal cortex. Of these hormones, aldosterone is the principal mineralocorticoid, cortisol (hydrocortisone) is the major glucocorticoid, and androgens are the chief sex hormones. All of the adrenal cortical hormones have a similar structure in that all are steroids and are synthesized from acetate and cholesterol. Each of the steps involved in the synthesis of the various hormones requires a specific enzyme (see Fig. 49.9). The ACTH secreted by the anterior pituitary gland controls the secretion of the glucocorticoids and the adrenal androgens.

Cortisol, aldosterone, and the adrenal androgens are secreted in an unbound state and bind to plasma proteins for transport in the circulatory system. Cortisol binds largely to corticosteroid-binding globulin and to a lesser extent to albumin. Aldosterone and androgens circulate mostly bound to albumin. It has been suggested that the pool of protein-bound hormones may extend the duration of their action by delaying metabolic clearance.

The main site for metabolism of the adrenal cortical hormones is the liver, where they undergo a number of metabolic conversions before being conjugated and made water-soluble. They are then eliminated in either the urine or the bile.

KEY POINTS

**ADRENAL CORTICAL HORMONES**

- The manifestations of primary adrenal cortical insufficiency are related mainly to mineralocorticoid deficiency (impairment of ability to regulate salt and water elimination) and glucocorticoid deficiency (impairment of ability to regulate blood glucose and control the effects of the immune and inflammatory responses).
- Adrenal cortical excess results in derangements in glucose metabolism, disorders of sodium and potassium regulation (increased sodium retention and potassium loss), impaired ability to respond to stress because of inhibition of inflammatory and immune responses, and signs of increased androgen levels such as hirsutism.

Adrenal Androgens

The adrenal androgens are synthesized primarily by the zona reticularis and the zona fasciculata of the cortex (see Fig. 49.9A). These sex hormones probably exert little effect on normal sexual function. There is evidence, however, that the adrenal androgens (the most important of which is dehydroepiandrosterone [DHEA] and its sulfate [DHEAS]) contribute to the pubertal growth of body hair, particularly pubic and axillary hair in women. They may also play a role in steroid hormone economy of the pregnant woman and the fetal-placental unit. DHEAS is increasingly being used for treating both Addison disease and adults who have decreased levels of DHEAS. Adrenal androgens are physiologically important in women with Addison disease, and replacement with 25 to 50 mg of DHEAS daily should be considered. Because the testes produce these hormones, there is no rationale for using it in men. The levels of DHEAS decline to approximately 10% to 20% of the levels of a 20-year-old by 80 years of age (adrenopause). The value of routine replacement of DHEAS in the adrenopause is largely unproven. DHEAS levels may represent another aging marker since it is involved with cardiovascular, immunological, and endocrine systems and may be a trend indicator for prevention of specific problems with aging.

Mineralocorticoids

The mineralocorticoids play an essential role in regulating potassium and sodium levels and water balance. They are produced in the zona glomerulosa, the outer layer of cells of the adrenal cortex. Aldosterone secretion is regulated by the renin–angiotensin mechanism and by blood levels of potassium. Increased levels of aldosterone promote sodium retention by the distal tubules of the kidney while increasing urinary losses of potassium.

Aldosterone is significant for balancing sodium, chloride, and potassium as well as maintaining the total body volume. To understand the importance of aldosterone consider that aldosterone controls approximately 90% of the mineralocorticoid function of the adrenals but cortisol also provides for mineralocorticoid function. Although aldosterone is responsible for about 3000 times greater the amount of mineralocorticoid activity than cortisol, there is nearly 2000 times more serum cortisol than aldosterone. Due to the potency of aldosterone it is crucial that the body does not have excess or deficiency of this potent steroid. The consequences of excess aldosterone are low potassium and muscle weakness, while low amounts of aldosterone cause high potassium and cardiac toxicity.

Glucocorticoids

The glucocorticoid hormones, mainly cortisol, are synthesized in the zona fasciculata and the zona reticularis of the adrenal gland. The blood levels of these hormones are regulated by negative feedback mechanisms of the hypothalamic–pituitary–adrenal (HPA) system (Fig. 49.10). Just as other pituitary hormones are controlled by releasing factors from the hypothalamus, corticotropin-releasing hormone (CRH) is important in controlling the release of ACTH. Cortisol levels increase as
ACTH levels rise and decrease as ACTH levels fall. There is considerable diurnal variation in ACTH levels, which reach their peak in the early morning (around 6 to 8 AM) and decline as the day progresses. This appears to be due to rhythmic activity in the CNS, which causes bursts of CRH secretion and, in turn, ACTH secretion. This diurnal pattern is reversed in people who work during the night and sleep during the day. The rhythm may also be changed by physical and psychological stresses, endogenous depression, manic-depressive psychosis, and liver disease or other conditions that affect cortisol metabolism.

The glucocorticoids perform a necessary function in response to stress and are essential for survival. When produced as part of the stress response, these hormones aid in regulating the metabolic functions of the body and controlling the inflammatory response. The actions of cortisol are summarized in Table 49.4. Many of the anti-inflammatory actions attributed to cortisol result from the administration of pharmacologic levels of the hormone.

### Metabolic Effects

Cortisol stimulates glucose production by the liver, promotes protein breakdown, and causes mobilization of fatty acids. As body proteins are broken down, amino acids are mobilized and transported to the liver, where they are used in the production of glucose (*i.e.*, gluconeogenesis). Mobilization of fatty acids converts cell metabolism from the use of glucose for energy to the use of fatty acids instead. As glucose production by the liver rises and peripheral glucose use falls, a moderate resistance to insulin develops. In people with diabetes and those who are diabetes prone, this has the effect of raising the blood glucose level.

Psychological Effects. The glucocorticoid hormones appear to be involved directly or indirectly in emotional behavior. Receptors for these hormones have been identified in brain tissue, which suggests that they play a role in the regulation of behavior. People treated with adrenal cortical hormones have been known to display behavior ranging from mildly aberrant to psychotic.22

Immunologic and Inflammatory Effects. Cortisol influences multiple aspects of immunologic function and inflammatory responsiveness. Large quantities of cortisol are required for an effective anti-inflammatory action. This is achieved by the administration of pharmacologic rather than physiologic doses of synthetic cortisol. The increased cortisol blocks inflammation at an early stage by decreasing capillary permeability and stabilizing the lysosomal membranes so that inflammatory mediators are not released. Cortisol suppresses the immune response by reducing humoral and cell-mediated immunity. With this lessened inflammatory response comes a reduction in fever. During the healing phase, cortisol suppresses fibroblast activity and thereby lessens scar formation. Cortisol also inhibits prostaglandin synthesis, which may account in large part for its anti-inflammatory actions.

Pharmacologic Suppression of Adrenal Function

A highly significant aspect of long-term therapy with pharmacologic preparations of the glucocorticoids is adrenal insufficiency on withdrawal of drugs. The deficiency results from suppression of the HPA system. Chronic suppression causes atrophy of the adrenal gland, and the abrupt withdrawal of drugs can cause acute adrenal insufficiency. Recovery to a state of normal adrenal function may be prolonged, requiring up to 12 months or more.22

Tests of Adrenal Function

Several diagnostic tests can be used to evaluate adrenal cortical function and the HPA system.11,22 Blood levels of cortisol, aldosterone, and ACTH can be measured using immunoassay methods. A 24-hour urine specimen measuring the excretion of various metabolic end products of adrenal hormones provides information about alterations in the biosynthesis of the adrenal cortical hormones. The 24-hour urinary free cortisol, late-night (between 11 PM and midnight) serum or salivary cortisol levels, and the overnight 1-mg dexamethasone suppression test are excellent screening tests for Cushing syndrome.11,22

Suppression and stimulation tests afford a means of assessing the state of the HPA feedback system. For example, a test dose of ACTH can be given to assess the response of the adrenal cortex to stimulation. Similarly, administration of dexamethasone, a synthetic glucocorticoid drug, provides a means of measuring negative feedback suppression of ACTH. Adrenal tumors and ectopic ACTH-producing tumors are usually unresponsive to ACTH suppression by dexamethasone. CRH tests can be used to diagnose a pituitary ACTH-secreting tumor (i.e., Cushing disease).22 Corticotropin (cosyntropin) stimulation testing is the most frequently used diagnostic test to assess testing responsiveness of the HPA axis.22

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH), or the adrenogenital syndrome, describes a congenital disorder caused by an autosomal recessive trait in which a deficiency exists in any of the enzymes necessary for the synthesis of cortisol22 (see Fig. 49.10). A common characteristic of all types of CAH is a defect in the synthesis of cortisol that results in increased levels of ACTH and adrenal hyperplasia.21 The increased levels of ACTH over-stimulate the pathways for production of adrenal androgens. Mineralocorticoids may be produced in excessive or insufficient amounts, depending on the precise enzyme deficiency. Infants of both sexes are affected. Boys are seldom diagnosed at birth unless they have enlarged genitalia or lose salt and manifest adrenal crisis.23 In female infants, an increase in androgens is responsible for creating the virilization syndrome of ambiguous genitalia with an enlarged clitoris, fused labia, and urogenital sinus (Fig. 49.11). In male and female children, other secondary sex characteristics are normal, and fertility is unaffected if appropriate therapy is instituted.

A spectrum of 21-hydroxylase deficiency states exists, ranging from simple virilizing CAH to a complete salt-losing enzyme deficiency. Simple virilizing CAH impairs the synthesis of cortisol, and steroid synthesis is shunted to androgen production. Persons with these deficiencies usually produce sufficient aldosterone or aldosterone intermediates to prevent signs and symptoms of mineralocorticoid deficiency. The salt-losing form is accompanied by deficient production of aldosterone and its intermediates. This results in fluid and electrolyte disorders after the fifth day of life (including hypotension, vomiting, dehydration, and shock). Hyperkalemia is not always present so it should not be considered a major screening diagnostic parameter.25

The 11-β-hydroxylase deficiency is rare and manifests a spectrum of severity. Affected people have excessive androgen production and impaired conversion of 11-deoxycorticosterone to corticosterone. The overproduction of 11-deoxycorticosterone, which has mineralocorticoid activity, is responsible for the hypertension that accompanies this deficiency. Diagnosis of CAH depends on the precise biochemical evaluation of metabolites in the cortisol pathway and on clinical signs and symptoms. Genetic testing is also invaluable. However, correlation between the phenotype and genotype is not always straightforward.19,22

Medical treatment of CAH includes oral or parenteral glucocorticoid replacement. Fludrocortisone acetate, a mineralocorticoid, may also be given to children who are salt losers. Depending on the degree of virilization, reconstructive surgery during the first 2 years of life is indicated to reduce the size of the clitoris, separate the labia, and exteriorize the vagina.
Chapter 49  Disorders of Endocrine Control of Growth and Metabolism

Adrenal Cortical Insufficiency

There are two forms of adrenal insufficiency—primary and secondary23 (see Table 49.5 for distinguishing features). Primary adrenal insufficiency, or Addison disease, is caused by destruction of the adrenal gland. Secondary adrenal insufficiency results from a disorder of the HPA system.

**Primary Adrenal Cortical Insufficiency**

Addison disease is reserved for primary adrenal insufficiency in which adrenal cortical hormones are deficient and ACTH levels are elevated because of lack of feedback inhibition.

**Etiology and Pathogenesis.** This disease is a relatively rare disorder in which all the layers of the adrenal cortex are destroyed. Autoimmune destruction is the most common cause of Addison disease in the United States. Before 1950, tuberculosis was the major cause of Addison disease in the United States and Canada, and it continues to be a major cause of the disease in countries where it is more prevalent. Rare causes include metastatic carcinoma, fungal infection (particularly histoplasmosis), cytomegalovirus infection, amyloid disease, and hemochromatosis. Bilateral adrenal hemorrhage may occur in persons taking anticoagulants, during open heart surgery, and during birth or major trauma. Adrenal insufficiency

can be caused by acquired immunodeficiency syndrome, in which the adrenal gland is destroyed by a variety of opportunistic infectious agents. Drugs that inhibit synthesis or cause excessive breakdown of glucocorticoids can also result in adrenal insufficiency (e.g., ketoconazole).

Clinical Manifestations. The adrenal cortex has a large reserve capacity, and the manifestations of adrenal insufficiency usually do not become apparent until approximately 90% of the gland has been destroyed. These manifestations are related primarily to mineralocorticoid deficiency, glucocorticoid deficiency, and hyperpigmentation resulting from elevated ACTH levels. Although lack of the adrenal androgens (i.e., DHEAS) exerts few effects in men because the testes produce these hormones, women have sparse axillary and pubic hair.

Mineralocorticoid deficiency causes increased urinary losses of sodium, chloride, and water, along with decreased excretion of potassium (Fig. 49.12). The result is hyponatremia, loss of extracellular fluid, decreased cardiac output, and hyperkalemia. There may be an abnormal appetite for salt. Orthostatic hypotension is common. Dehydration, weakness, and fatigue are common early symptoms. If loss of sodium and water is extreme, cardiovascular collapse and shock ensue. Because of a lack of glucocorticoids, the person with Addison disease has poor tolerance to stress. This deficiency causes hypoglycemia, lethargy, weakness, fever, and gastrointestinal symptoms such as anorexia, nausea, vomiting, and weight loss.

Hyperpigmentation results from elevated levels of ACTH. The skin looks bronzed or suntanned in exposed and unexposed areas, and the normal creases and pressure points tend to become especially dark. The gums and oral mucous membranes may become bluish-black. The amino acid sequence of ACTH is strikingly similar to that of melanocyte-stimulating hormone; hyperpigmentation occurs in greater than 90% of persons with Addison disease and is helpful in distinguishing the primary and secondary forms of adrenal insufficiency.

Treatment. Addison disease, like type 1 diabetes mellitus, is a chronic metabolic disorder that requires lifetime hormone replacement therapy. The daily regulation of the chronic phase of Addison disease is usually accomplished with oral replacement therapy, with higher doses being given during periods of stress. The pharmacologic agent that is used should have both glucocorticoid and mineralocorticoid activity. Mineralocorticoids are needed only in primary adrenal insufficiency. Hydrocortisone is usually the drug of choice. In mild cases, hydrocortisone alone may be adequate. Fludrocortisone (a mineralocorticoid) is used for persons who do not obtain a sufficient salt-retaining effect from hydrocortisone. DHEAS replacement may also be helpful in the female patient.

Because people with the disorder are likely to have episodes of hyponatremia and hypoglycemia, they need to have a regular schedule for meals and exercise. People with Addison disease also have limited ability to respond to infections, trauma, and other stresses. Such situations require immediate medical attention and treatment. People with Addison disease should be advised to wear a medical alert bracelet or medal.

Secondary Adrenal Cortical Insufficiency

Secondary adrenal insufficiency can occur as the result of hypopituitarism or because the pituitary gland has been surgically removed. Tertiary adrenal insufficiency results from a hypothalamic defect. However, a far more common cause than either of these is the rapid withdrawal of glucocorticoids that have been administered therapeutically for asthma or an exacerbation of multiple sclerosis. These drugs suppress the HPA system, with resulting adrenal cortical atrophy and loss of cortisol production. This suppression continues long after drug therapy has been discontinued and can be critical during periods of stress or when surgery is performed.
Acute adrenal crisis is a life-threatening situation.23 If Addison disease is the underlying problem, exposure to even a minor illness or stress can precipitate nausea, vomiting, muscular weakness, hypotension, dehydration, and vascular collapse. The onset of adrenal crisis may be sudden, or it may progress over a period of several days. The symptoms may occur suddenly in children with salt-losing forms of CAH.23 Massive bilateral adrenal hemorrhage causes an acute fulminating form of adrenal insufficiency. Hemorrhage can be caused by meningococcal septicemia, adrenal trauma, anticoagulant therapy, adrenal vein thrombosis, or adrenal metastases.

Adrenal insufficiency is treated with hormone replacement therapy that includes a combination of glucocorticoids and mineralocorticoids. For acute adrenal insufficiency, the five Ss of management should be followed: (1) Salt replacement, (2) Sugar (dextrose) replacement, (3) Steroid replacement, (4) Support of physiologic functioning, and (5) Search for and treat the underlying cause (e.g., infection). Extracellular fluid volume should be restored with several liters of 0.9% saline and 5% dextrose. Glucocorticoid replacement is accomplished through the intravenous administration of either dexamethasone or hydrocortisone. Dexamethasone is preferred acutely for two reasons: it is long acting (12 to 24 hours) and it does not interfere with measurement of serum or urinary steroids during subsequent corticotropin (ACTH) stimulation tests if diagnosis needs to be established. Thereafter, hydrocortisone is given either intravenously or intramuscularly at 6-hour intervals and then tapered over 1 to 3 days to maintenance levels. Oral hydrocortisone replacement therapy can be resumed once the saline infusion has been discontinued and the person is taking food and fluids by mouth. Mineralocorticoid therapy is not required when large amounts of hydrocortisone are being given, but as the dose is reduced it is usually necessary to add fludrocortisone. Glucocorticoid and mineralocorticoid replacement therapy is monitored using heart rate and blood pressure measurements; serum electrolyte values; and titration of plasma renin activity into the upper-normal range.22

Glucocorticoid Hormone Excess (Cushing Syndrome)

The term Cushing syndrome refers to the manifestations of hypercortisolism from any cause.23 Three important forms of Cushing syndrome result from excess glucocorticoid production by the body. One is a pituitary form, which results from excessive production of ACTH by a tumor of the pituitary gland. This form of the disease was the one originally described by Cushing. Therefore, it is called Cushing disease. The second form is the adrenal form, caused by a benign or malignant adrenal tumor. The third form is ectopic Cushing syndrome, caused by a nonpituitary ACTH-secreting tumor. Certain extrapituitary malignant tumors such as small cell carcinoma of the lung may secrete ACTH or, rarely, CRH, and produce Cushing syndrome. Cushing syndrome can also result from long-term therapy with one of the potent pharmacologic preparations of glucocorticoids; this form is called iatrogenic Cushing syndrome.

Clinical Manifestations

The major manifestations of Cushing syndrome represent an exaggeration of the many actions of cortisol (see Table 49.4). Altered fat metabolism causes a peculiar deposition of fat characterized by a protruding abdomen; subclavicular fat pads or “buffalo hump” on the back; and a round, plethoric “moon face” (Figs. 49.13 and 49.14). There is muscle weakness, and the extremities are thin because of protein breakdown and muscle wasting. In advanced cases, the skin over the forearms and legs becomes thin, having the appearance of parchment. Purple striae, or stretch marks, from stretching of the catabolically weakened skin and subcutaneous tissues are distributed...
over the breast, thighs, and abdomen. Osteoporosis may develop because of destruction of bone proteins and alterations in calcium metabolism, resulting in back pain, compression fractures of the vertebrae, and rib fractures. As calcium is mobilized from bone, renal calculi may develop.

The glucocorticoids possess mineralocorticoid properties. This causes hypokalemia, as a result of excessive potassium excretion, and hypertension, resulting from sodium retention. Inflammatory and immune responses are inhibited, resulting in increased susceptibility to infection. Cortisol increases gastric acid secretion, which may provoke gastric ulceration and bleeding. An accompanying increase in androgen levels causes hirsutism, mild acne, and menstrual irregularities in women. Excess levels of the glucocorticoids may give rise to extreme emotional lability, ranging from mild euphoria and absence of normal fatigue to grossly psychotic behavior.

**Diagnosis and Treatment**

Diagnosis of Cushing syndrome depends on the finding of cortisol hypersecretion. The determination of 24-hour excretion of cortisol in urine provides a reliable and practical index of cortisol secretions. One of the prominent features of Cushing syndrome is loss of the diurnal pattern of cortisol secretion. The overnight 1-mg dexamethasone suppression test is also used as a screening tool for Cushing syndrome.

Other tests include measurement of the plasma levels of ACTH. ACTH levels should be normal or elevated in ACTH-dependent Cushing syndrome (Cushing disease and ectopic ACTH), and low in non–ACTH-dependent Cushing syndrome (adrenal tumors). Various suppression or stimulation tests of the HPA system are performed to delineate the cause further. MRI or CT scans afford a means for locating adrenal or pituitary tumors.

Untreated, Cushing syndrome produces serious morbidity and even death. The choice of surgery, irradiation, or pharmacologic treatment is determined largely by the cause of the hypercortisolism. The goal of treatment for Cushing syndrome is to remove or correct the source of hypercortisolism without causing permanent pituitary or adrenal damage. Transsphenoidal removal of a pituitary adenoma or a hemi-hypophysectomy is the preferred method of treatment for Cushing disease. This allows removal of only the tumor rather than the entire pituitary gland. After successful removal, the person must receive cortisol replacement therapy for 6 to 12 months or until adrenal function returns. People may also receive pituitary radiation therapy, but the full effects of treatment may not be realized for 3 to 12 months. Unilateral or bilateral adrenalectomy may be done in the case of adrenal adenoma. When possible, ectopic ACTH-producing tumors are also removed. Pharmacologic agents that block steroid synthesis (i.e., mitotane, ketoconazole, and metyrapone) may be used to treat people with ectopic tumors or adrenal carcinomas that cannot be resected.

Many of these people also require *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia prophylaxis because of the profound immunosuppression caused by the excessive glucocorticoid levels.

**Incidental Adrenal Mass**

An incidentaloma is a mass lesion found unexpectedly in an adrenal gland by an imaging procedure (done for other reasons), most commonly CT (but also MRI and ultrasonography). Incidentalomas can also occur in other organs (e.g., pituitary, thyroid). The two most important points to establish regarding incidentalomas are if they are malignant and if they are hormonally active.

Primary adrenal carcinoma is quite rare, but other cancers, particularly lung cancers, commonly metastasize to the adrenal gland (other cancers include breast, stomach, pancreas, colon, kidney, melanomas, and lymphomas). The size and imaging characteristics of the mass may help determine whether the tumor is benign or malignant. Appropriate screening to exclude a hormonally active lesion includes tests to rule out pheochromocytoma, Cushing syndrome, and Conn syndrome (mineralocorticoid excess).

**IN SUMMARY**

The adrenal cortex produces three types of hormones: mineralocorticoids, glucocorticoids, and adrenal androgens. The mineralocorticoids, along with the renin–angiotensin mechanism, aid in controlling body levels of sodium and potassium. The glucocorticoids have anti-inflammatory actions and aid in regulating glucose, protein, and fat metabolism during periods of stress. These hormones are under the control of the HPA system. The adrenal androgens exert little effect on daily control of body function, but they probably contribute to the development of body hair in women. CAH describes a genetic defect in the cortisol...
pathway resulting from a deficiency of one of the enzymes needed for its synthesis. Depending on the enzyme involved, the disorder causes virilization of female infants and, in some instances, fluid and electrolyte disturbances because of impaired mineralocorticoid synthesis.

Chronic adrenal insufficiency can be caused by destruction of the adrenal gland (Addison disease) or by dysfunction of the HPA system. Adrenal insufficiency requires replacement therapy with adrenal cortical hormones. Acute adrenal insufficiency is a life-threatening situation. Cushing syndrome refers to the manifestations of excessive glucocorticoid levels. This syndrome may be a result of pharmacologic doses of glucocorticoids, a pituitary or adrenal tumor, or an ectopic tumor that produces ACTH. The clinical manifestations of Cushing syndrome reflect the very high level of glucocorticoid that is present.

An incidentaloma is a mass lesion found unexpectedly in an adrenal gland (and other glands) by an imaging procedure done for other reasons. They are being recognized with increasing frequency, emphasizing the need for correct diagnosis and treatment.

REVIEW EXERCISES

1. A 59-year-old man was referred to a neurologist for evaluation of headaches. Subsequent MRI studies revealed a large suprasellar mass (2.5 × 2.4 cm), consistent with a pituitary tumor. His history is positive for hypertension and, on direct inquiry, he believes that his hands are slightly larger than previously, and he is experiencing increased sweating. Family history is negative, as are weight change, polyuria and polydipsia, visual disturbance, and erectile dysfunction. Subsequent laboratory findings reveal a baseline serum growth hormone (GH) of 8.7 ng/mL (normal is 0 to 5 ng/mL), which is unsuppressed after oral glucose tolerance testing; glucose intolerance; and increased insulin-like growth factor-1 (IGF-1) on two occasions (1044 and 1145 µg/L [upper limit of normal is 480 µg/L]). Other indices of pituitary function are within the normal range.
   A. What diagnosis would this man’s clinical features, MRI, and laboratory findings suggest?
   B. What is the reason for asking the patient about weight change, polyuria and polydipsia, visual disturbance, and erectile dysfunction?
   C. How would you explain his impaired glucose tolerance?
   D. What are the possible local effects of a large pituitary tumor?

2. A 76-year-old woman presents with weight gain, subjective memory loss, dry skin, and cold intolerance. On examination she is found to have a multinodular goiter. Laboratory findings reveal a low serum T₄ and elevated TSH.
   A. What diagnosis would this woman’s history, physical, and laboratory tests suggest?
   B. Explain the possible relationship between the diagnosis and her weight gain, dry skin, cold intolerance, and subjective memory loss.
   C. What type of treatment would be indicated?

3. A 45-year-old woman presents with a history of progressive weakness, fatigue, weight loss, nausea, and increased skin pigmentation (especially of creases, pressure areas, and nipples). Her blood pressure is 120/78 mm Hg when supine and 105/52 mm Hg when standing. Laboratory findings reveal a serum sodium of 120 mEq/L (normal is 135 to 145 mEq/L); potassium level of 5.9 mEq/L (normal is 3.5 to 5 mEq/L); and low plasma cortisol and high ACTH levels.
   A. What diagnosis would this woman’s clinical features and laboratory findings suggest?
   B. Would her diagnosis be classified as a primary or secondary endocrine disorder?
   C. What is the significance of her darkened skin?
   D. What type of treatment would be indicated?

According to the American Diabetes Association (ADA), diabetes mellitus (DM) is a chronic health problem affecting 25.8 million people in the United States (approximately 8.3% of the population). It is so prevalent that the term “diabetes” is used interchangeably with diabetes mellitus, even though another form of diabetes exists (diabetes insipidus; see Chapter 39). One million of these people have type 1 diabetes; the remainder have type 2 diabetes. In addition, another 79 million people have been categorized with “prediabetes.” Prediabetes and diabetes affect people in all age groups and from all walks of life. Diabetes is more prevalent among American Indians/Alaska Natives (16.8%), non-Hispanic African Americans (12.6%), and Hispanic Americans (11.85%).

Diabetes, and the resulting impact of short-term and long-term blood glucose fluctuations, can lead to a variety of complications, ranging from acute medical emergencies to disability and death. Diabetes is a significant risk factor in coronary heart disease and stroke, and it is the leading cause of blindness and chronic kidney disease, as well as a common cause of lower extremity amputations. Optimizing glycemic control, through a variety of interventions, minimizes the complications associated with diabetes.
Glucose, Fat, and Protein Metabolism

The body uses glucose, fatty acids, and other substrates as fuel to satisfy its energy needs. Although the respiratory and circulatory systems combine efforts to furnish the body with the oxygen needed for metabolic purposes, it is the liver, in concert with hormones from the endocrine pancreas, that controls the body’s fuel supply (Fig. 50.1).

Glucose Metabolism

Glucose is a six-carbon molecule. It is an efficient fuel that, when metabolized in the presence of oxygen, breaks down to form carbon dioxide and water. Although many tissues and organ systems are able to use other forms of fuel, such as fatty acids and ketones, the brain and nervous system rely almost exclusively on glucose as a fuel source. Because the brain can neither synthesize nor store more than a few minutes’ supply of glucose, normal cerebral function requires a continuous supply from the circulation. Severe and prolonged hypoglycemia can cause brain death, and even moderate hypoglycemia can result in substantial brain dysfunction.

Body tissues obtain glucose from the blood. In people without diabetes, fasting blood glucose levels are tightly regulated between 70 and 100 mg/dL (4.4 to 5.0 mmol/L). After a meal, blood glucose levels rise, and insulin is secreted in response to this rise in glucose. Approximately two thirds of the glucose that is ingested with a meal is removed from the blood and stored in the liver as glycogen. Between meals, the liver releases glucose as a means of maintaining the blood glucose within its normal range.

Glucose that is not needed for energy is removed from the blood and stored as glycogen or converted to fat. When tissues such as those in the liver and skeletal muscle become saturated with glycogen, the additional glucose is converted into fatty acids by the liver and then stored as triglycerides in fat cells. When blood glucose levels fall below normal, as they do between meals, glycogen is broken down by a process called glycogenolysis, and glucose is released. Although skeletal muscle has glycogen stores, it lacks the enzyme glucose-6-phosphatase that allows glucose to be broken down sufficiently to pass through the cell membrane and enter the bloodstream, limiting its usefulness to the muscle cell.

In addition to mobilizing its glycogen stores, the liver synthesizes glucose from amino acids, glyceral, and lactic acid in a process called gluconeogenesis. This glucose may be released directly into the circulation or stored as glycogen.

Fat Metabolism

Fat is the most efficient form of fuel storage, providing 9 kcal/g of stored energy, compared with the 4 kcal/g provided by carbohydrates and proteins. Fats make up a significant portion of a traditional American diet. Therefore, the use of fats by the body for energy is as important as the use of carbohydrates. In addition, many of the carbohydrates consumed in the diet are converted to triglycerides for storage in adipose tissue.

A triglyceride contains three fatty acids linked by a glycerol molecule. The mobilization of fatty acids for use as an energy source is facilitated by the action of enzymes (lipases) that break triglycerides into a glycerol molecule and three fatty acids. The glycerol molecule can enter the glycolytic pathway and be used along with glucose to produce energy, or it can be used to produce glucose. The fatty acids are transported to tissues where they are used for energy. Almost all body cells, with the exception of the brain, nervous tissue, and red blood cells, can use fatty acids interchangeably with glucose for energy.

Although many cells use fatty acids as a fuel source, fatty acids cannot be converted to the glucose needed by the brain for energy.

A large share of the initial degradation of fatty acids occurs in the liver, especially when excessive amounts of fatty acids are being used for energy. The liver uses only a small amount of the fatty acids for its own energy needs; it converts the rest into ketones and releases them into the blood. In situations that favor fat breakdown, such as DM and fasting, large amounts of ketones are released into the bloodstream. Because ketones are organic acids, they cause ketoacidosis when they are present in excessive amounts.

Protein Metabolism

Proteins are essential for the formation of all body structures, including genes, enzymes, contractile structures in muscle, matrix of bone, and hemoglobin of red blood cells. Amino acids are the building blocks of proteins. Significant quantities of amino acids are present in body proteins. Unlike glucose and fatty acids, there is only a limited facility for the storage of excess amino acids in the body. Most of the stored amino acids are contained in body proteins. Amino acids in excess of those needed for protein synthesis are converted to fatty acids, ketones, or glucose and then stored or used as metabolic fuel.

Because fatty acids cannot be converted to glucose, the body must break down proteins and use the amino acids as a major substrate for gluconeogenesis during periods when metabolic needs exceed food intake.
**Glucose-Regulating Hormones**

The hormonal control of blood glucose resides largely with the endocrine pancreas. The pancreas is made up of two major tissue types—the acini and the islets of Langerhans (Fig. 50.2). The acini secrete digestive juices into the duodenum, whereas the islets of Langerhans secrete hormones into the blood. Each islet is composed of beta cells that secrete insulin and amylin, alpha cells that secrete glucagon, and a small number of delta cells that secrete somatostatin. In addition, at least one other type of cell, the PP cell, is present in small numbers in the islets and secretes a hormone of uncertain function called *pancreatic polypeptide*. This less understood hormone is involved in various digestive functions and may play a role in regulating feeding behavior.

**Insulin**

Although several hormones are known to increase blood glucose levels, insulin is the only hormone known to have a direct effect in lowering blood glucose levels. The actions of insulin are threefold:

1. It promotes glucose uptake by target cells and provides for glucose storage as glycogen.
2. It prevents fat and glycogen breakdown.
3. It inhibits gluconeogenesis and increases protein synthesis (Table 50.1).

gluconeogenesis, or the building of glucose from new sources, mainly amino acids.\textsuperscript{3} When sufficient glucose and insulin are present, protein breakdown is minimal because the body is able to use glucose and fatty acids as a fuel source. In children and adolescents, insulin is needed for normal growth and development.\textsuperscript{4}

The active form of insulin is composed of two polypeptide chains—an A chain and a B chain (Fig. 50.3). Active insulin is formed in the beta cells from a larger molecule called proinsulin.\textsuperscript{3} The active form of insulin is produced by modification of proinsulin by cleavage of the C-peptide structure linking the A and B chains.\textsuperscript{3} The C-peptide chains can be measured clinically, and this measurement can be used to study beta cell function. For example, people with type 2 diabetes with very little or no remaining beta cell function will have very low or nonexistent levels of C-peptide in the blood. Thus, these people will likely need insulin replacement for treatment.

Blood glucose levels regulate the release of insulin from the pancreatic beta cells. Insulin levels increase as blood glucose levels rise and decrease when blood glucose levels decline. Blood glucose enters the beta cell by a specific glucose transporter (GLUT-2). It is then phosphorylated, by an enzyme called glucokinase, to form adenosine triphosphate (ATP), which is needed to close the potassium channels and depolarize the cell. Depolarization, in turn, results in opening of the calcium channels and insulin secretion.\textsuperscript{3}

Secretion of insulin after exposure to glucose occurs in a biphasic, pulsatile fashion with an initial rapid release of preformed insulin followed by a more sustained release of newly synthesized insulin.\textsuperscript{3} After exposure to glucose, which is a nutrient secretagogue, a first-phase release of stored preformed insulin occurs, followed by a second-phase release of newly synthesized insulin. Diabetes may result from dysregulation or deficiency in the steps of this process (Fig. 50.4). Insulin secreted by the beta cells enters the portal circulation and travels directly to the liver, where approximately 50\% is used or degraded. Insulin, which is rapidly bound to peripheral tissues or destroyed by the liver or kidneys, has a half-life of approximately 15 minutes once it is released into the general circulation.\textsuperscript{3} To initiate its effects on target tissues, insulin binds to a membrane receptor.

\end{figure}
Glucagon secretion is regulated by blood glucose. A decrease in blood glucose concentration to a hypoglycemic level produces an immediate increase in glucagon secretion, and an increase in blood glucose to hyperglycemic levels produces a decrease in glucagon secretion. Glucagon levels also increase during strenuous exercise as a means of preventing a decrease in blood glucose.

**Amylin, Somatostatin, and Gut-Derived Hormones**

Islet amyloid polypeptide, or amylin, is a hormone that is secreted by the beta cells along with insulin and C-peptide. Plasma levels of amylin increase after a meal or a glucose infusion. Amylin appears to work with insulin to regulate plasma glucose concentrations in the blood stream, suppressing postprandial secretion of glucagon and slowing gastric emptying.

Somatostatin is a polypeptide hormone containing only 14 amino acids that acts locally in the islets of Langerhans. High-fat, high–carbohydrate, and particularly high-protein meals stimulate the release of somatostatin; insulin inhibits its release. Somatostatin also decreases gastrointestinal activity after ingestion of food. Somatostatin’s contribution toward insulin and glucagon release is not well established and the regulation of this hormone’s release has proven difficult to study due to the small number of islet cells that produce this hormone.

Several gut-derived hormones have been identified as having what is termed an incretin effect, meaning that they increase insulin release after an oral nutrient load. This suggests that gut-derived factors can stimulate insulin secretion after a predominantly carbohydrate meal. The incretin effect accounts for approximately 50% of the insulin secreted in response to an oral nutrient load.

**Counter-Regulatory Hormones**

Other hormones that can affect blood glucose include the catecholamines, growth hormone, and the glucocorticoids. These hormones, along with glucagon, are sometimes called counter-regulatory hormones because they counteract the storage functions of insulin in regulating blood glucose levels during periods of fasting, exercise, and other situations that either limit glucose intake or deplete glucose stores.

Epinephrine. Epinephrine from the adrenal medulla helps to maintain blood glucose levels during periods of stress. Epinephrine, a catecholamine, has the potent effect of causing glycogenolysis in the liver, thus causing large quantities of glucose to be released into the blood. It also inhibits insulin release from the beta cells and thereby decreases the movement of glucose into muscle cells, while at the same time increasing the breakdown of muscle glycogen stores. Although the glucose that is released from muscle glycogen cannot be...
released into the blood, the mobilization of these stores for muscle use conserves blood glucose for use by other tissues such as the brain and the nervous system. Epinephrine also has a direct lipolytic effect on adipose cells, thereby increasing the mobilization of fatty acids for use as an energy source. The blood glucose–elevating effect of epinephrine is also an important homeostatic mechanism during periods of hypoglycemia.

**Growth Hormone.** Growth hormone has many metabolic effects. It increases protein synthesis in all cells of the body, mobilizes fatty acids from adipose tissue, and antagonizes the effects of insulin. The most important physiologic effect of growth hormone is stimulation of longitudinal growth by increasing the formation of new bone and cartilage. The secretion of growth hormone is normally inhibited by insulin and increased levels of blood glucose. During periods of fasting, when both blood glucose levels and insulin secretion fall, growth hormone levels increase. Exercise such as running and cycling, and various stresses, including anesthesia, fever, and trauma, increase growth hormone levels. Chronic hypersecretion of growth hormone, as occurs in acromegaly, can lead to glucose intolerance and the development of DM. The production of growth hormone is pulsatile and circulating levels increase during childhood, peak at puberty, and decrease with aging.

**Glucocorticoid Hormones.** The glucocorticoid hormones, which are synthesized in the adrenal cortex along with other corticosteroid hormones, are critical to survival during periods of fasting and starvation. They stimulate gluconeogenesis by the liver, producing an increase in hepatic glucose production. The main role of these hormones is to increase blood glucose. Glucocorticoids also modulate the immune response, exerting an overall anti-inflammatory response. Synthetic use of glucocorticoids, such as prednisone, is a common treatment for inflammatory diseases with a subsequent impact on blood glucose levels.

There are several steroid hormones with glucocorticoid activity. The most important of these is cortisol, which accounts for approximately 95% of all glucocorticoid activity. Almost any type of stress, whether physical or emotional, causes an immediate increase in adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary gland, followed within minutes by greatly increased secretion of cortisol by the adrenal gland. Hypoglycemia is a potent stimulus for cortisol secretion.

**IN SUMMARY**

The body uses glucose, fatty acids, and other substrates as fuel to satisfy its energy needs. Body tissues, including the brain, which depends exclusively on glucose for its energy, obtain glucose from the blood. The liver stores excess glucose as glycogen and it uses gluconeogenesis to convert amino acids, lactate, and glycerol into glucose during fasting or when glucose intake does not keep pace with demand. Blood glucose levels reflect the difference between the amount of glucose released into the circulation by the liver and the amount of glucose removed from the blood by body tissues. Fats, which serve as an efficient source of fuel for the body, are stored in adipose tissue as triglycerides, which consist of three fatty acids linked to a glycerol molecule. In situations that favor fat breakdown, such as fasting or DM, the triglycerides in adipose tissue are broken down and the fatty acids are used as fuel or transported to the liver, where they are converted to ketones. Proteins, which are made up of amino acids, are essential for the formation of all body structures. Unlike glucose and fatty acids, there is only a limited facility for storage of excess amino acids in the body. Because fatty acids cannot be converted to glucose, the body must break down proteins and use the amino acids for gluconeogenesis.

Energy metabolism is controlled by a number of hormones, including insulin, glucagon, epinephrine, growth hormone, and the glucocorticoids. Of these hormones, only insulin has the effect of lowering the blood glucose level. Insulin’s blood glucose–lowering action results from its ability to increase the transport of glucose into body cells and decrease hepatic production and release of glucose into the bloodstream. Insulin also has the effect of decreasing lipolysis and the use of fats as a fuel source. Other hormones—glucagon, epinephrine, growth hormone, and the glucocorticoids—maintain or increase blood glucose concentrations and are referred to as counter-regulatory hormones. Glucagon and epinephrine promote glycogenolysis. Glucagon and the glucocorticoids increase gluconeogenesis. Growth hormone decreases the peripheral use of glucose. Epinephrine and glucagon also increase the use of fat for energy by increasing the release of fatty acids from adipose cells.

**DIABETES MELLITUS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the distinguishing features of type 1 and type 2 DM and cite the criteria for gestational diabetes.
- Define the metabolic syndrome and describe its associations with the development of type 2 diabetes.
- Characterize the blood glucose–lowering actions of the hypoglycemic agents used in treatment of type 2 diabetes.
- Name and describe the types (according to duration of action) of insulin.

Diabetes mellitus (DM) refers to a group of common metabolic disorders that share the characteristic of hyperglycemia. Prior to the discovery of insulin in the 1920s, diabetes...
was a fatal disease. The incidence of type 2 diabetes has risen dramatically over the past century and will continue to rise in the United States with the increasing prevalence of obesity, aging of the population, decreasing mortality, and growth of minority populations. Diabetes is a disorder of carbohydrate, protein, and fat metabolism resulting from an imbalance between insulin availability and insulin need. Factors contributing to imbalance include reduced insulin secretion, decreased glucose utilization, and increased glucose production. A person with uncontrolled diabetes is unable to transport glucose into fat and muscle cells. As a result, body cells are starved, and the breakdown of fat and protein is increased to generate alternative fuels.

Classification and Etiology

Although DM clearly is a disorder of insulin availability, it is not a single disease. The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus developed a revised system for the classification of diabetes in 1997 (Chart 50.1). Two broad categories of DM are type 1 and type 2. Type 2 diabetes currently accounts for about 90% to 95% of the cases of diabetes. Other categories of DM are gestational diabetes mellitus (GDM) (i.e., diabetes that develops during pregnancy) and other specific types of diabetes, many of which occur secondary to other conditions (e.g., Cushing syndrome, acromegaly, pancreatitis).

The revised classification system also includes a system for diagnosing diabetes according to stages of glucose intolerance (Table 50.2). The revised criteria recognized a group of people whose glucose levels, although not meeting criteria for diabetes, are, nevertheless, too high to be considered normal. This group of people, labeled together as people with prediabetes, includes impaired glucose tolerance (IGT) and impaired fasting glucose (IFG). A fasting plasma glucose (FPG) of less than 100 mg/dL (5.5 mmol/L) or a 2-hour oral glucose tolerance test (OGTT) result of less than 140 mg/dL is considered normal. IGT reflects abnormal plasma glucose measurements (140 to 199 mg/dL [7.8 to 11.0 mmol/L]) 2 hours after a 75-g oral glucose load. IFG is defined by an elevated FPG concentration (100 to 125 mg/dL [5.6 to 6.9 mmol/L]). IGT and IFG (i.e., prediabetes) categories are associated with increased risk of atherosclerotic heart disease and increased risk of progression to type 2 diabetes. IGT and IFG have different rates of progression to diabetes because of different

*Fasting is defined as no caloric intake for at least 8 hours.
†IFG and IGT are prediabetes states and can occur in isolation or together in a given subject.
‡In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a separate day.
§OGGT with 2-hour measurement of venous plasma or serum glucose after a 75-g carbohydrate load.

FPG, fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGGT, oral glucose tolerance test; DM, diabetes mellitus.

Type 1A Immune-Mediated Diabetes. Type 1A diabetes, commonly referred to simply as type 1 diabetes, is characterized by immune-mediated destruction of beta cells.9 This type of diabetes, formerly called juvenile diabetes, occurs more commonly in young people but can occur at any age.9 The rate of beta cell destruction is quite variable, being rapid in some people and slow in others. The rapidly progressive form is commonly observed in children, but also may occur in adults. The slowly progressive form usually occurs in adults and is sometimes referred to as latent autoimmune diabetes in adults (LADA).

Type 1 diabetes is a catabolic disorder characterized by an absolute lack of insulin, an elevation in blood glucose, and a breakdown of body fats and proteins.9 The absolute lack of insulin in people with type 1 DM means that they are particularly prone to the development of ketoacidosis. One of the actions of insulin is the inhibition of lipolysis (i.e., fat breakdown) and release of free fatty acids (FFA) from fat cells.7 In the absence of insulin, ketosis develops when these fatty acids are released from fat cells and converted to ketones in the liver. Because of the loss of insulin response, all people with type 1A diabetes require exogenous insulin replacement to reverse the catabolic state, control blood glucose levels, and prevent ketosis.9

Type 1A diabetes is thought to be an autoimmune disorder resulting from a genetic predisposition (i.e., diabetogenic genes); an environmental triggering event, such as an infection; and a T-lymphocyte–mediated hypersensitivity reaction against some beta cell antigen. Susceptibility to type 1A DM involves multiple genes. The major susceptibility gene for type 1A DM is located in the human leukocyte antigen (HLA) region on chromosome 6.7 Much evidence has focused on the inherited major histocompatibility complex (MHC) genes on chromosome 6 that encode HLAs. Although the risk of developing type 1 diabetes is increased 10-fold in relatives of people with the disease, the overall risk is relatively low. Approximately 3% to 4% of children develop type 1 diabetes when a parent has the disease.9 Diabetes autoantibodies have been used to predict risk for type 1 diabetes and to classify people with diabetes as having an immune-mediated beta cell destructive process.10

Type 1A diabetes–associated autoantibodies may exist for years before the onset of hyperglycemia. There are two major types of autoantibodies—insulin autoantibodies (IAAs), and islet cell autoantibodies and antibodies directed at other islet autoantigens, including glutamic acid decarboxylase (GAD) and the protein tyrosine phosphatase IA-2.9 Testing for antibodies to GAD or IA-2 and for IAAs using sensitive radiobinding assays can identify more than 85% of cases of new or future type 1 diabetes.10 The appearance of IAAs may precede that of antibodies to GAD or IA-2, and IAAs may be the only antibodies detected at diagnosis in young children.10 These people also may have other autoimmune disorders such as Graves disease, rheumatoid arthritis, and Addison disease. Research continues to investigate the role of diabetes autoantibodies in the future of type 1 diabetes interventions.

The fact that type 1 diabetes is thought to result from an interaction between genetic and environmental factors has led to research into methods directed at prevention and early control of the disease.11 These methods include the identification of genetically susceptible people and early intervention in newly diagnosed people with type 1 diabetes. After the diagnosis of type 1 diabetes, there is often a short period of beta cell regeneration, during which symptoms of diabetes disappear and insulin injections are reduced or not needed. This is sometimes called the honeymoon period. Immune interventions (immunomodulation) designed to interrupt the destruction of beta cells before development of type 1 diabetes are being investigated in various trials.6 Unfortunately, none of the interventions studied to date has shown real clinical utility.6
In the unit opener case study we met Emily Toronto, the 7-year-old diagnosed with type 1 diabetes. Emily had classic symptoms of severe hyperglycemia, the associated dehydration (osmotic diuresis), and metabolic acidosis. Because she was at risk for diabetes, due to her family history, she may have had testing for the presence of diabetes autoantibodies. Regardless of whether Emily has type 1A or type 1B, the treatment of her acute or long-term management is the same. Treatment of her acute needs will be discussed in more detail in the section on diabetic ketoacidosis (DKA).

Type 2 Diabetes Mellitus and the Metabolic Syndrome

Type 2 DM accounts for the majority of cases of diabetes, approximately 90% to 95%. It is a heterogeneous condition that describes the presence of hyperglycemia in association with relative insulin deficiency. Autoimmune destruction of the beta cells does not occur. Although many people with type 2 diabetes are adults and overweight, recent trends indicate type 2 diabetes has become a more common occurrence in obese adolescents and children. Also, people with type 2 diabetes eventually may require insulin. Therefore, the previous terms related to type 2 diabetes, such as adult onset diabetes and non–insulin-dependent diabetes, can generate confusion and are thus obsolete.

Type 2 diabetes has a strong genetic component. A number of genetic and acquired pathogenic factors have been implicated in the progressive impairment of beta cell function in persons with prediabetes and type 2 diabetes. People with one parent with type 2 diabetes have an increased risk for developing the disease. If both parents have the disease, the risk is approximately 40%. Despite strong familial predisposition, the genetics of type 2 diabetes is poorly defined. Research in the field of type 2 diabetes has identified genetic alterations associated with altered insulin secretions, but these studies are ongoing.

The metabolic abnormalities that lead to type 2 diabetes include:

1. Insulin resistance.
2. Deranged secretion of insulin by the pancreatic beta cells.
3. Increased glucose production by the liver (Fig. 50.6).

In contrast to type 1 diabetes, where absolute insulin deficiency is present, people with type 2 diabetes can have high, normal, or low insulin levels. Insulin resistance is the decreased ability of insulin to act effectively on target tissues, especially muscle, liver, and fat. It is the predominant characteristic of type 2 diabetes and results from a combination of factors such as genetic susceptibility and obesity. Table 50.3 compares the characteristics of type 1 and type 2 DM.

Insulin resistance initially stimulates an increase in insulin secretion, often to a level of modest hyperinsulinemia, as the beta cells attempt to maintain a normal blood glucose level. In time, the increased demand for insulin secretion leads to beta cell exhaustion and failure. This results in elevated postprandial blood glucose levels and an eventual increase in glucose production by the liver. Because people with type 2 diabetes do not have an absolute insulin deficiency, they are less prone to ketoacidosis compared to people with type 1 diabetes.

HLA, human leukocyte antigen.

In the basal state, hepatic insulin resistance is manifested by overproduction of glucose despite fasting hyperinsulinemia, with the rate of glucose production being the primary determinant of the elevated FPG in people with type 2 diabetes. Although the insulin resistance seen in people with type 2 diabetes can be caused by a number of factors, it is strongly associated with obesity and physical inactivity.

Specific causes of beta cell dysfunction are unclear but seem to include an initial decrease in the beta cell mass related to genetic or prenatal factors (e.g., intrauterine growth retardation); increased apoptosis or decreased beta cell regeneration; beta cell exhaustion due to long-standing insulin resistance; glucotoxicity (i.e., glucose toxicity–induced beta cell desensitization); lipotoxicity (i.e., toxic effects of lipids on beta cells); and amyloid deposition or other conditions that have the potential to reduce beta cell mass.

**Insulin Resistance and the Metabolic Syndrome.** There is increasing evidence to suggest that insulin resistance not only contributes to the hyperglycemia in people with type 2 diabetes, but may play a role in other metabolic abnormalities. These include obesity, high levels of plasma triglycerides and low levels of high-density lipoproteins (HDL), hypertension, systemic inflammation (as detected by C-reactive protein [CRP] and other mediators), abnormal fibrinolysis, abnormal function of the vascular endothelium, and macrovascular disease (coronary artery, cerebrovascular, and peripheral arterial disease). This constellation of abnormalities is often referred to as the insulin resistance syndrome, syndrome X, or, the preferred term, metabolic syndrome. The clinical signs, laboratory abnormalities, and associated illnesses associated with this syndrome are described in Chart 50.3. Insulin resistance and increased risk of developing type 2 diabetes are also seen in women with polycystic ovary syndrome.

A major factor in people with metabolic syndrome that leads to type 2 diabetes is obesity. Approximately 80% to 90% of people with type 2 diabetes are overweight. Obese people have increased resistance to the action of insulin and impaired suppression of glucose production by the liver, resulting in both hyperglycemia and hyperinsulinemia. The type of obesity is an important consideration in the development of type 2 diabetes, with visceral obesity being associated with a greater degree of insulin resistance than peripheral obesity.

**CHART 50.3 FREQUENTLY OBSERVED CONCOMITANTS OF THE INSULIN RESISTANCE/METABOLIC SYNDROME**

**Clinical Signs**
- Central (upper body) obesity with increased waist circumference
- Acanthosis nigricans (hypertrophic, hyper pigmented skin changes)

**Laboratory Abnormalities**
- Elevated fasting and/or postprandial glucose
- Insulin resistance with hyperinsulinemia
- Dyslipidemia characterized by increased triglycerides and low HDL cholesterol
- Abnormal thrombolysis
- Hyperuricemia
- Endothelial and vascular smooth muscle dysfunction
- Albuminuria

**Comorbid Illnesses**
- Hypertension
- Atherosclerosis
- Hyperandrogenism with polycystic ovary syndrome

Chapter 50  Diabetes Mellitus and the Metabolic Syndrome

of type 2 diabetes. It has been found that people with upper body (or central) obesity are at greater risk for developing type 2 diabetes and metabolic disturbances than people with lower body (or peripheral) obesity. Waist circumference and waist–hip ratio (WHR), which are both surrogate measures of central obesity, have been shown to correlate well with insulin resistance. For management, weight loss with an initial loss of 5% to 10% of body weight should be incorporated into the treatment plan, as well as addressing the diabetes and other related metabolic abnormalities.

It has been theorized that the insulin resistance and increased glucose production in obese people with type 2 diabetes may stem from an increased concentration of FFAs. This has several consequences:

1. Excessive and chronic elevation of FFAs can cause beta cell dysfunction (lipotoxicity).
2. FFAs act at the level of the peripheral tissues to cause insulin resistance and glucose underutilization by inhibiting glucose uptake and glycogen storage.
3. The accumulation of FFAs and triglycerides reduces hepatic insulin sensitivity, leading to increased hepatic glucose production and hyperglycemia, especially in the fasting state.

Thus, the increase in FFAs that occurs in obese people (especially visceral obesity) with a genetic predisposition to type 2 diabetes may eventually lead to beta cell dysfunction, increased insulin resistance, and greater hepatic glucose production. A further consequence is the diversion of excess FFAs to nonadipose tissues, including the liver, skeletal muscle, heart, and pancreatic beta cells. In the liver, the uptake of FFAs from the portal blood can lead to hepatic triglyceride accumulation and nonalcoholic fatty liver disease.

KEY POINTS

DIABETES MELLITUS

- DM is a disorder of carbohydrate, fat, and protein metabolism brought about by impaired beta cell synthesis or release of insulin, or the inability of tissues to use insulin.
- Type 1 diabetes results from loss of beta cell function and an absolute insulin deficiency.
- Type 2 diabetes results from impaired ability of the tissues to use insulin (insulin resistance) accompanied by a relative lack of insulin or impaired release of insulin in relation to blood glucose levels (beta cell dysfunction).

Other Specific Types of Diabetes

A small percentage of the overall number of cases of diabetes consist of specific types of diabetes associated with certain other conditions and syndromes. Such diabetes can occur with pancreatic disease or the removal of pancreatic tissue and with endocrine diseases, such as acromegaly, Cushing syndrome, or pheochromocytoma. Endocrine disorders that produce hyperglycemia do so by increasing the hepatic production of glucose or decreasing the cellular use of glucose. Several specific types of diabetes are associated with monogenic defects in beta cell function. Other causes for diabetes can be genetic defects in beta cell function or insulin secretion, drug treatment, or chemicals.

Several medications commonly used for treatment of other diseases can cause significant alterations in glucose. For example, diuretics, specifically thiazide and loop diuretics, can elevate blood glucose. These diuretics increase potassium loss, which is thought to impair beta cell release of insulin. Other drugs and therapies known to cause hyperglycemia include diazoxide, glucocorticoids, oral contraceptives, antipsychotic agents, and total parenteral nutrition (i.e., hyperalimentation). Drug-related increases in blood glucose usually are reversed after the drug has been discontinued although many of them are taken for chronic conditions and must be considered in the long-term treatment of glucose control.

Gestational Diabetes

GDM is any degree of glucose intolerance that occurs initially during pregnancy. GDM affects approximately 7% of pregnancies. It occurs most commonly in African American, Hispanic/Latino American, and American Indian women. It most frequently affects:

- Women with a family history of diabetes.
- Women with a history of stillbirth or spontaneous abortion.
- Women who had a newborn with fetal anomaly in a previous pregnancy.
- Women who had a previous large- or heavy-for-date infant.
- Women who are obese.
- Women who are of advanced maternal age.
- Women who have had five or more pregnancies.

Diagnosis. In light of the increasing incidence of obesity and onset of type 2 diabetes in younger populations, the ADA established revised guidelines for GDM. A recent multinational, epidemiologic study showed the risk of adverse maternal and neonatal outcomes rises in direct relation to the mother’s glucose level. This study, the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study, influenced the new guidelines that state all women should be tested for GDM between 24 and 28 weeks using a 75-g OGTT. The ingestion of glucose is followed by a venous blood sample for glucose concentration at 1- and 2-hour intervals (ADA). If the plasma glucose level is greater than 92 mg/dL (5.1 mmol/L) fasting, 180 (10.0 mmol/L) at 1 hour or 153 mg/dL (8.5 mmol/L) at 2 hours, a diagnosis of GDM is made (Table 50.4). These new standards will most likely cause a significant increase in the reported number of women with GDM but will support improved glycemic control.
risk factors for diabetes should be tested at their first prenatal visit and would then be classified as type 2 diabetes if indicated. Diagnosis and careful medical management are essential because women with GDM are at higher risk for complications of pregnancy, mortality, and fetal abnormalities. Fetal abnormalities include macrosomia (i.e., large body size), hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia.

**Treatment.** Treatment of GDM includes close observation of mother and fetus because even mild hyperglycemia has been shown to be detrimental to the fetus. Maternal fasting and postprandial blood glucose levels should be measured regularly. Fetal surveillance depends on the degree of risk for the fetus. The frequency of growth measurements and determinations of fetal distress depends on available technology and gestational age. All women with GDM require nutritional guidance because nutrition is the cornerstone of therapy. The nutrition plan should provide the necessary nutrients for maternal and fetal health, result in normoglycemia and proper weight gain, and prevent ketosis. Not all women are able to maintain normoglycemia with a nutrition plan alone. For those who need additional support, medication may be warranted. Insulin has long been the treatment of choice when endogenous insulin production is inadequate. In addition, the oral agent glyburide (Glynase, Micronase, Diabeta) is now deemed safe for use in GDM. Self-monitoring of blood glucose levels is essential.

Women with GDM have a 35% to 65% risk of developing type 2 diabetes within 20 years of their pregnancy. Predictors of future diabetes or prediabetes include maternal obesity, elevated FPG on OGTT, and family history. Women in whom GDM is diagnosed should be followed after delivery to detect diabetes early in its course.

### Clinical Manifestations of Diabetes Mellitus

DM may have a rapid or an insidious onset. In type 1 diabetes, signs and symptoms often arise suddenly. Type 2 diabetes usually develops more insidiously, often existing for years without detection. Its presence may be detected during a routine medical examination or when a person seeks medical care for other reasons.

The most commonly identified signs and symptoms of diabetes are referred to as the *three polys*:

1. Polyuria (i.e., excessive urination)
2. Polydipsia (i.e., excessive thirst)
3. Polyphagia (i.e., excessive hunger)

These three symptoms are closely related to the hyperglycemia and glycosuria of diabetes. Glucose is a small, osmotically active molecule. When blood glucose levels are sufficiently elevated, the amount of glucose filtered by the glomeruli of the kidney exceeds the amount that can be reabsorbed by the renal tubules. This results in glycosuria accompanied by large losses of water in the urine. Thirst results from the intracellular dehydration that occurs as blood glucose levels rise and water is pulled out of body cells, including those in the hypothalamic thirst center. This early symptom may be easily overlooked in people with type 2 diabetes, particularly in those who have had a gradual increase in blood glucose levels. Polyphagia is usually not present in people with type 2 diabetes. In type 1 diabetes, it probably results from cellular starvation and the depletion of cellular stores of carbohydrates, fats, and proteins.

Weight loss despite normal or increased appetite is a common occurrence in people with uncontrolled type 1 diabetes. The cause of weight loss is twofold. First, loss of body fluids results from osmotic diuresis. Vomiting may exaggerate the fluid loss in ketoacidosis. Second, body tissue is lost because the lack of insulin forces the body to use its fat stores and cellular proteins as sources of energy. In terms of weight loss, there is often a marked difference between type 2 diabetes and type 1 diabetes. Weight loss is a frequent phenomenon in people with uncontrolled type 1 diabetes, whereas many people with uncontrolled type 2 diabetes often have problems with obesity. Despite this fact, those with undiagnosed type 2 diabetes may experience unexplained weight loss because circulating insulin is not being utilized, leading to the depletion of energy sources.

Other signs and symptoms of hyperglycemia include recurrent blurred vision, fatigue, and skin infections. In type 2 diabetes, these are often the symptoms that prompt a person to seek medical treatment. Blurred vision develops as the lens and retina are exposed to hyperosmolar fluids. Lowered plasma volume produces weakness and fatigue. Chronic skin infections can occur and are more common in people with type 2 diabetes. Hyperglycemia and glycosuria favor the growth of yeast organisms.

### Diagnostic Tests

The diagnosis of DM is confirmed through the use of laboratory tests that measure blood glucose levels (see Table 50.2). Testing for diabetes should be considered in all people 45 years of age and older. Testing should be considered at a younger
age in people who are obese, have a first-degree relative with diabetes, are members of a high-risk group, have delivered an infant weighing more than 9 lb or been diagnosed with GDM, have hypertension or hyperlipidemia, or have met the criteria for IGT or IFG (i.e., prediabetes) on previous testing.8

Blood Tests

Blood glucose measurements are used in both the diagnosis and management of diabetes. Diagnostic tests include the FPG, casual plasma glucose, and the glucose tolerance test. Glycosylated hemoglobin (A1C, previously termed HbA1c) was added to the list of diagnostic test for diabetes in 2009.8 Previously, A1C had been used only as measure of glucose control over time. Laboratory and capillary or finger-stick glucose tests are used for glucose management in people with diagnosed diabetes. Table 50.5 lists A1C values with correlations of mean plasma glucose levels. People with diabetes should be knowledgeable about their A1C value and the correlation and associations with long-term glycemic control.

Fasting Blood Glucose Test. The FPG has long been the preferred diagnostic test when a fasting blood sample is available.8 Glucose levels are measured after food has been withheld for at least 8 hours. An FPG level below 100 mg/dL (5.6 mmol/L) is considered normal (see Table 50.2). A level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L) is significant and is defined as impaired fasting glucose. If the FPG level is 126 mg/dL (7.0 mmol/L) diabetes is diagnosed.5,8

Casual Blood Glucose Test. A casual plasma glucose is one that is done without regard to the time of the last meal. A casual plasma glucose concentration that is unequivocally elevated (≥200 mg/dL [11.1 mmol/L]) in the presence of classic symptoms of diabetes such as polydipsia, polyphagia, polyuria, and blurred vision is diagnostic of DM at any age.5,8

Oral Glucose Tolerance Test. The OGTT is an important screening test for diabetes. The test measures the body’s ability to store glucose by removing it from the blood. In men and women, the test measures the plasma glucose response to 75 g of concentrated glucose solution at selected intervals, usually 1 and 2 hours. In people with normal glucose tolerance, blood glucose levels return to normal within 2 to 3 hours after ingestion of a glucose load, in which case it can be assumed that sufficient insulin is present to allow glucose to leave the blood and enter body cells. Because a person with diabetes lacks the ability to respond to an increase in blood glucose by releasing adequate insulin to facilitate storage, blood glucose levels rise above those observed in normal people and remain elevated for longer periods (see Table 50.2).3

Capillary Blood Glucose Monitoring. Technological advances have provided the means for monitoring blood glucose levels by using a drop of capillary blood. This procedure has provided health professionals with a rapid and economical means for monitoring blood glucose and has given people with diabetes a way of maintaining near-normal blood glucose levels through self-monitoring of blood glucose. These methods use a drop of capillary blood obtained by pricking the finger or forearm with a special needle or small lancet. The drop of capillary blood is placed on or absorbed by a reagent strip, and glucose levels are determined electronically using a glucose meter. Alternate site testing, using locations other than fingertips, should be cautioned at time of suspected hypoglycemia due to wide discordance in values at times of rapid glucose fluctuations.18

Laboratory tests that use plasma for measurement of blood glucose give results that are 10% to 15% higher than the finger-stick method, which uses whole blood.18 Most monitors approved for home use calibrate blood glucose readings to plasma values for easier comparison to lab values. Continuous glucose monitoring systems are becoming available to fine-tune glucose management. The various systems have small catheters implanted in the subcutaneous tissue to provide frequent samples. Endocrine centers are increasingly using this technology in selected people to achieve optimal glycemic management. The variety and accuracy of these systems is continually improving. However, finger-stick glucose monitoring remains the standard of care.18

Glycated Hemoglobin Testing. Glycated hemoglobin, also referred to as glycohemoglobin, glycosylated hemoglobin, HbA1c, or A1C (the preferred term), is a term used to describe hemoglobin into which glucose has been incorporated. Hemoglobin normally does not contain glucose when it is released from the bone marrow. During its 120-day life span in the red blood cell, hemoglobin normally becomes glycated to form hemoglobins A1a and A1b (2% to 4%), and A1C (4% to 6%). Because glucose entry into red blood cells is not insulin dependent, the rate at which glucose becomes attached to the hemoglobin molecule depends on blood glucose levels. Glycosylation is essentially irreversible, and the level of A1C present in the blood provides an index of blood glucose levels over the previous 6 to 12 weeks.9 In uncontrolled diabetes or diabetes with hyperglycemia, there is an increase in the level of A1C.

The ADA recommends initiating corrective measures for A1C levels greater than 7%. However, the goal has been redefined as lowering the A1C to less than 7.0%, or even achieving normal glycemic levels of less than 6.0%. Recommendations to people regarding optimal control take into account many factors including any associated risk of injury. A1C has been a key indicator for long-term control as it has strong predictive value for complications of diabetes. Many practitioners welcome its more recent inclusion as a diagnostic tool for diabetes.

**Urine Tests**

The ease, accuracy, and convenience of self-administered blood glucose monitoring techniques have made urine testing for glucose obsolete for most people with diabetes. These tests only reflect urine glucose levels and are influenced by such factors as the renal threshold for glucose, fluid intake and urine concentration, urine testing methodologies, and some drugs. It is recommended that all people with diabetes self-monitor their blood glucose. Urine ketone determinations remain an important part of monitoring diabetic control, particularly in people with type 1 diabetes who are at risk for development of ketoacidosis, and in pregnant diabetic women to check the adequacy of nutrition and glycemic control.11

Emily and her family will need to learn how and when to check urine testing for ketones as well as using a finger-stick machine to monitor blood glucose levels.

**Treatment**

The desired outcome of glycemic control in both type 1 and type 2 diabetes is normalization of blood glucose as a means of preventing short- and long-term complications. Treatment plans involve medical nutrition therapy, exercise, and antidiabetic agents. People with type 1 diabetes require insulin therapy from the time of diagnosis. Weight loss and dietary management may be sufficient to control blood glucose levels in some people with type 2 diabetes who adopt lifestyle changes long term. However, most require follow-up care because insulin secretion from the beta cells may decrease or insulin resistance may persist or worsen, in which case oral antidiabetic agents are prescribed.

Among the methods used to achieve these treatment goals are diabetes self-management education (DSME) and problem solving. Individual treatment goals should take into account the person’s age and other disease conditions, the person’s capacity to understand and carry out the treatment regime, and socioeconomic factors that might influence compliance with the treatment plan.13 Long-term glycemic management is critical to the delay and prevention of diabetes complications and is heavily dependent on the person’s knowledge of the multiple components of care.

**Dietary Management**

Dietary management is a founding component of diabetes care. The term medical nutrition therapy, which was introduced in 1994 by the ADA, is defined as the use of specific nutrition services to treat an illness, injury, or condition and involves both the assessment of the nutrition status and the treatment measure, including nutrition therapy, counseling, and use of specialized nutritional supplements.2 Previously considered rigid and complex, today’s medical nutrition therapy (MNT) is more evidence-based and individualized. The diabetic diet has undergone marked changes over the years, particularly in the recommendations for distribution of calories among carbohydrates, proteins, and fats. There is no longer a specific diabetic or ADA diet but rather a dietary prescription based on nutrition assessment and treatment goals. A coordinated team effort, including the person with diabetes, is needed to individualize the nutrition plan.

Goals and principles of diet therapy differ between type 1 and type 2 diabetes and between lean and obese people. Integral to diabetes management is a prescribed plan for nutrition therapy.2 Therapy goals include maintenance of near-normal blood glucose levels, achievement of optimal lipid levels, adequate calories to maintain and attain reasonable weights, prevention and treatment of chronic diabetes complications, and improvement of overall health through optimal nutrition. Initial guidelines may include 45% to 60% carbohydrate, 20% to 35% fat, and 10% to 20% protein.2

For a person with type 1 diabetes, the usual food intake is assessed and used as a basis for adjusting insulin therapy to fit with the person’s lifestyle. Eating consistent amounts and types of food at specific and routine times are encouraged. Home blood glucose provide for immediate feedback on nutritional intake, glycemic response, and influence of physical activity.19 For those with type 1 diabetes, improvements in insulin regimes and increasing use of insulin pumps allow for more flexibility with meals.18

Most people with type 2 diabetes are overweight. Nutrition therapy goals focus on achieving glucose, lipid, and blood pressure goals, and weight loss if indicated. Mild to moderate weight loss (5% to 10% of total body weight) has been shown to improve diabetes control, even if desirable weight is not achieved.20 Dietary considerations for cardiac risk factors also play a role in individualizing care for those with type 2 diabetes. National dietary guidelines for saturated fat, sodium, and fiber also play a role in dietary planning for those with diabetes.19 The registered dietitian plays an essential role in the diabetes care team and is able to select from a variety of methods such as carbohydrate counting, food exchanges, healthy food choices, glycemic index, and total available glucose to tailor the meal plan to meet individual needs. Simpler recommendations have been associated with improved client understanding and dietary adherence. Carbohydrate counting uses product label information that is easily available to people with diabetes.2 Regardless of food source, total grams of carbohydrate are counted, placing an emphasis on the nutrient that most affects blood glucose control.
**Exercise**

The benefits of exercise are numerous in relation to diabetes and associated conditions. Cardiovascular fitness and psychological well-being are desirable for all people but for many people with type 2 diabetes, the benefits of exercise include a decrease in body fat, better weight control, and improvement in insulin sensitivity. Exercise is so important in diabetes management that a planned program of regular exercise usually is considered an integral part of the therapeutic regimen for every person with diabetes. In general, sporadic exercise has only transient benefits. A regular exercise or training program is the most beneficial; it is better for cardiovascular conditioning and can maintain a muscle–fat ratio that enhances peripheral insulin receptivity.

In people with diabetes, the beneficial effects of exercise are accompanied by an increased risk of hypoglycemia, especially for those taking insulin injections. Although muscle uptake of glucose increases significantly, the ability to maintain blood glucose levels is hampered by failure to suppress the absorption of injected insulin and activate the counter-regulatory mechanisms that maintain blood glucose. Not only is there an inability to suppress insulin levels, but insulin absorption may increase. This increased absorption is more pronounced when insulin is injected into the subcutaneous tissue of the exercised muscle, but it occurs even when insulin is injected into other body areas. Even after exercise ceases, insulin’s lowering effect on blood glucose continues. In some people with type 1 diabetes, the symptoms of hypoglycemia occur several hours after cessation of exercise, perhaps because subsequent insulin doses (in people using multiple daily insulin injections) are not adjusted to accommodate the exercise-induced decrease in blood glucose. The cause of hypoglycemia in people who do not administer a subsequent insulin dose is unclear. It may be related to the fact that the liver and skeletal muscles increase their uptake of glucose after exercise as a means of replenishing their glycogen stores, or that the liver and skeletal muscles are more sensitive to insulin during this time. People with diabetes should be aware that delayed hypoglycemia can occur after exercise and that they may need to alter their diabetes medication dose, their carbohydrate intake, or both.

Although of benefit to people with diabetes, exercise must be weighed on the risk–benefit scale. Before beginning an exercise program, persons with diabetes should undergo an appropriate evaluation for macrovascular and microvascular disease. The goal of exercise is safe participation in activities consistent with a person’s lifestyle. As with nutrition guidelines, exercise recommendations need to be individualized. Each person should have goals, which include amounts of exercise, duration of exercise, blood glucose levels before initiation of exercise, and problem-solving skills. Considerations include the potential for hypoglycemia, hyperglycemia, ketosis, cardiovascular ischemia and arrhythmias (particularly silent ischemic heart disease), exacerbation of proliferative retinopathy, and lower extremity injury. For people with type 1 diabetes who exercise during periods of poor control (i.e., when blood glucose is elevated, exogenous insulin levels are low, and ketonemia exists), blood glucose and ketones rise to even higher levels because the stress of exercise is superimposed on preexisting insulin deficiency and increased counter-regulatory hormone activity.

**Oral and Injectable Antidiabetic Medications**

The last few years have seen not only new medications for diabetes treatment, but new categories of medications. No longer are the choices oral agents or insulin. Medications to treat diabetes now include newer injectable antidiabetic agents (e.g., amylin analogs and glucagon-like peptide-1 [GLP-1] analogs). Because people with type 1 diabetes are deficient in insulin, they are in need of exogenous insulin replacement therapy from the start. People with type 2 diabetes can have increased hepatic glucose production; decreased peripheral utilization of glucose; decreased utilization of ingested carbohydrates; and, over time, impaired insulin secretion and excessive glucagon secretion from the pancreas. The antidiabetic agents used in the treatment of type 2 diabetes attack each one of these areas and sometimes all. If good glycemic control cannot be achieved with one or a combination of antidiabetic agents, insulin can be added or used by itself.

Oral antidiabetic agents fall into five categories: (1) insulin secretagogues (i.e., sulfonylureas, repaglinide, and nateglinide), (2) biguanides, (3) α-glucosidase inhibitors, (4) dipeptidyl peptidase-4 (DPP-4) enzyme inhibitors, (5) thiazolidinediones (TZDs) (Table 50.6). In addition, a GLP-1 agonist and amylin agonist in injectable formulations are now widely used.
Insulin Secretagogues: Sulfonylureas. The sulfonylureas were discovered accidentally in 1942, when scientists noticed that one of the sulfonamide drugs being developed at the time caused hypoglycemia. These drugs reduce blood glucose by stimulating the release of insulin from beta cells in the pancreas. These agents are effective only when some residual beta cell function remains. The sulfonylureas act by binding to a high-affinity sulfonylurea receptor on the beta cell that is linked to an ATP-sensitive potassium channel.6

The sulfonylureas are used in the treatment of type 2 diabetes and cannot be substituted for insulin in people with type 1 diabetes, who have an absolute insulin deficiency. The sulfonylureas traditionally are grouped into first- and second-generation agents (see Table 50.6). These agents differ in dosage and duration of action. The second-generation drugs (e.g., glyburide, glipizide, glimepiride) are considerably more potent that the first-generation drugs and are more widely prescribed than the first-generation agents.5

Because the sulfonylureas increase insulin levels and the rate at which glucose is removed from the blood, it is important to recognize that they can cause hypoglycemic reactions. This problem is more common in elderly people with impaired hepatic and renal function who take the longer-acting sulfonylureas. At one time sulfonylureas were a mainstay of treatment for type 2 diabetes. With the increase in approaches to pharmacologic treatment of diabetes, agents with less threat of hypoglycemia may be more desirable.15

Insulin Secretagogues: Repaglinide and Nateglinide. Repaglinide and nateglinide are nonsulfonylurea insulin secretagogues that require the presence of glucose for their main action. These agents exert their action by

<td>closing the ATP-dependent potassium channel in the beta cells. Insulin release is glucose dependent and diminishes at low glucose levels. These agents, which are rapidly absorbed from the gastrointestinal tract, are taken shortly before meals (repaglinide 15 to 30 minutes and nateglinide 1 to 30 minutes) to address postprandial glucose excursion by helping to restore first-phase insulin response. Both repaglinide and nateglinide can produce hypoglycemia; thus, proper timing of meals in relation to drug administration is essential.</td>

†2010—Restricted use only status by the FDA due to association with increased risk of myocardial infarction.

Biguanides. Currently metformin (Glucophage) is the only biguanide in this category. Metformin inhibits hepatic glucose production and increases the sensitivity of peripheral tissues to the actions of insulin. Because metformin does not stimulate insulin secretion, it does not produce hypoglycemia as a side effect. Secondary benefits of metformin therapy include weight loss and improved lipid profiles. Whereas the primary action of the sulfonylurea drugs is to increase insulin secretion, metformin exerts its beneficial effects on glycemic control through increased peripheral use of glucose and decreased hepatic glucose production (main effect). To decrease the risk of lactic acidosis, metformin is contraindicated in people with elevated serum creatinine levels (a test of renal function), clinical and laboratory evidence of hepatic disease, and any condition associated with hypoxemia or dehydration. Because metformin is generally well tolerated, effective, and has some secondary benefits, it has become a commonly prescribed medication for type 2 diabetes. Metformin has also been studied in conjunction with lifestyle modification for the prevention of diabetes in at-risk populations.

α-Glucosidase Inhibitors. In people with type 2 diabetes, sulfonylureas, biguanides, or both may have beneficial effects on FPG levels. However, postprandial hyperglycemia persists in more than 60% of these people and probably accounts for sustained increases in A1C levels. An alternative approach to the problem of postprandial hyperglycemia is the use of drugs such as acarbose and miglitol, inhibitors of α-glucosidase, which is a small intestine brush border enzyme that breaks down complex carbohydrates. By delaying the breakdown of complex carbohydrates, the α-glucosidase inhibitors delay the absorption of carbohydrates from the gut and blunt the postprandial increase in plasma glucose and insulin levels. Although not a problem with monotherapy or combination therapy with a biguanide, hypoglycemia may occur with concurrent sulfonylurea treatment. If hypoglycemia does occur, it should be treated with glucose (dextrose) and not sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

Thiazolidinediones. The TZDs (or glitazones) are the only class of drugs that directly target insulin resistance, a fundamental defect in the pathophysiology of type 2 diabetes. The TZDs improve glycemic control by increasing insulin sensitivity in the insulin-responsive tissues—liver, skeletal muscle, and fat—allowing the tissues to respond to endogenous insulin more efficiently without increased output from already dysfunctional beta cells. Pioglitazone and rosiglitazone are the most potent insulin sensitizers and were approved by the U.S. Food and Drug Administration (FDA) in 1999. Because of the previous problem with liver toxicity in this class of drugs, liver enzymes should be monitored according to guidelines. In addition, rosiglitazone is currently restricted in its use. Studies on rosiglitazone over the last few years associated the drug with an increased risk of myocardial infarction.

In fact, in 2010 the FDA put the use of rosiglitazone on restriction due to increased risk of cardiac events in people treated with this drug. Since then the use of this drug has decreased dramatically and people who continue to use it must enroll in a special program as it will no longer be available at retail pharmacies. This finding was not seen with pioglitazone and it remains approved for use as monotherapy and in combination therapy. However, pioglitazone can cause fluid accumulation and is, therefore, contraindicated in people with New York Heart Association stage III and IV heart failure.

The mechanism of action of the TZDs is complex and not fully understood. The action of the TZDs is associated with binding to the peroxisome proliferator–activated receptor gamma (PPAR-γ) nuclear receptor (Fig. 50.8). Adiponectin is produced by adipocytes and directly sensitizes the body to the actions of insulin and may be a part of the missing link in explaining insulin resistance in persons with type 2 diabetes. The TZDs are thought to decrease insulin resistance, at least in part, by increasing adipocyte production of adiponectin. Additional effects of TZDs are numerous, and include correction of many of the abnormal metabolic features associated with type 2 diabetes.

Dipeptidyl Peptidase-4 Enzyme Inhibitors. DPP-4 inhibitors are a relatively new and emerging classification of drugs, which are grouped in the category of incretin therapy. Incretins are insulinotropic substances released into the circulation by the gastrointestinal tract after a meal, especially one high in carbohydrates. Incretins act by stimulating insulin secretion by the beta cell. In normal people, incretins account for approximately 20% to 60% of insulin secretion after a meal. The main incretins secreted are GLP-1 and glucose-dependent insulinotropic polypeptide (GIP). The enzyme DPP-4 rapidly degrades both GLP-1 and GIP. DPP-4 enzyme inhibitors work by inhibiting the DPP-4 enzyme and increasing GLP-1 and GIP levels, which then increase insulin release. GLP-1 also helps to suppress glucagon release. The first oral agent of this category sitagliptin (Januvia)
was introduced in 2006 and is approved for monotherapy or in combination with other oral antidiabetics. Since that time there are two others—saxagliptin (Onglyza) and, most recently, linagliptin (Tragenta).

Glucagon-Like Peptide-1 (GLP-1) Agonists. The incretin hormones, including GLP-1, are known to play a major role in endogenous glucose control. The action of these hormones, in response to nutrient intake, results in the glucose-dependent secretion of insulin and lowering of blood glucose. As a synthetic analog of GLP-1, exenatide (Byetta) was the first type of incretin to become available for treatment of diabetes. Exenatide is approved as an injectable monotherapy or combination adjunctive therapy for people with type 2 diabetes in association with diet and exercise. The drug has been shown to have multiple actions such as potentiation of glucose-mediated insulin release, slowed gastric emptying, and a central loss of appetite with associated weight loss. Exenatide is injected subcutaneously 60 minutes before a meal. The major side effects are nausea and weight loss. Liraglutide (Victoza) is the second GLP-1 inhibitor to be approved in the United States and more are expected. Innovations in treatment such as once weekly dosing of GLP-1 inhibitors are being tested, which may make this category even more desirable.

Amylin Analogs
Pramlintide, a synthetic analog of amylin, is an injectable antidiabetic agent that modulates postprandial glucose levels and is approved for use in type 1 and type 2 diabetes. Amylin is a 37-amino-acid peptide that is produced, stored, and cosecreted with insulin in response to glucose and other beta cell stimulators. Therefore, in states of diabetes in which the beta cells and insulin secretion are largely depleted or dysfunctional, amylin secretion is also lost or dysfunctional. Pramlintide is injected (in a separate injection from insulin) before meals in those people who are unable to achieve their target postprandial blood glucose levels. Pramlintide, which has a rapid onset of action, suppresses glucagon release, slows gastric emptying, and tends to decrease appetite. The major side effect of pramlintide is nausea.

Insulin
Type 1 DM always requires treatment with insulin, and many people with type 2 diabetes eventually require insulin therapy. Exogenous insulin is engineered identical to human insulin. Insulin is destroyed in the gastrointestinal tract and must be administered by subcutaneous injection. All insulins are measured in units (the international unit of insulin is defined as the amount of insulin required to lower the blood glucose of a fasting 2-kg rabbit from 145 to 120 mg/dL). Most types of insulin are available in U-100 strength (i.e., 100 units of insulin/1 mL). Insulin preparations are categorized according to onset, peak, and duration of action. Scientists hope to find an alternative to injected insulin but, to date, none has proven effective. An inhaled form of insulin (Exubera) was on the market for a short time in the United States, but was withdrawn for commercial reasons.

Insulin types are classified by length and peaking of action. There are four principal types of insulin:

- Rapid-acting
- Short-acting
- Intermediate-acting
- Long-acting (Table 50.7)

The rapid-acting insulins (lispro, aspart, and glulisine) are produced by recombinant technology with an amino acid substitution. These insulins have a more rapid onset, peak, and duration of action than short-acting regular insulin, approximately 5 to 15 minutes. The rapid-acting insulins, which are used in combination with intermediate or long-acting insulins, are usually administered immediately before a meal. Due to the rapid onset of this category of insulin, it can also be administered during, or immediately after, a meal. This can be of great benefit for people with unpredictable oral intake (i.e., pediatric populations, unstable adults).

Short-acting insulin (regular) is a soluble crystalline insulin whose effects begin within 30 minutes after subcutaneous injection and generally last for 5 to 8 hours. The intermediate-acting insulin is NPH (neutral protamine Hagedorn). This insulin has slower onset and a longer duration of action. It requires several hours to reach therapeutic levels, so its use in type 1 diabetes requires supplementation with rapid- or short-acting insulin. This insulin, in combination with short-acting insulin, was the mainstay of type 1 diabetes treatment and common for the type 2 diabetes population requiring insulin for adequate control. Premixed solutions of NPH and short-acting insulins were very common. This regime was not optimal as it did not allow flexibility of meals (carbohydrate intake), and peak of action was less predictable, increasing the chance of hypoglycemia.

Long-acting insulins, glargine (Lantus) and detemir (Levimir), have a slower, more prolonged absorption than NPH insulin and provide a relatively constant concentration over 12 to 24 hours. All forms of insulin have the potential to produce hypoglycemia or “insulin reaction” as a side effect. The advantage of a “peakless” insulin is the provision of basal coverage in type 1 and, when appropriate, type 2 diabetes.

Intensive Insulin Treatment Regimens. Two intensive treatment regimens—multiple daily injections (MDIs) and continuous subcutaneous infusion of insulin—closely simulate the normal pattern of insulin secretion by the body. With each method, a basal insulin level is maintained, and bolus doses of short- or rapid-acting insulin are delivered before meals. The person with diabetes determines the choice of management in collaboration with the health care team.

With multiple daily injections, the basal insulin requirements are met by an intermediate- or long-acting insulin administered once or twice daily. Boluses of rapid- or short-acting insulin are used before meals. The development of convenient injection devices (e.g., pen injectors) has made it
caused by pump failure, catheter clogging, and infections at the needle site are also possible complications. Candidate selection is crucial to the successful use of the insulin pump and those who are selected must work closely with a health care professional. Traditionally CSII was thought of as therapy for people with type 1 diabetes but there is growing use in people with type 2 DM. Today's insulin pumps are very sophisticated and can allow multiple settings based on a person's specific needs. In the field of diabetes care, significant effort is under way to produce a "closed loop" insulin pump, which can sense glucose levels and respond with insulin secretion without manual intervention.

Emily Toronto, the child with type 1 diabetes, will require insulin for the rest of her life. She may require very little initially due to the “honeymoon phase” mentioned previously. Pediatric insulin regimes are quite individualized and make use of different strategies to maximize glycemic control while considering safety concerns of this age group. When she becomes older and more independent with her care she will like be independent with an intensive insulin regime. Emily and her family will also be informed of the use of insulin pumps for CSII and make a decision regarding if, or when, Emily may use this therapy.

†Lantus insulin should never be mixed with or administered using the same syringe used to administer any other type of insulin.

**Diabetic Ketoacidosis**

DKA most commonly occurs in a person with type 1 diabetes, in whom the lack of insulin leads to mobilization of fatty acids from adipose tissue because of the unsuppressed adipose cell lipase activity that breaks down triglycerides into fatty acids and glycerol. The increase in fatty acid levels leads to ketone production by the liver (Fig. 50.9). It can occur at the onset of the disease, often before the disease has been diagnosed.

Stress increases the release of gluconeogenic hormones and predisposes the person to the development of ketoacidosis. DKA is often preceded by physical or emotional stress, such as infection, pregnancy, or extreme anxiety. Recent evidence suggests the hyperglycemia is associated with a severe inflammatory state. In clinical practice, ketoacidosis also occurs with the omission or inadequate use of insulin. One example of this is a teenager with type 1 diabetes who decides to stop using insulin.

**Etiology and Pathogenesis.** The three major metabolic derangements in DKA are hyperglycemia, ketosis, and metabolic acidosis. The definitive diagnosis of DKA consists of hyperglycemia (blood glucose levels >250 mg dL [13.8 mmol/L]), low serum bicarbonate (<15 mEq/L [15 mmol/L]), and low pH.
(≤7.3), with ketonemia (positive at 1:2 dilution) and moderate ketonuria.26 Hyperglycemia leads to osmotic diuresis, dehydration, and a critical loss of electrolytes. Hyperosmolality of extracellular fluids from hyperglycemia leads to a shift of water and potassium from the intracellular to the extracellular compartment. Extracellular sodium concentration is frequently low or normal despite enteric water losses because of the intracellular–extracellular fluid shift.26 This dilutional effect is referred to as pseudohyponatremia.9 Serum potassium levels may be normal or elevated, despite total potassium depletion resulting from protracted polyuria and vomiting. Metabolic acidosis is caused by the excess ketoacids that require buffering by bicarbonate ions. This leads to a marked decrease in serum bicarbonate levels. The severity of DKA is classified on the severity of the metabolic acidosis.26

Clinical Manifestations. A day or more of polyuria, polydipsia, nausea, vomiting, and marked fatigue, with eventual stupor that can progress to coma commonly precedes DKA. Abdominal pain and tenderness may be experienced without abdominal disease.26 The breath has a characteristic fruity smell because of the presence of the volatile ketoacids.27 Hypotension and tachycardia may be present because of a decrease in blood volume. A number of the signs and symptoms that occur in DKA are related to compensatory mechanisms. The heart rate increases as the body compensates for a decrease in blood volume, and the rate and depth of respiration increase (i.e., Kussmaul respiration) as the body attempts to prevent further decreases in pH.26

Treatment. The goals in treating DKA are to improve circulatory volume and tissue perfusion, decrease blood glucose, correct the acidosis, and correct electrolyte imbalances.26,27 These objectives are usually accomplished through the administration of insulin and intravenous fluid and electrolyte replacement solutions. Because insulin resistance accompanies severe acidosis, low-dose insulin therapy is used.26 An initial loading dose of regular insulin is often given intravenously, followed by continuous low-dose infusion. Frequent laboratory tests are used to monitor blood glucose and serum electrolyte levels and to guide fluid and electrolyte replacement. It is important to replace fluid and electrolytes and correct pH while bringing the blood glucose concentration to a normal level. Too rapid a drop in blood glucose may cause hypoglycemia. A sudden change in the osmolality of extracellular fluid can also occur when blood glucose levels are lowered too rapidly, and this can cause cerebral edema, more common in children than in adults.27 Serum potassium levels often fall as acidosis is corrected and potassium moves from the extracellular into the intracellular compartment. Thus, it may be necessary to add potassium to the intravenous infusion. Identification and treatment of the underlying cause, such as infection, are also important. The most common complications from overtreatment of DKA are hypoglycemia and hypokalemia.26 Increasing use of evidence-based order sets have supported safer care of DKA in the acute setting.

Emily Toronto exhibited all the criteria for DKA, including hyperglycemia (650 mg/dL), ketosis, and metabolic acidosis with an arterial blood gas of pH = 7.29, pCO₂ = 42 mm Hg, and HCO₃⁻ = 10 mEq/L. Her hyperglycemia, polydipsia, and vomiting have caused dehydration. Her immediate needs are hydration with correction of electrolyte imbalance, treatment of hyperglycemia with insulin, and close monitoring of vital signs and laboratory values. Once she is stabilized it will be important to educate the family; the risk of DKA will continue for Emily in certain circumstances, but can often be prevented.

Hyperosmolar Hyperglycemic State
HHS is characterized by hyperglycemia (blood glucose >600 mg/dL [33.3 mmol/L]), hyperosmolality (plasma osmolality >320 mOsm/L) and dehydration, the absence of ketosis, and depression of the sensorium.28 HHS may occur in various conditions, including type 2 diabetes, acute pancreatitis, severe infection, myocardial infarction, and treatment with oral or parenteral nutrition solutions.27 It is seen most frequently in people with type 2 diabetes.26

Etiology and Pathogenesis. A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss occurs.26 Dehydration is usually more severe than DKA. As the plasma volume contracts, renal insufficiency develops and the resultant limitation of renal glucose losses leads to increasingly higher blood glucose levels and severity of the hyperosmolar state.28 In hyperosmolar states, the increased serum osmolality has the effect of pulling water out of body cells, including brain cells. The condition may be complicated by thromboembolic events arising because of the high serum osmolality.

Clinical Manifestations and Treatment. The most prominent manifestations are weakness, dehydration, polyuria, neurologic signs and symptoms, and excessive thirst. Neurologic signs including hemiparesis, seizures, and coma can occur.26 The onset of HHS can evolve over days to weeks but the onset of neurologic symptoms, especially in older people, may be mistaken for a stroke.

Successful treatment of HHS requires correction of dehydration, hyperglycemia, electrolyte imbalance, and frequent patient monitoring.26 The treatment of HHS requires judicious medical observation and care as water moves back into brain cells, posing a threat of cerebral edema.27 Extensive potassium losses that also have occurred during the diuretic phase of the disorder require correction. Because many people with HHS have coexisting chronic conditions, the identification of
Hypoglycemia

Hypoglycemia is generally defined as cognitive impairment with a blood glucose concentration of less than 60 mg/dL. It occurs most commonly in people treated with insulin injections, but prolonged hypoglycemia can also result from some oral hypoglycemic agents.

Etiology and Pathogenesis. There are many factors that can precipitate hypoglycemia in a person with type 1 diabetes, including error in insulin dose, failure to eat, increased exercise, decreased insulin need after removal of a stress situation, medication changes, and a change in insulin injection site. Alcohol decreases liver gluconeogenesis, and people with diabetes need to be cautioned about its potential for causing hypoglycemia, especially if it is consumed in large amounts or on an empty stomach.

Clinical Manifestations. Hypoglycemia usually has a rapid onset and progression of symptoms. The signs and symptoms of hypoglycemia can be divided into two categories: (1) those caused by altered cerebral function, and (2) those related to activation of the autonomic nervous system. Because the brain relies on blood glucose as its main energy source, hypoglycemia produces behaviors related to altered cerebral function. Headache, difficulty in problem solving, disturbed or altered awareness, and confusion may occur. At the onset of the hypoglycemic episode, activation of the parasympathetic nervous system often causes hunger. The initial parasympathetic response is followed by activation of the sympathetic nervous system; this causes anxiety, tachycardia, sweating, and constriction of the skin vessels (i.e., the skin is cool and clammy).

The signs and symptoms of hypoglycemia are highly variable, and not everyone manifests all or even most of the symptoms. The signs and symptoms are particularly variable in children and in older adults. Older adults may not display the typical autonomic responses associated with hypoglycemia but frequently develop signs of impaired function of the central nervous system, including mental confusion. Some people develop hypoglycemic unawareness. Unawareness of hypoglycemia should be suspected in people who do not report symptoms when their blood glucose concentrations are less than 50 to 60 mg/dL (2.8 to 3.3 mmol/L). This occurs most commonly in people who have a longer duration of diabetes and A1C levels within the normal range. Some medications, such as β-adrenergic blocking drugs, interfere with the sympathetic response normally seen in hypoglycemia. If hypoglycemia occurs with α-glucosidase inhibitors, it should be treated with glucose (dextrose) and not sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

Treatment. The most effective treatment of an insulin reaction is the immediate administration of 15 to 20 g of glucose in a concentrated carbohydrate source, which can be repeated as necessary. Monosaccharides such as glucose, which can be absorbed directly into the bloodstream, work best. Complex carbohydrates can be administered after the acute reaction has been controlled to sustain blood glucose levels. It is important not to overtreat hypoglycemia and cause hyperglycemia. This is supported by testing the blood glucose 15 minutes following the ingestion of glucose, and if necessary, repeating the 15-g concentrated carbohydrate (15/15 rule).

Alternative methods for increasing blood glucose may be required when the person having the reaction is unconscious or is unable to swallow. This is categorized as severe hypoglycemia and requires the intervention of another person. Glucagon may be given intramuscularly or subcutaneously. Glucagon acts by hepatic glycogenolysis to raise blood sugar. A small amount of glucose gel (available in most pharmacies) may be inserted into the buccal pouch when glucagon is unavailable. In situations of severe or life-threatening hypoglycemia, it may be necessary to administer glucose (20 to 50 mL of a 50% solution) intravenously.

Counter-Regulatory Mechanisms and the Somogyi Effect and Dawn Phenomenon

The Somogyi effect describes a cycle of insulin-induced posthypoglycemic episodes. In 1924, Joslin et al. noticed that hypoglycemia was associated with alternate episodes of hyperglycemia. In people with diabetes, insulin-induced hypoglycemia produces a compensatory increase in blood levels of catecholamines, glucagon, cortisol, and growth hormone. These counter-regulatory hormones cause blood glucose to become elevated and produce some degree of insulin resistance. The cycle begins when the increase in blood glucose and insulin resistance is treated with larger insulin doses.

Clinically, high blood glucose levels in the morning can complicate medical treatment of diabetes if not fully understood to be a counter-regulatory result of hypoglycemia. The hyperglycemic episode often occurs during the night or at a time when it is not recognized, rendering the diagnosis of the phenomenon more difficult. Without proper evaluation, an increase in medication can exacerbate the situation. When a Somogyi situation is suspected, people may be asked to test blood sugars in the middle of the night to identify possible hypoglycemia. The use of continuous insulin sensors, in selected patients, can also help to identify this situation.

The dawn phenomenon is characterized by increased levels of fasting blood glucose or insulin requirements, or both, between 5 and 9 AM without antecedent hypoglycemia (as opposed to the Somogyi). It occurs in people with type 1 or type 2 diabetes. It has been suggested that the dawn phenomenon is not fully understood but has been attributed to an increased rate of insulin clearance, decreased insulin sensitivity, or both. Several hormones such as growth hormone, cortisol, and glucagon have been studied in relation to this phenomenon. The dawn phenomenon has been found to occur in the majority of those with type 1 diabetes. The impact varies...
depending on a variety of factors such as blood sugar control and adequacy of counter-regulatory systems. Advances in diabetes care especially the advanced insulin pumps can address varied needs of basal insulin in early morning hours.

**Chronic Complications**

The chronic complications of diabetes include disorders of the microvasculature (i.e., neuropathies, nephropathies, and retinopathies), disorders of gastrointestinal motility, macrovascular complications (i.e., coronary artery, cerebral vascular, and peripheral vascular disease), and foot ulcers (Fig. 50.10). The level of chronic hyperglycemia is the best-established concomitant factor associated with diabetic complications.

The causes and development of complications in diabetes are not fully understood but may relate to a variety of factors. Excess amounts of sorbitol may alter cellular function. Abnormal glycoproteins may damage the basement membranes related to eyes, kidneys, and vascular circulation. Tissue oxygenation is believed to be a significant cause of microvascular complications due to a defect in red blood cell function. These abnormalities and others are theorized to cause an increase in free reactive oxygen species (i.e., free radicals) in response to chronic hyperglycemia.

The Diabetes Control and Complications Trial (DCCT), which was conducted with 1441 patients with type 1 diabetes, demonstrated that the incidence of retinopathy, nephropathy, and neuropathy can be reduced by intensive diabetic treatment. Similar results have been demonstrated by the United Kingdom Prospective Diabetes Study (UKPDS) in 5000 people with type 2 diabetes.

Recent studies have also determined the positive benefits of excellent glycemic control during hospitalization, surgery, and acute illness states. All people with diabetes admitted to acute health care facilities need to be identified and have an order for blood glucose monitoring. Goals for blood glucose control for hospitalized people are as close to 110 mg/dL (5.6 mmol/L) as possible, and generally less than 140 mg/dL (7.8 mmol/L) for critically ill people and generally less than 180 mg/dL (10 mmol/L) for non–critically ill people.

**Neuropathies**

The risk of neuropathies, along with other chronic complications, has been shown to increase in the presence of long-term hyperglycemia. Symptoms usually become apparent in the second decade of the disease. Although the incidence of neuropathies is high among people with diabetes, it is difficult to document exactly how many people are affected by these disorders because of the diversity in clinical manifestations and because the condition may be unrecognized or unreported.

Two types of pathologic changes have been observed in connection with diabetic neuropathies. The first is a thickening of the walls of the nutrient vessels that supply the nerve, leading to the assumption that vessel ischemia plays a major role in the development of these neural changes. The second finding is a segmental demyelinization process that affects the Schwann cell. This demyelination process is accompanied by a slowing of nerve conduction.

Although there are several methods for classifying the diabetic neuropathies, a simplified system divides them into the somatic and autonomic nervous system neuropathies (Chart 50.4).

**Somatic Neuropathy.** A distal symmetric polyneuropathy, in which loss of function occurs in a stocking–glove pattern, is the most common form of peripheral neuropathy. Somatic sensory involvement usually occurs first and is usually bilateral and symmetric, and associated with diminished perception of vibration, pain, and temperature, particularly in the lower extremities. In addition to the discomforts associated with the loss of sensory or motor function, lesions in the peripheral nervous system predispose a person with diabetes to other complications. Peripheral neuropathy is often associated with...
the insensate foot. The loss of feeling, touch, sensation, and position sense increases the risk of falling, serious burns, and injuries to the feet. Neuropathy of the lower extremities is associated with 61% of lower extremity amputations and the mortality rate within 5 years after such amputations ranges from 39% to 80%.

Painful diabetic neuropathy involves the somatosensory neurons that carry pain impulses. Treatment of this painful disorder is available with pharmacologic and holistic interventions. Use of varied agents such as antidepressants, anticonvulsants may have side effects that limit their usefulness. In addition to debilitating pain and impaired quality of life, the treatment of peripheral neuropathy and the subsequent interventions related to this complication place a financial burden on health care resources. Loss of income, disability, wound treatment, surgery, infections, prosthetics, and more are associated with this chronic and common complication.

Autonomic Neuropathy. The autonomic neuropathies involve disorders of sympathetic and parasympathetic nervous system function. There may be disorders of vasomotor function, decreased cardiac responses, inability to empty the bladder, and sexual dysfunction. Defects in vasomotor reflexes can lead to dizziness and syncope when the person moves from the supine to the standing position. In the male, disruption of sensory and autonomic nervous system function may cause sexual dysfunction. Diabetes is the leading physiologic cause of erectile dysfunction (ED), and it occurs in both type 1 and type 2 diabetes. The current availability of pharmacologic treatment of ED can offer improved management of this common complication but individually must be appropriately screened due to cardiac implications and other conditions associated with diabetes.

Disorders of Gastrointestinal Motility
Gastrointestinal motility disorders are common in people with long-standing diabetes. Although the pathogenesis of these disorders is poorly understood, neuropathy and metabolic abnormalities secondary to hyperglycemia are thought to play an important role. The symptoms vary in severity and include constipation, diarrhea and fecal incontinence, nausea and vomiting, and upper abdominal discomfort referred to as dyspepsia.

Gastroparesis (delayed emptying of stomach) is commonly seen in persons with diabetes. The disorder is characterized by complaints of epigastric discomfort, nausea, postprandial vomiting, bloating, and early satiety. Erratic blood glucose can occur due to delayed food absorption. Diagnostic measures include the use of endoscopy or barium radiography to exclude mechanical obstruction due to peptic ulcer disease or cancer. Management includes the use of prokinetic agents (e.g., metoclopramide, erythromycin) as well as antiemetic agents. Strict glycemic control along with small frequent meals is also advised.

Diarrhea is another common symptom seen mostly in persons with poorly controlled type 1 diabetes and autonomic neuropathy. The pathogenesis is thought to be multifactorial. Diabetic diarrhea is typically intermittent, watery, painless, and nocturnal and may be associated with fecal incontinence or may alternate with constipation. Management includes soluble dietary fiber and the use of antidiarrheal agents (loperamide, diphenoxylate). Clonidine (an α₂-adrenergic agonist) and octreotide (a long-acting somatostatin analog) have been used with some success in persons with rapid transit. Antibiotics are used for those with small bowel bacterial overgrowth secondary to slow transit. As with gastroparesis, strict control of blood glucose is important.

Nephropathies
Diabetic nephropathy is the leading cause of chronic kidney disease, accounting for 40% of new cases. The complication affects people with both type 1 and type 2 diabetes and many of those who have diabetic nephropathy also have some degree of retinopathy. The occurrence of diabetic nephropathy is also associated with increased cardiac risk, and a primary cause of death for those with diabetic kidney disease is cardiovascular disease. The term diabetic nephropathy is used to describe the combination of lesions that often occur concurrently in the diabetic kidney. The most common kidney lesions
in people with diabetes are those that affect the glomeruli. Various glomerular changes may occur in people with diabetic nephropathy, including capillary basement membrane thickening, diffuse glomerulosclerosis, and nodular glomerulosclerosis. Changes in the capillary basement membrane take the form of thickening of basement membranes along the length of the glomeruli. Nodular glomerulosclerosis is a form of glomerulosclerosis that involves the development of nodular lesions in the glomerular capillaries of the kidneys, causing impaired blood flow with progressive loss of kidney function and, eventually, renal failure. Nodular glomerulosclerosis is thought to occur only in people with diabetes. Changes in the basement membrane in diffuse glomerulosclerosis allow plasma proteins to escape into the urine, causing proteinuria.

Various factors shared by siblings. The risk for development of nephropathy, including capillary basement membrane thickening, diffuse glomerulosclerosis, and nodular glomerulosclerosis. Changes in the capillary basement membrane take the form of thickening of basement membranes along the length of the glomeruli. Nodular glomerulosclerosis is a form of glomerulosclerosis that involves the development of nodular lesions in the glomerular capillaries of the kidneys, causing impaired blood flow with progressive loss of kidney function and, eventually, renal failure. Nodular glomerulosclerosis is thought to occur only in people with diabetes. Changes in the basement membrane in diffuse glomerulosclerosis allow plasma proteins to escape into the urine, causing proteinuria. The development of hypoproteinemia, edema, and others.

Diabetic nephropathy is the most common pattern of eye disease. Diabetic retinopathy is characterized by abnormal retinal vascular permeability, microaneurysm formation, neovascularization and associated hemorrhage, scarring, and retinal detachment. Retinopathy develops in varying degrees in almost all people with diabetes. Pregnancy, puberty, and cataract surgery can accelerate these changes. Among the suggested risk factors associated with diabetic retinopathy are poor glycemic control, elevated blood pressure, and hyperlipidemia. The strongest case for control of blood glucose comes from the DCCT and UKPDS studies, which demonstrated a reduction in retinopathy with improved glucose control.

Because of the risk of retinopathy, it is important that people with diabetes have regular dilated eye examinations. They should have an initial examination for retinopathy shortly after the diagnosis of diabetes is made. The recommendation for follow-up examinations is based on the type of examination that was done and the findings of that examination. Generally, all people with diabetes should have an annual eye exam with more frequent exams for those with persistently poor glucose control or evidence of eye disease.

People with macular edema, moderate to severe nonproliferative retinopathy, or any proliferative retinopathy should receive the care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Methods used in the treatment of diabetic retinopathy include the destruction and scarring of the proliferative lesions with laser photocoagulation. Photocoagulation is directed to areas of chronic leakage to reduce chronic leakage in people with macular edema.

### Retinopathies

Diabetes is the leading cause of vision loss and blindness in the United States. Although people with diabetes are at increased risk for development of cataracts and glaucoma, retinopathy is the most common pattern of eye disease. Diabetic retinopathy is estimated to be the most frequent cause of newly diagnosed blindness among Americans between the ages of 20 and 74 years.

Diabetic retinopathy is characterized by abnormal retinal vascular permeability, microaneurysm formation, neovascularization and associated hemorrhage, scarring, and retinal detachment. Retinopathy develops in varying degrees in almost all people with diabetes. Pregnancy, puberty, and cataract surgery can accelerate these changes. Among the suggested risk factors associated with diabetic retinopathy are poor glycemic control, elevated blood pressure, and hyperlipidemia. The strongest case for control of blood glucose comes from the DCCT and UKPDS studies, which demonstrated a reduction in retinopathy with improved glucose control.

Because of the risk of retinopathy, it is important that people with diabetes have regular dilated eye examinations. They should have an initial examination for retinopathy shortly after the diagnosis of diabetes is made. The recommendation for follow-up examinations is based on the type of examination that was done and the findings of that examination. Generally, all people with diabetes should have an annual eye exam with more frequent exams for those with persistently poor glucose control or evidence of eye disease.

Methods used in the treatment of diabetic retinopathy include the destruction and scarring of the proliferative lesions with laser photocoagulation. Photocoagulation is directed to areas of chronic leakage to reduce chronic leakage in people with macular edema.

### Key Points

**Chronic Complications of Diabetes**

- The chronic complications of diabetes result from elevated blood glucose levels and associated impairment of lipid and other metabolic pathways.
- Macrovascular disorders such as coronary heart disease, stroke, and peripheral vascular disease reflect the combined effects of unregulated blood glucose levels, elevated blood pressure, and hyperlipidemia.
- The chronic complications of diabetes are best prevented by measures aimed at tight control of blood glucose levels, maintenance of normal lipid levels, and control of hypertension.
**Chapter 50  Diabetes Mellitus and the Metabolic Syndrome 1329**

**Macrovascular Complications**

DM is a major risk factor for coronary artery disease, cerebrovascular disease, and peripheral vascular disease. The prevalence of these macrovascular complications is increased twofold to fourfold in people with diabetes. Approximately 50% to 75% of all people with type 2 diabetes die of a macrovascular problem.

Multiple risk factors for macrovascular disease, including obesity, hypertension, hyperglycemia, hyperinsulinemia, hyperlipidemia, altered platelet function, endothelial dysfunction, systemic inflammation (as evidenced by increased CRP), and elevated fibrinogen levels, are frequently found in people with diabetes. There appear to be differences between type 1 and type 2 diabetes in terms of duration of disease and the development of macrovascular disease. People with type 1 diabetes are at an increased risk of cardiovascular events but may not have other classic risk factors, such as obesity. In people with type 2 diabetes, macrovascular disease may be present at the time of diagnosis. Increased risk for cardiovascular events in this group may be related to the components of metabolic syndrome. Aggressive management of cardiovascular risk factors should include smoking cessation, hypertension, lipid lowering, diabetes control, and antiplatelet agents (aspirin or clopidogrel) if not contraindicated. Lifestyle changes, which decrease cardiovascular risk factors should be strongly encouraged and supported by the health care team. Diet, exercise, weight loss, and glycemic control can help reduce the incidence of cardiovascular events.

**Diabetic Foot Ulcers**

Foot problems are common among people with diabetes and may become severe enough to cause ulceration, infection, and, eventually, the need for amputation. In people with diabetes, lesions of the feet represent the effects of neuropathy and vascular insufficiency. Approximately 60% to 70% of people with diabetic foot ulcers have neuropathy without vascular disease, 15% to 20% have vascular disease, and 15% to 20% have neuropathy and vascular disease.

Distal symmetric neuropathy is a major risk factor for foot ulcers. People with sensory neuropathies have impaired pain sensation and are often unaware of the constant trauma to the feet caused by poorly fitting shoes, improper weight bearing, hard objects or pebbles in the shoes, or infections such as athlete’s foot. Neuropathy prevents people from detecting pain; thus injuries and infections often go undetected. Motor neuropathy with weakness of the intrinsic muscles of the foot may result in foot deformities, which lead to focal areas of high pressure. When the abnormal focus of pressure is coupled with loss of sensation, a foot ulcer can occur. Common sites of trauma are the back of the heel, the plantar metatarsal area, or the great toe, where weight is borne during walking (Fig. 50.11).

All persons with diabetes should receive a full foot examination at least once a year. This examination should include assessment of protective sensation, foot structure and biomechanics, vascular status, and skin integrity. Evaluation of neurologic function should include a somatosensory test using either the Semmes-Weinstein monofilament or vibratory sensation. The Semmes-Weinstein monofilament is a simple, inexpensive device for testing sensory status (Fig. 50.12). The monofilament is held in the hand or attached to a handle at one end. When the unattached or unsupported end of the monofilament is pressed against the skin until it buckles or bends slightly, it delivers 10 g of pressure at the point of contact. The test consists of having the person being tested report the sensation when touched by the monofilament.

Because of the constant risk of foot problems, prevention of injury or early detection is critical. It is important that people with diabetes wear shoes that have been fitted correctly...
and inspect their feet daily, looking for blisters, open sores, and fungal infection (*e.g.*, athlete’s foot) between the toes. If their eyesight is poor, a family member should do this for them. Education supporting prompt medical attention for skin lesions is needed to prevent serious complications. Smoking should be avoided because it causes vasoconstriction and contributes to vascular disease. Because cold produces vasoconstriction, appropriate foot coverings should be used to keep the feet warm and dry. Toenails should be cut straight across to prevent ingrown toenails. The toenails are often thickened and deformed, requiring the services of a podiatrist. Self-treatment of foot problems in this population, such as difficult toe nails, calluses, and other issues, should be strongly discouraged.

Advances in the field of chronic wound care have increased treatment options for this population. Ulcers that are resistant to standard therapy may respond to application of growth factors. Growth factors provide a means by which cells communicate with each other and can have profound effects on cell proliferation, migration, and extracellular matrix synthesis. Use of hyperbaric oxygen therapy, wound care specialty services, and minimally invasive surgeries provide options for chronic wounds, but add to the financial burden of diabetes on health care resources.

### Infections

Although not specifically an acute or a chronic complication, infections are a common concern of people with diabetes. Certain types of infections occur with increased frequency in people with diabetes: soft tissue infections of the extremities, osteomyelitis, urinary tract infections and pyelonephritis, candidal infections of the skin and mucous surfaces, dental caries and periodontal disease. Suboptimal response to infection in a person with diabetes is caused by the presence of chronic complications, such as vascular disease and neuropathies, and by the presence of hyperglycemia and altered neutrophil function. Sensory deficits may cause a person with diabetes to ignore minor trauma and infection, and vascular disease may impair circulation and delivery of blood cells and other substances needed to produce an adequate inflammatory response and effect healing. Hyperglycemia and glycosuria may influence the growth of microorganisms and increase the severity of the infection. In acute illness, increased efforts to control blood sugars for surgical patients and medical conditions cite an impact on infections.

Once an individual is diagnosed with diabetes, regardless of the type, they should work with a health care team to achieve optimal glycemic control and have regular screenings for diabetes complications. These recommendations include A1C testing two to four times a year depending on control, annual dilated eye exam, foot exam, lipid profile, microalbumin, serum creatinine, blood pressure, and weight. Prevention and delay of complications is possible with adherence to lifestyle interventions that support health such as good nutrition, exercise, and preventative care.

### IN SUMMARY

DM is a disorder of carbohydrate, protein, and fat metabolism resulting from an imbalance between insulin availability and insulin need. The disease can be classified as type 1 diabetes, in which there is destruction of beta cells and an absolute insulin deficiency, or type 2 diabetes, in which there is a lack of insulin availability or effectiveness. Type 1 diabetes can be further subdivided into type 1A immune-mediated diabetes, which is thought to be caused by autoimmune mechanisms, and type 1B idiopathic diabetes, for which the cause is unknown. GDM develops during pregnancy, and although glucose tolerance often returns to normal after childbirth, it indicates an increased risk for the development of diabetes. The metabolic syndrome represents a constellation of metabolic abnormalities characterized by obesity, insulin resistance, high triglyceride levels and low HDL levels, hypertension, cardiovascular disease, insulin resistance, and increased risk for development of type 2 diabetes.

The most commonly identified symptoms of type 1 diabetes are polyuria, polydipsia, polyphagia, and weight loss despite normal or increased appetite. Although persons with type 2 diabetes may present with one or more of these symptoms, they are often asymptomatic initially. The diagnosis of DM is based on clinical signs of the disease, fasting blood glucose levels, random plasma glucose measurements, and results of the glucose tolerance test. Glycosylation involves the irreversible attachment of glucose to the hemoglobin molecule; the measurement of A1C provides an index of blood glucose levels over several months. Self-monitoring provides a means of maintaining near-normal blood glucose levels through frequent testing of blood glucose and adjustment of insulin dosage.

Dietary management focuses on maintaining a well-balanced diet, controlling calories to achieve and maintain an optimum weight, and regulating the distribution of carbohydrates, proteins, and fats. Two types of antidiabetic agents are used in the management of diabetes: injectable agents and oral diabetic drugs. Injectable agents traditionally have included the family of insulin agents but now include newer agents, such as amylin and GLP-1 analogs. Oral diabetic drugs include a variety of options. Type 1 diabetes (always), and type 2 (sometimes), requires treatment with injectable insulin. Oral antidiabetic drugs include the insulin secretagogues, biguanides, α-glucosidase inhibitors, TZDs, and DPP-4 enzyme inhibitors. These drugs require a functioning pancreas and may be used in the treatment of type 2 diabetes.

The metabolic disturbances associated with diabetes affect almost every body system. The acute complications of diabetes include DKA, hyperglycemic hyperosmolar state, and hypoglycemia in people with insulin-treated
diabetes. The chronic complications of diabetes affect the microvascular system (including the retina, kidneys, and peripheral nervous system) and the macrovascular system (coronary, cerebrovascular, and peripheral arteries). The diabetic foot is usually a combination of both microvascular and macrovascular dysfunction. Infection is also a frequent cofactor in the diabetic foot. Chronic hyperglycemia plays a key role in complications, and individuals should receive significant education and support to learn to control blood sugar and minimize complications.

**REVIEW EXERCISES**

1. A 6-year-old boy is admitted to the emergency department with nausea, vomiting, and abdominal pain. He is very lethargic; his skin is warm, dry, and flushed; his pulse is rapid; and he has a sweet smell to his breath. His parents relate that he has been very thirsty during the past several weeks, his appetite has been poor, and he has been urinating frequently. His initial plasma glucose is 420 mg/dL (23.1 mmol/L), and a urine test for ketones is strongly positive.

A. What is the most likely cause of this boy’s elevated blood glucose and ketonuria?

B. Explain his presenting signs and symptoms in terms of the elevated blood glucose and metabolic acidosis.

C. What are the priorities of treatment?

D. What associated electrolyte disturbances would you expect and why?

2. A 53-year-old accountant presents for his routine yearly examination. His history indicates that he was found to have a fasting glucose of 120 mg/dL (6.7 mmol/L) on two prior occasions. Currently, he is asymptomatic. He has no other medical problems and does not use any medications. He neither smokes nor drinks alcohol. His father had type 2 diabetes at age 60 years. His physical examination reveals a blood pressure of 125/80 mm Hg, BMI (body mass index) of 32 kg/m², and waist circumference of 45 inches (114 cm). Laboratory study results are as follows: complete blood count (CBC), thyroid-stimulating hormone (TSH), and alanine aminotransferase (ALT) are within normal limits. The lipid panel shows that his HDL cholesterol (30 mg/dL [0.8 mmol/L]) and LDL cholesterol (136 mg/dL [3.5 mmol/L]) are within the normal range, and triglycerides are elevated (290 mg/dL [2.3 mmol/L]; normal is <165 mg/dL [1.9 mmol/L]).

**A. What is this man’s probable diagnosis?**

**B. Based on this man’s blood glucose level and the ADA diabetes classification system, what diabetic status would you place this man in? Does he need a 75-g OGTT for further assessment of his IFG?**

**C. His OGTT test result reveals a 2-hour glucose value of 175 mg/dL (9.63 mmol/L). What is the diagnosis? What type of treatment would be appropriate for this man?**

Mr. E. Topers, a 57-year-old African American, has had benign prostate hyperplasia for about 5 years.

His grandfather and one uncle both had prostate cancer. He has a 20-year, pack-a-day cigarette history, which he stopped 15 years ago. He has controlled hypertension, type 2 diabetes mellitus, and hyperlipidemia. In the past year, his body mass index (BMI, in kg/m²) decreased to 26 (slightly overweight) from 28 (overweight). He has been taking an alpha1-adrenergic antagonist to relax the smooth muscle in his prostate and thus improve urine flow. Last year, his score on the American Urologic Association (AUA) Symptom Score Index was 1 or 2, indicating very mild symptoms. Today, his AUA score is 11, indicating that his symptoms are affecting his quality of life. He is getting up three times per night to void, urinates often during the day, and is experiencing some urge incontinence. Additionally, he frequently feels like he needs to urinate and has some dribbling after urinating. His last prostate-specific antigen (PSA) level was 7 ng/mL (<4.0 ng/mL is considered normal), and his other blood work was within normal limits. Today his PSA is greater than 12 ng/mL, and his blood urea nitrogen (BUN) and creatinine concentrations are elevated significantly. His uroflow examination shows obstruction with a flow of less than 7 mL/second (average normal flow is 12 mL/second). His digital rectal exam (DRE) reveals that his prostate is significantly enlarged (+3 to +4) and firm (+2; +1 in the previous test). He is scheduled for a transrectal ultrasound and biopsy of his prostate. The findings are positive for prostate cancer. However, his Gleason Staging Score is 3, which indicates a slow growing cancer. You will read more about Mr. Topers in Chapters 51 and 52.

Neural Control
Changes with Aging

The male genitourinary system comprises the paired gonads, or testes, genital ducts, accessory organs, and penis (Fig. 51.1). The dual function of the testes is to produce androgens (i.e., male sex hormones), mainly testosterone, and spermatozoa (i.e., male germ cells). The internal accessory organs produce the fluid constituents of semen, and the ductile system aids in the storage and transport of spermatozoa. The functions of the penis include urine elimination and sexual function. This chapter focuses on the structure of the male reproductive system, spermatogenesis and control of male reproductive function, neural control of sexual function, and changes in function that occur at puberty and as a result of the aging process.

Embryonic Development

The sex of a person is determined at the time of fertilization by the sex chromosomes. In the early stages of embryonic development, the tissues from which the male and female reproductive organs develop are undifferentiated. The sex-determining region of the Y chromosome (SRY) gene is located in the short arm of the Y chromosome and determines gender. Until approximately the 7th week of gestation, it is impossible to determine whether an embryo is male or female unless the chromosomes...
are studied. Until this time, the male and female genital tracts consist of two Wolffian ducts, from which the male genitalia develop, and two Müllerian ducts, from which the female genital structures develop. During this period of gestation, the gonads (*i.e.*, ovaries and testes) are also undifferentiated.1

Between the 6th and 8th weeks of gestation, the testes begin their development under the influence of the Y chromosome. Differentiation of the indifferent gonad into a testis is initiated by the actions of the *SRY* gene. In the presence of the *SRY* gene, the embryonic gonads develop into testes, and, in its absence, the gonads develop into ovaries.

During this time, the testicular cells of the male embryo begin producing an anti-Müllerian hormone (AMH) and testosterone.1 The AMH suppresses the Müllerian ducts and prevents development of the uterus and fallopian tubes in the male. In parallel, testosterone stimulates the Wolffian ducts to develop into the epididymis, vas deferens, and seminal vesicles.1 Testosterone is also the precursor of a third hormone, dihydrotestosterone (DHT), which functions in the formation of the male urethra, prostate, and external genitalia. The enzyme 5α-reductase is involved in the conversion of testosterone to DHT, predominantly in the peripheral tissues.1 Although testosterone and DHT share the same nuclear androgen receptor, they have marked differences in tissue activity. DHT exerts most of its effects on the external genitalia, including the prostate, but is also subsequently important for the development of facial and body hair, including temporal hair recession. In the absence of testosterone (and DHT), a male embryo with an XY chromosomal pattern develops female external genitalia.1,2

**Testes and Scrotum**

The testes, or male gonads, are two egg-shaped structures located outside the abdominal cavity in the scrotum.3 The adult male testes are approximately 15 to 25 mL in volume (>4 mL indicates pubertal onset), with 80% of this volume being cells involved in spermatogenesis and 20% in testosterone production. Embryologically, the testes develop in the abdominal cavity and then descend through the inguinal canal into a pouch of peritoneum (which becomes the tunica vaginalis) in the scrotum.4 Testicular descent occurs in two stages. The first stage occurs between 7 and 12 weeks of fetal life, with AMH being responsible for descent to the inguinal region. The second stage occurs between 7 and 9 months of fetal life, with testosterone being responsible for descent into the scrotum.4 As they descend, the testes pull their arteries, veins, lymphatics, nerves, and conducting excretory ducts with them. These structures are encased by the cremaster muscle and layers of fascia that constitute the spermatic cord.4

After descent of the testes, the inguinal canal closes almost completely. Failure of this canal to close predisposes to the development of an inguinal hernia later in life. An inguinal hernia or “rupture” is a protrusion of the parietal peritoneum and part of the intestine through an abnormal opening from the abdominal cavity. A loop of small bowel may become incarcerated in an inguinal hernia (strangulated hernia), in which case its lumen may become obstructed and its vascular supply compromised.

The testes are enclosed in a double-layered membrane, the tunica vaginalis, which is derived embryologically from the abdominal peritoneum.3 An outer covering, the tunica albuginea, is a tough, white, fibrous sheath that resembles the sclera of the eye. The tunica albuginea protects the testes and gives them their ovoid shape. The cremaster muscles, which are bands of skeletal muscle arising from the internal oblique muscles of the trunk, elevate the testes. The testes receive their arterial blood supply from the long testicular arteries, which branch from the abdominal artery. The testicular veins, which drain the testes, arise from a venous network called the pampiniform plexus that surrounds the testicular artery. The testes are innervated by fibers from both divisions of the autonomic nervous system.4 Associated sensory nerves transmit pain impulses, resulting in excruciating pain, especially when the testes are hit forcibly.
The scrotum, which houses the testes, is made up of a thin outer layer of skin that forms rugae, or folds, and is continuous with the perineum and outer skin of the groin. Under the outer skin lies a thin layer of fascia and smooth muscle (i.e., dartos muscle). This layer contains a septum that separates the two testes. The dartos muscle responds to changes in temperature. When it is cold, the muscle contracts, bringing the testes closer to the body and the scrotum becomes shorter and heavily wrinkled. When it is warmer, the muscle relaxes, allowing the scrotum to fall away from the body.

The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C below body temperature. Two systems maintain the temperature of the testes at a level consistent with sperm production. One system is the pampiniform plexus of testicular veins that surrounds the testicular artery. This plexus absorbs heat from the arterial blood, cooling it as it enters the testes. The other system is the cremaster muscles, which respond to decreases in testicular temperature by moving the testes closer to the body. Prolonged exposure to elevated temperatures, as a result of prolonged fever or the dysfunction of thermoregulatory mechanisms, can impair spermatogenesis. Some tight-fitting undergarments hold the testes against the body and are thought to contribute to a decrease in sperm counts and infertility by interfering with the thermoregulatory function of the scrotum. Cryptorchidism, the failure of the testes to descend into the scrotum, also exposes the testes to higher temperatures. The spermatozoa continue their migration through the ductus deferens, also called the vas deferens. The ampulla of the vas deferens serves as a storage reservoir for sperm. Sperm are stored in the ampulla until they are released through the penis during ejaculation (Fig. 51.3). Surgical disconnection of the vas deferens in the scrotal area (e.g., vasectomy) serves as an effective method of male contraception. Because sperm are stored in the ampulla, men can remain fertile for 4 to 5 weeks after performance of a vasectomy.

The human testis can produce up to 300 million sperm cells/day. Mature spermatozoa are approximately 60 µm long. Approximately 3 mL of semen is expressed with each ejaculate and each milliliter is made up of about 100 million sperm. However, approximately 20% of the sperm in any ejaculate are not morphologically normal and about 25% are immobile.

**Accessory Organs**

The male accessory organs consist of the seminal vesicles, the prostate gland, and the bulbourethral glands. Spermatozoa are transported through the reproductive structures by movement of the seminal fluid, which is combined with secretions from the genital ducts and accessory organs. The spermatozoa plus the secretions from the genital ducts and accessory organs make up the semen.

The seminal vesicles consist of two highly tortuous tubes that secrete fluid for the semen. Each of the paired seminal vesicles is lined with secretory epithelium containing an abundance of fructose, prostaglandins, and several other proteins. The fructose secreted by the seminal vesicles provides the energy for sperm motility. The prostaglandins are thought to assist in fertilization by making the cervical mucus more receptive to sperm and by causing peristaltic contractions in the uterus and fallopian tubes to move the sperm toward the ovaries.
Mr. Topers who was introduced to you at the beginning of Unit 11 has benign prostatic hyperplasia (BPH) and prostate cancer. He is experiencing symptoms of obstruction, including dribbling after urinating and the continuous sensation of having to urinate. These symptoms are most likely due to further enlargement of his prostate gland. His uroflow examination showed obstruction with a flow of less than 7 mL/second so the prostate is pressing on his urethra and narrowing it, causing his urine to back up. He needs to be assessed for a lower urinary tract infection by obtaining a urine culture. He has selected a total prostatectomy due to his family history. Surgery is scheduled for the end of the week.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the small mucosal glands associated with the urethral mucosa, the intermediate submucosal glands that lie peripheral to the mucosal glands, and the large main prostatic glands that are situated toward the outside of the gland. It is the overgrowth of the mucosal glands that causes BPH in older men.

The prostate gland also functions in the elimination of urine and consists of a thin, fibrous capsule that encloses the circularly oriented smooth muscle fibers and collagenous tissue that surround the urethra where it joins the bladder. The segment of urethra that traverses the prostate gland is called the prostatic urethra. It is lined by a thin, longitudinal layer of smooth muscle that is continuous with the bladder wall. The smooth muscle incorporated with the prostate gland is derived primarily from the longitudinal bladder musculature. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, enlargement of the gland can produce urinary obstruction.

The prostate gland is a fibromuscular and glandular organ lying just inferior to the bladder. The prostate gland secretes a thin, milky, alkaline fluid containing citric acid, calcium, acid phosphate, a clotting enzyme, and a profibrinolysin. During ejaculation, the capsule of the prostate contracts and the added fluid increases the bulk of the semen. Both vaginal secretions and the fluid from the vas deferens are strongly acidic. Because sperm mobilization occurs at a pH of 6.0 to 6.5, the alkaline nature of the prostatic secretions is essential for successful fertilization of the ovum. The bulbourethral or Cowper glands lie on either side of the membranous urethra and secrete alkaline mucus, which further aids in neutralizing acids from the urine that remain in the urethra.

The prostate gland also functions in the elimination of urine and consists of a thin, fibrous capsule that encloses the circularly oriented smooth muscle fibers and collagenous tissue that surround the urethra where it joins the bladder. The segment of urethra that traverses the prostate gland is called the prostatic urethra. It is lined by a thin, longitudinal layer of smooth muscle that is continuous with the bladder wall. The smooth muscle incorporated with the prostate gland is derived primarily from the longitudinal bladder musculature. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, enlargement of the gland can produce urinary obstruction.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the small mucosal glands associated with the urethral mucosa, the intermediate submucosal glands that lie peripheral to the mucosal glands, and the large main prostatic glands that are situated toward the outside of the gland. It is the overgrowth of the mucosal glands that causes BPH in older men.

Penis

The penis is the external genital organ through which the urethra passes. Anatomically, the external penis consists of a shaft that ends in a tip called the glans (Fig. 51.4). The loose skin of the penis shaft folds to cover the glans, forming the prepuce, or foreskin. The glans of the penis contains many sensory nerves, making this the most sensitive portion of the penile shaft. It is the foreskin that is removed during circumcision.
After completing this section of the chapter, you should be able to meet the following objectives:

• Describe the process of spermatogenesis.
• State the functions of testosterone.
• Draw a diagram illustrating the secretion, site of action, and feedback control of gonadotropin-releasing hormone, luteinizing hormone, follicle-stimulating hormone, and inhibin.

SPERMATOGENESIS AND HORMONAL CONTROL OF MALE REPRODUCTIVE FUNCTION

During childhood, the gonads remain essentially quiescent. At puberty, the male gonads and testes begin to mature and to carry out spermatogenesis and hormone production. At approximately 10 or 11 years of age, the adenohypophysis, or anterior pituitary, under the control of the hypothalamus, begins to secrete the gonadotropins that stimulate testicular function and cause the interstitial Leydig cells to begin producing testosterone. At approximately the same time, hormonal stimulation induces mitotic activity of the germ cells that develop into sperm. After cell maturation has begun, the testes begin to enlarge rapidly as the individual tubules grow. Full maturity and spermatogenesis are usually attained by 15 or 16 years of age.

Spermatogenesis

Spermatogenesis refers to the generation of spermatozoa or sperm. It begins at an average age of 13 years and continues throughout the reproductive years of a man’s life. Spermatogenesis occurs in the seminiferous tubules of the testes (see Fig. 51.2). These tubules, if placed end to end, would measure approximately 750 feet. The outer layer of the seminiferous tubules is made up of connective tissue and smooth muscle. The inner lining of the seminiferous tubules is made up of connective tissue and smooth muscle. The inner lining is composed of Sertoli cells, which are embedded with sperm in various stages of development (i.e., spermatocytes to sperm) and they secrete a special fluid that contains nutrients to bathe and nourish the immature germ cells. They provide digestive enzymes that play a role in spermiation (i.e., converting the spermatocytes to sperm) and they are thought to play a role in shaping the head and tail of the sperm. Sertoli cells also secrete several hormones, including AMH, which is secreted by the testes during fetal life to inhibit development of fallopian tubes; estradiol, the principal feminizing sex hormone, which seems to be required in the male for spermatogenesis; and inhibin, which controls the function of Sertoli cells through feedback inhibition of follicle-stimulating hormone (FSH) from the anterior pituitary gland. For spermatogenesis to occur, FSH binds to specific receptors in Sertoli cells. A high concentration of intratesticular testosterone is also required.

IN SUMMARY

The male reproductive system consists of a pair of gonads (i.e., testes), a system of excretory ducts (i.e., seminiferous tubules and efferent ducts), the accessory organs (i.e., epididymis, seminal vesicles, prostate, and Cowper glands), and the penis. The sex of a person is determined by the sex chromosomes at the time of fertilization. During the 7th week of gestation, the XY chromosome pattern and the SRY gene in the male embryo are responsible for the development of the testes; with the subsequent production of AMH and testosterone, development of the internal and external male genital structures occurs. Before this period of embryonic development, the tissues from which the male and female reproductive structures develop are undifferentiated. In the absence of testosterone production (and its derivative DHT), the male embryo with an XY chromosomal pattern develops female external genitalia.
containing a single set of 23 chromosomes rather than a pair of 46 chromosomes, as occurs during mitotic cell division in other body cells.

The spermatid elongates into a spermatozoon, or mature sperm cell, with a head and tail (see Fig. 51.5B). The outside of the anterior two thirds of the head, called the acrosome, contains enzymes necessary for penetration and fertilization of the ovum.1 The to-and-fro flagellar motion of the tail imparts movement to the sperm. The energy for this process is supplied by the mitochondria in the tail. Normal sperm move in a straight line at a velocity of 1 to 4 mm/minute. This allows them to move through the female genital tract. As the sperm grow to full size, they move to the epididymis to mature further and gain mobility. A small quantity of sperm can be stored in the epididymis, but most are stored in the vas deferens or the ampulla of the vas deferens. With excessive sexual activity, storage may be no longer than a few days. The sperm can live for many weeks in the male genital tract; however, in the female genital tract, their life expectancy is 1 or 2 days.1 Frozen sperm have been preserved for years. The entire process of spermatogenesis and sperm maturation takes approximately 90 days. The sperm count in a normal ejaculate is approximately 100 to 400 million. Infertility may occur when insufficient numbers of motile, healthy sperm are present. A “fertile sample” on seminal fluid analysis is associated with a count greater than 20 million/mL, greater than 50% motility, normal morphology, and a volume of 1.5 to 6 mL.5,6 The field of reproductive endocrinology has greatly expanded with technology that is capable of making it possible for the majority of people interested in having a baby to be successful.

**Hormonal Control of Male Reproductive Function**

**Testosterone and Other Male Sex Hormones**

The male sex hormones are called androgens. The testes secrete several male sex hormones, including testosterone, dihydrotestosterone, and androstenedione. Testosterone, which is the most abundant of these hormones, is considered the main testicular hormone.3 The adrenal cortex also produces androgens, although in much smaller quantities (<5% of the total male androgens) than those produced in the testes. The testes also secrete small quantities of estradiol and estrone.1,4

Testosterone is produced and secreted by the interstitial Leydig cells in the testes. Under the influence of luteinizing hormone (LH), Leydig cells produce approximately 6 mg/day of testosterone.1 It is metabolized in the liver and excreted by the kidneys. In the bloodstream, testosterone exists in a free (unbound) or a bound form. The bound form is attached to plasma proteins, including albumin and the sex hormone-binding globulin (SHBG) produced by the liver. Only approximately 2% of circulating testosterone is unbound and therefore able to enter the cell and exert its metabolic effects. Much of the testosterone that becomes fixed to the tissues is converted to DHT by 5α-reductase, especially in certain

---

**FIGURE 51.5** - The various stages of spermatogenesis. (A) Cross-section of seminiferous tubule. (B) Stages of development of spermatozoa.

In the first stage of spermatogenesis, small and unspecialized diploid germinal cells located immediately adjacent to the tubular wall, called the spermatogonia, undergo rapid mitotic division and provide a continuous source of new germinal cells. As these cells multiply, the more mature spermatogonia divide into two daughter cells, which grow and become the primary spermatocytes—the precursors of sperm.3 Over several weeks, large primary spermatocytes divide by a process called meiosis to form two smaller secondary spermatocytes. Each of the secondary spermatocytes divides to form two spermatids, each containing 23 chromosomes. Meiosis is a unique form of cell division that occurs only in the gonads. It consists of two consecutive nuclear divisions with formation of four daughter cells, each
target tissues such as the prostate gland. Some of the actions of testosterone depend on this conversion, whereas others do not.1 Testosterone can also be aromatized or converted to estradiol in the peripheral tissues.

Testosterone (and DHT) exerts a variety of biologic effects in the male (Chart 51.1). In the male embryo, testosterone is essential for the appropriate differentiation of the internal and external genitalia, and it is necessary for descent of the testes in the fetus. Testosterone is essential to the development of primary and secondary male sex characteristics during puberty and for their maintenance during adult life.1 It causes growth of pubic, chest, and facial hair; it produces changes in the larynx that result in the male bass voice; and it increases the thickness of the skin and increases the activity of the sebaceous glands, predisposing to acne.

All or almost all of the actions of testosterone and other androgens result from increased protein synthesis in target tissues. Androgens function as anabolic agents in males and females to promote metabolism and musculoskeletal growth. Testosterone and the androgens have a great effect on the development of increasing musculature during puberty, with boys averaging approximately a 50% increase in muscle mass compared with girls. Box 51.1 describes the abuse of androgens by athletes to enhance athletic performance.

**Action of the Hypothalamic and Anterior Pituitary Hormones**

The hypothalamus and the anterior pituitary gland play an essential role in promoting spermatogenic activity in the testes and maintaining the endocrine function of the testes by means of the gonadotropic hormones. The synthesis and release of the gonadotropic hormones from the pituitary gland are regulated by gonadotropin-releasing hormone (GnRH), which is synthesized by the hypothalamus and secreted into the hypothalamic–hypophyseal portal circulation (Fig. 51.6).1

Two gonadotropic hormones are secreted by the pituitary gland: FSH and LH. The production of testosterone by the interstitial Leydig cells is regulated by LH (see Fig. 51.6). FSH binds selectively to Sertoli cells surrounding the seminiferous tubules, where it functions in the initiation of spermatogenesis. Under the influence of FSH, Sertoli cells produce androgen-binding protein, plasminogen activator, and inhibin. Androgen-binding protein binds testosterone and serves as a carrier of testosterone in Sertoli cells and as a storage site for testosterone. Although FSH is necessary for the initiation of spermatogenesis, full maturation of the spermatozoa requires testosterone (the intratesticular concentration of testosterone is 100-fold greater than serum levels). Androgen-binding protein also serves as a carrier of testosterone from the testes to the epididymis. Plasminogen activator, which converts plasminogen to plasmin, functions in the final detachment of mature spermatozoa from Sertoli cells.

Circulating levels of the gonadotropic hormones are regulated in a negative feedback manner by testosterone. High levels of testosterone suppress LH secretion through a direct action on the pituitary and an inhibitory effect on the hypothalamus. FSH is thought to be inhibited by a substance called inhibin, produced by Sertoli cells. Inhibin suppresses FSH release from the pituitary gland. The pituitary gonadotropic hormones and Sertoli cells in the testes form a classic negative feedback loop in which FSH stimulates inhibin and inhibin suppresses FSH.1,4 Unlike the cyclic hormonal pattern in females, in males, FSH,

---

**Chart 51.1**

**MAIN ACTIONS OF TESTOSTERONE**

- Induces differentiation of the male genital tract during fetal development
- Induces development of primary and secondary sex characteristics
- Gonadal function
- External genitalia and accessory organs
- Male voice timbre
- Male skin characteristics
- Male hair distribution
- Anabolic effects
  - Promotes protein metabolism
  - Promotes musculoskeletal growth
  - Influences subcutaneous fat distribution
- Promotes spermatogenesis (in FSH-primed tubules) and maturation of sperm
- Stimulates erythropoiesis

---

**Box 51.1**

**ABUSE OF ANDROGENS TO ENHANCE ATHLETIC PERFORMANCE**

- Athletes use synthetic androgens to improve their skill and endurance by bulking up their muscles.
- Athletes have taken virtually all androgens produced for human and veterinary purposes.
- Occasionally, athletes take several medications simultaneously in an attempt to increase the overall effect on performance, which can cause potentially more deleterious side effects.
- Hormones are frequently taken in doses that far exceed physiologic levels.
- There are potential harmful effects to taking these supplements including acne, decreased testicular size, and azoospermia.
- The detrimental effects may persist for months after use of the agents has ceased, depending on the type and dose administered.
- Because testosterone can be aromatized to estradiol in the peripheral tissues, androgens can also produce gynecomastia (breast enlargement).
Chapter 51  Structure and Function of the Male Genitourinary System

1341

LH, and testosterone secretion and spermatogenesis occur at relatively unchanging rates during adulthood.\(^1\)

**Hypogonadism**

Hypogonadism can be primary (testicular failure due to problem in the testes) or secondary (failure resulting from lack of stimulation by gonadotropins [LH and FSH] from the pituitary).\(^1\) Tertiary hypogonadism also occurs and is caused by lack of stimulation of LH and FSH secretion from the pituitary, due to decreased or absent GnRH secretion from the hypothalamus. In men, primary hypogonadism is characterized by low androgens and sperm count and is due to lack of negative feedback at the hypothalamic–pituitary level, coupled with high levels of gonadotropins (i.e., low testosterone and high LH and FSH). Secondary (and tertiary) hypogonadism, which also is characterized by low androgens and
sperm count, is due to lack of secretion of gonadotropins from the hypothalamic–pituitary level, coupled with low levels of gonadotropins (i.e., low testosterone and low LH and FSH).

**Clinical Manifestations.** The clinical features of male hypogonadism depend on whether the impairment involves only spermatogenesis (FSH increase reflects Sertoli cell damage) or if testosterone secretion is also impaired (LH increase reflects Leydig cell damage). There are only two clinical manifestations of impaired spermatogenesis: subfertility/infertility and decreased testicular size (80% of testicular size is related to sperm production and 20% to testosterone production). In contrast, there are several possible clinical manifestations of impaired testosterone secretion, which are determined by its time of onset. Onset occurring in the adult is associated with fatigue, depression, decreased libido, erectile dysfunction (ED), loss of secondary sex characteristics, changes in body composition (including loss of muscle mass and increase in fat mass), and decreased bone density or osteoporosis.7–9 When hypogonadism is diagnosed the clinician should follow up thoroughly with a comprehensive cardiovascular examination since hypogonadism is, along with ED and type 2 DM, a predictor of cardiac disease.9

It is more challenging to identify the correct etiology and complete pathophysiology of hypogonadism in adolescents. However, there are multiple treatment options to induce puberty and manage the adolescent’s symptoms of hypogonadism.10

**Diagnosis.** Diagnosis of hypogonadism includes measurement of total testosterone levels (ideally at 8:00 AM, when the testosterone level is at its peak) in the ambulatory man. If the initial total testosterone level is low, the diagnosis of hypogonadism should be confirmed with either a repeat measurement of total testosterone or a measure of free (bioavailable) testosterone. Once the diagnosis of hypogonadism is established, the LH and FSH levels should also be measured. A subsequently high LH and FSH indicates a primary hypogonadism (hypergonadotrophic hypogonadism), and low or inappropriately normal LH and FSH a secondary or tertiary hypogonadism (hypogonadotropic hypogonadism). Seminal fluid analysis should be considered in both types of hypogonadism if fertility is a concern. In men with hypergonadotropic hypogonadism, other pituitary hormones should be assessed and a pituitary magnetic resonance imaging (MRI) scan done. In cases of hypergonadotrophic hypogonadism, a karyotype (chromosome) analysis may be indicated because Klinefelter syndrome is the most common chromosomal abnormality associated with male hypogonadism. The usual karyotype is 47,XXY, although mosaicism or variants can present with a similar phenotype (the normal male is 46,XY and the normal female is 46,XX). Males with Klinefelter syndrome characteristically have small, firm testes (unlike many other cases of hypogonadism, in which the testicular consistency is soft).11 Other common causes of primary hypogonadism are listed in Chart 51.2.

**Chart 51.2 COMMON CAUSES OF PRIMARY GONADAL FAILURE**

- Chromosomal abnormalities (e.g., Klinefelter syndrome)
- Disorders of androgen biosynthesis
- Cryptorchidism
- Alkylating and antineoplastic agents
- Other medications (e.g., ketoconazole and glucocorticoids)
- Infections—mumps orchitis (gonadal failure is a much more common manifestation when mumps occurs after puberty)
- Radiation (direct and indirect testicular radiation)
- Environmental toxins
- Trauma
- Testicular torsion
- Autoimmune damage
- Chronic systemic diseases (many of these can result in both primary and secondary hypogonadism, e.g., cirrhosis, hemochromatosis, chronic renal failure, and AIDS)
- Idiopathic

**Treatment.** Testosterone for treatment of androgen deficiency should be administered only to men with confirmed hypogonadism (as evidenced by a distinctly subnormal serum testosterone concentration). The principal goal of testosterone therapy is to restore the serum testosterone concentration to the normal range while keeping in mind the risks and benefits especially with men diagnosed or at risk for BPH and/or prostate cancer.

**IN SUMMARY**

The function of the male reproductive system is under the negative feedback control of the hypothalamus and the anterior pituitary gonadotropin hormones FSH and LH. Spermatogenesis is initiated by FSH and the production of testosterone is regulated by LH. Testosterone, the major male sex hormone, is produced by the interstitial Leydig cells in the testes. In addition to its role in the differentiation of the internal and external genitalia in the male embryo, testosterone is essential for the development of secondary male characteristics during puberty, the maintenance of these characteristics during adult life, and spermatozoa maturation.

Hypogonadism refers to a decrease in testicular function. It can present as a primary hypogonadism originating in the testes; a secondary hypogonadism arising from lack of stimulation from the pituitary gonadotropins (LH and FSH); or as a tertiary hypogonadism due to decreased or absent GnRH secretion from the hypothalamus.
In the male, the stages of the sexual act involve erection, emission, ejaculation, and detumescence. The physiology of the sexual act involves a complex interaction between spinal cord reflexes, higher neural centers, the vascular system, and the endocrine system.

**Neural Control**

The most important source of impulse stimulation for initiating the male sexual act is the glans penis, which contains a highly organized sensory system. Afferent impulses from sensory receptors in the glans penis pass through the pudendal nerve to ascending fibers in the spinal cord by way of the sacral plexus. Stimulation of other perineal areas, such as the anal epithelium, the scrotum, and the testes, can transmit signals to higher brain centers, such as the limbic system and cerebral cortex, through the cord, adding to sexual arousal.1

The psychic element to sexual stimulation, such as thinking sexual thoughts, can cause erection and ejaculation.1 Although psychic involvement and higher-center functions contribute to the sex act, they are not necessary for sexual performance. Genital stimulation can produce erection and ejaculation in some men with complete transection of the spinal cord.

Erection involves the shunting of blood into the corpus cavernosum. It is controlled by the sympathetic, parasympathetic, and nonadrenergic–noncholinergic (NANC) systems. Nitric oxide is the locally released NANC mediator that produces relaxation of vascular smooth muscle. In the flaccid or detumescent state, sympathetic discharge through α-adrenergic receptors maintains constriction of the arteries that supply the penis and vascular sinuses of the corpora cavernosa and corpus spongiosum (Fig. 51.7). Parasympathetic stimulation produces erection by inhibiting sympathetic neurons that cause detumescence and by stimulating the release of nitric oxide to effect a rapid relaxation of the smooth muscle in the sinusoidal spaces of the corpus cavernosum. During sexual stimulation, parasympathetic impulses also cause the urethral and bulbourethral glands to secrete mucus to aid in lubrication. Parasympathetic innervation is effected through the pelvic nerve and sacral segments of the spinal cord. Sympathetic innervation exits the spinal cord at the L1 and L2 levels.

Emission and ejaculation, which constitute the culmination of the male sexual act, are a function of the sympathetic nervous system. As with erection, emission and ejaculation are mediated through spinal cord reflexes. With increasing intensity of the sexual stimulus, reflex centers of the spinal cord begin to emit sympathetic impulses that leave the cord at the L1 and L2 levels and pass through the hypogastric plexus to the genital organs to initiate emission, which is the forerunner of ejaculation. Emission causes the sperm to move from the epididymis to the urethra. Efferent impulses from the spinal cord produce contraction of smooth muscle in the vas deferens and ampulla that move sperm forward and close the internal urethral sphincter to prevent retrograde ejaculation into the bladder.1

Ejaculation represents the expulsion of the sperm from the urethra. It involves contraction of the seminal vesicles and prostate gland, which add fluid to the ejaculate and propel it forward. Ejaculation is accompanied by contraction of the ischiocavernous and bulbocavernous muscles at the base of the penis. The filling of the internal urethra elicits signals that are transmitted through the pudendal nerves from the spinal cord, giving the sudden feeling of fullness of the genital organs. Rhythmic increases in pressure in the urethra cause the semen to be propelled to the exterior, resulting in ejaculation. At the same time, rhythmic contractions of the pelvic and trunk muscles produce thrusting movements of the pelvis and penis, which help propel the ejaculate into the vagina.

The period of emission and ejaculation is called male orgasm. After ejaculation, erection ceases within 1 to 2 minutes. A man usually ejaculates approximately 2 to 5 mL of semen. The ejaculate may vary with frequency of intercourse. It is less with frequent ejaculation and may increase to two to four times its normal amount during periods of abstinence. The semen that is ejaculated is 98% fluid and approximately 2% sperm.

**Changes with Aging**

Like other body systems, the male reproductive system undergoes degenerative changes as a result of the aging process; it becomes less efficient with age. The declining physiologic efficiency of male reproductive function occurs gradually and involves the endocrine, circulatory, and neuromuscular systems. Compared with the marked physiologic changes in...
aging females, the changes in the aging male are more gradual and less drastic. Gonadal and reproductive failure usually are not related directly to age because a man remains fertile into advanced age; 80- and 90-year-old men have been known to father children.1

As the male ages, his reproductive system becomes measurably different in structure and function from that of the younger male. Male sex hormone levels, particularly of testosterone, decrease with age, but the rate varies in different men and is affected by multiple variables.12 Beginning at about 25 to 30 years of age in healthy, nonobese men, testosterone levels gradually decrease at approximately 10% per decade. The term andropause has been used to describe an ill-defined collection of symptoms in aging men, generally men older than 50 years, who have some degree of hypogonadism associated with aging.12 The existence and significance of andropause has important public health implications given the current number of men older than 65 years of age, with the number expected to double over the next 30 years.

The sex hormones play a part in the structure and function of the reproductive system and other body systems from conception to old age; they affect protein synthesis, salt and water balance, bone growth, and cardiovascular function. Low testosterone levels have an atherogenic effect that may be part of the etiology of the higher incidence of cardiovascular disease in androgen-deficient men.9,12 Decreasing levels of testosterone affect sexual energy, muscle strength, and the genital tissues. The testes become smaller and lose their firmness. The seminiferous tubules, which produce spermatozoa, thicken and begin a degenerative process that finally inhibits sperm production, resulting in a decrease in viable spermatozoa. The prostate gland enlarges and its contractions become weaker. The force of ejaculation decreases because of a reduction in the volume and viscosity of the seminal fluid. The seminal vesicle changes little from childhood to puberty. The pubertal changes increase in the fluid capacity of the gland remain throughout adulthood and decline after 60 years of age. After 60 years of age, the walls of the seminal vesicles thin, the epithelium shrinks, and the muscle layer is replaced by connective tissue. Age-related changes in the penis consist of fibrotic changes in the trabecula in the corpus spongiosum, with progressive sclerotic changes in arteries and veins. Sclerotic changes also follow in the corpora cavernosa, with the condition becoming generalized in 55- to 60-year-old men.

Erectile dysfunction is commonly seen in older men with type 2 DM, cardiovascular disease and hyperlipidemia.9 Erectile dysfunction has largely replaced the term impotence. It is defined as the persistent inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. Aging is a major etiologic factor in this condition. Diseases that accompany aging can have a direct bearing on male reproductive function. Various cardiovascular, respiratory, hormonal, neurologic, and hematologic disorders can be responsible for secondary impotence. For example, vascular disease affects male potency because it may impair blood flow to the pudendal arteries or their tributaries, resulting in loss of blood volume with subsequent poor distention of the vascular spaces of erectile tissue. Other diseases affecting potency include hypertension, diabetes, cardiac disease, and malignancies of the reproductive organs. In addition, certain medications can have an effect on sexual function.

One of the greatest inhibitors of sexual functioning in older men is the loss of self-esteem and the development of a negative self-image. The emphasis on youth pervades much of our society. The image of success for a man often involves qualities of masculinity and sexual attractiveness. When queried about success, men often mention such things as work, managing money well, participating in sports or other activities, discussing politics or world events, advising younger persons, and being attractive to women. When a man feels good about himself and expresses self-confidence, sexual attractiveness is communicated regardless of age. Many older men live in environments that are not sensitive to the importance of helping them maintain a positive self-image. Premature cessation of the aforementioned esteem-building activities can contribute to loss of libido and zest for life in the older man.

Testosterone and other synthetic androgens may be used in older men with confirmed low androgen levels to improve muscle strength and vigor. Preliminary studies of androgen replacement in aging men with low androgen levels show an increase in lean body mass and a decrease in bone turnover. Before testosterone replacement therapy is initiated, all men should be screened for prostate cancer.8,9 Testosterone is available in several different formulations, including an injectable form, transdermal patch, topical gel, or buccal delivery system. Side effects of replacement therapy may include acne, gynecomastia, and reduced high-density lipoprotein cholesterol levels.7–9

At present, it is not recommended that routine treatment of older men with testosterone should be undertaken. A trial of testosterone administration, however, might be warranted in an older man whose serum testosterone concentration is less than 300 ng/dL (although some believe it should be even lower, i.e., <200 ng/dL) and who has manifestations of testosterone deficiency.5,9 If treatment is undertaken, the man should be screened before treatment and monitored during therapy for evidence of testosterone-dependent diseases.

**IN SUMMARY**

The sex act involves erection, emission, ejaculation, and detumescence. The physiology of these functions involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. Erection is mediated by the parasympathetic nervous system and emission and ejaculation by the sympathetic nervous system. Like other body systems, the male reproductive system undergoes changes as a result of the aging process. The changes occur gradually and involve parallel changes in endocrine, circulatory, and neuromuscular function. Testosterone levels decrease (andropause), the
size and firmness of the testes decrease, sperm production declines, and the prostate gland enlarges. There is usually a decrease in frequency of intercourse, intensity of sensation, speed of attaining erection, and force of ejaculation. However, sexual thought, interest, and activity usually continue into old age.

**REVIEW EXERCISES**

1. In the absence of the SRY gene on the Y chromosome, a developing embryo with an XY genotype will develop female genitalia.
   A. Explain.
2. Men who have had a vasectomy often remain fertile for 4 to 5 weeks after the procedure has been done.
   A. Explain.
3. A 55-year-old man presents with various vague symptoms (fatigue, depression). On examination, he is noted to have small testes (8 mL bilaterally), marked gynecomastia, and scanty body hair. He is obese at 122 kg, with a body mass index (BMI) of 34.2. Investigations reveal low testosterone and elevated gonadotropin (LH and FSH) levels.
   A. What endocrine diagnosis is related to this phenotype and these biochemical manifestations?

The male genitourinary system is subject to structural defects, inflammation, and neoplasms, all of which can affect urine elimination, sexual function, and fertility. This chapter discusses disorders of the penis, the scrotum and testes, and the prostate.

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the anatomic changes that occur with Peyronie disease.
- Explain the physiology of penile erection and relate it to erectile dysfunction and priapism.
- List the signs of penile cancer.

The penis is the external male genital organ through which the urethra passes to the exterior of the body. It is involved in urinary and sexual function. Disorders of the penis include congenital and acquired defects, inflammatory and infectious conditions, and neoplasms.

Congenital and Acquired Disorders

Hypospadias and Epispadias

Hypospadias and epispadias are congenital disorders of the penis resulting from embryologic defects in the development of the urethral groove and penile urethra (Fig. 52.1). In hypospadias, which affects approximately 1 in 350 male infants, the termination of the urethra is on the ventral or underside surface of the penis. The etiology in most cases is unknown. Single-gene defects, chromosomal abnormalities, and maternal
Phimosis and Paraphimosis

Phimosis refers to a tightening of the prepuce or penile foreskin that prevents its retraction over the glans. Embryologically, the foreskin begins to develop during the 8th week of gestation as a fold of skin at the distal edge of the penis that eventually grows forward over the base of the glans. By the 16th week of gestation, the prepuce and the glans are adherent. Only a small percentage of newborns have a fully retractable foreskin. With growth, a space develops between the glans and foreskin and the majority of boys have retractable foreskins.

Because the foreskin of many boys cannot be fully retracted in early childhood, it is important that the area be cleaned thoroughly. There is no need to retract the foreskin forcibly because this could lead to infection, scarring, or paraphimosis. As the child grows, the foreskin becomes retractable, and the glans and foreskin should be cleaned routinely. If symptomatic phimosis occurs after childhood, such as with uncircumcised men with multiple infections, it can cause difficulty with voiding or sexual activity. Circumcision is then the treatment of choice. Phimosis is also one of the most important predisposing factors for penile cancer.

In paraphimosis, the foreskin is so tight and constricted that it cannot cover the glans. A tight foreskin can constrict the blood supply to the glans and lead to ischemia and necrosis. Many cases of paraphimosis result from the foreskin being retracted for an extended period, as in the case of catheterized uncircumcised males.

Balanitis and Balanoposthitis

Balanitis is an acute or chronic inflammation of the glans penis, which generally occurs in 11% of adult men and 3% of boys. Men with poor hygiene, immunosuppression, or diabetes are more prone to balanitis. Balanoposthitis refers to inflammation of the glans and prepuce. It is usually encountered in men with phimosis or a large, redundant prepuce that interferes with cleanliness and predisposes to bacterial growth in the accumulated secretions and smegma (i.e., debris from the desquamated epithelia). If the balanoposthitis is not identified and treated, especially if the patient has phimosis, the condition may cause ulcerations of the mucosal surface of the glans. These ulcerations may lead to inflammatory scarring of the prepuce and further aggravate the condition.

Acute superficial balanoposthitis is characterized by erythema of the glans and prepuce. An exudate in the form of malodorous discharge may be present. Extension of the erythema and edema may result in phimosis. The condition may result from infection, trauma, or irritation. Infective balanoposthitis may be caused by a wide variety of organisms. Chlamydia and mycoplasmas have been identified as causative organisms in this disease. Gonococcal balanitis may develop as a complication of infection in uncircumcised men. The inflammatory reaction is nonspecific, and correct identification of the specific organism requires microbial smears and cultures.

Balanitis due to candidal infection may be a presenting feature or may result from poorly controlled diabetes mellitus. Balanitis can also result from noninfectious causes, such as circinate balanitis, which is seen in reactive arthritis. Lesions are superficial, painless ulcers that heal without scarring.

FIGURE 52.1 • Hypospadias and epispadias.
Balanitis xerotica obliterans is a chronic, sclerosing, atrophic process of the glans penis that occurs in uncircumcised men. It is clinically and histologically similar to the lichen sclerosus that is seen in women. Typically, the lesions consist of whitish plaques on the surface of the glans penis and the prepuce. The foreskin is thickened and fibrous and is not retractable. Treatment measures include circumcision and topical corticosteroids.

Peyronie Disease

Peyronie disease involves a localized and progressive fibrosis of unknown origin that affects the tunica albuginea (i.e., the tough, fibrous sheath that surrounds the corpora cavernosa) of the penis. Approximately 1% of men are impacted by this disorder. The disorder is characterized initially by an inflammatory process that results in dense fibrous plaque formation. The plaque is usually on the dorsal midline of the shaft, causing upward bowing of the shaft during erection (Fig. 52.2). Some men may develop scarring on both the dorsal and ventral aspects of the shaft, causing the penis to be straight but shortened or have a lateral bend. The fibrous tissue prevents lengthening of the involved area during erection, making intercourse difficult and painful. The disease usually occurs in men older than 40 years of age.

The manifestations of Peyronie disease include painful erection, bent erection, and the presence of a hard mass at the site of fibrosis. Approximately two thirds of men complain of pain as a symptom. Inflammation of the adjacent fascial tissue is thought to generate the pain. The pain usually disappears as the inflammation resolves. During the first year or so after formation of the plaque, while the scar tissue is undergoing the process of remodeling, penile distortion may increase, remain static, or resolve and disappear completely. In some cases, the scar tissue may progress to calcification and formation of bonelike tissue.

Diagnosis is based on history and physical examination. Doppler ultrasonography may be used to assess causation of the disorder. Surgical intervention can be used to correct the disorder. Indications for surgery include penile shortening, persistent pain, severe curvature, and penile narrowing or indentation.

Disorders of Erectile Function

Erection is a neurovascular process involving the autonomic nervous system, neurotransmitters and endothelial relaxing factors, the vascular smooth muscle of the arteries and veins supplying the penile tissue, and the trabecular smooth muscle of the sinusoids of the corpora cavernosa (Fig. 52.3). The penis is innervated by both the autonomic and somatic nervous systems. In the pelvis, the sympathetic and parasympathetic components of the autonomic nervous systems merge to form what are called the cavernous nerves. Erection is under the control of the parasympathetic nervous system, and ejaculation and detumescence (penile relaxation) are under sympathetic nervous system control. Somatic innervation, which occurs through the pudendal nerve, is responsible for penile sensation and contraction and relaxation of the extracorporeal striated muscles (bulbocavernous and ischiocavernous).

Penile erection is the first effect of male sexual stimulation, whether psychological or physical (Fig. 52.4). It involves increased inflow of blood into the corpora cavernosa due to
an extent that the penis becomes hard and elongated. At the same time, contraction of the somatically innervated ischiocavernous muscles forcefully compresses the blood-filled corpora cavernosa, producing a further rise in intercavernous pressures. During this phase of erection, inflow and outflow of blood cease.

Parasympathetic innervation must be intact and nitric oxide synthesis must be active for erection to occur. Nitric oxide activates guanyl cyclase, an enzyme that increases the concentration of cyclic guanosine monophosphate (cGMP), which in turn causes smooth muscle relaxation. Other smooth muscle relaxants (e.g., prostaglandin E1 analogs and α-adrenergic antagonists), if present in high enough concentrations, can independently cause sufficient cavernosal relaxation to result in erection. Many of the drugs that have been developed to treat erectile dysfunction act at the level of these mediators.

Detumescence or penile relaxation is largely a sympathetic nervous system response. It can result from a cessation of neurotransmitter release, the breakdown of second messengers such as cGMP, or sympathetic discharge during ejaculation. Contraction of the trabecular smooth muscle opens the venous channels so that the trapped blood can be expelled and penile flaccidity can return.

**KEY POINTS**

**DISORDERS OF PENILE ERECTION**

- Erection is a neurovascular process involving the autonomic nervous system, the somatic nervous system by way of the pudendal nerve, the vascular system, and the sinusoidal spaces of the corpora cavernosa.
- Erectile failure can result from disorders in one or a combination of the neural, vascular, or chemical mediator aspects of the erectile process.

**Erectile Dysfunction**

Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. In the United States alone, approximately 52% of men between 40 and 70 years of age report some degree of erectile dysfunction. Erectile dysfunction is classified as psychogenic, organic, or mixed psychogenic and organic.

**Psychogenic Causes.** Psychogenic causes of erectile dysfunction include performance anxiety, a strained relationship with a sexual partner, depression, and overt psychotic disorders. Psychogenic factors can be further exacerbated by the side effects of many of the therapies used to treat these disorders, which can themselves cause erectile dysfunction.
Organic Causes. Organic causes of erectile dysfunction span a wide range of pathologic processes. They include neurogenic, hormonal, vascular, drug-induced, and penile-related etiologies.

Neurogenic disorders such as Parkinson disease, stroke, and cerebrovascular trauma often contribute to erectile dysfunction by decreasing libido or preventing the initiation of erection. In spinal cord injury, the extent of neural impairment depends on the level, location, and extent of the lesion. Somatosensory involvement of the genitalia is essential to the reflex mechanisms involved in erection; this becomes important with aging and conditions such as diabetes that impair peripheral nerve function. Extensive pelvic surgery, especially radical prostatectomy, is a common cause of erectile dysfunction due to both direct and indirect nerve damage.

Hormonal causes of erectile dysfunction include a decrease in androgen levels because of both primary and secondary hypogonadism. Androgen levels may be decreased because of aging (andropause). Hyperprolactinemia from any cause interferes with both production and reproduction function. This is because prolactin acts centrally to inhibit the release of the hypothalamic gonadotropin-releasing hormone (GnRH) that controls the release of the pituitary gonadotropic hormones, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). Elevated prolactin levels may also interfere with normal functioning at the level of the gonad.

Common risk factors for generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, and pelvic irradiation. In hypertension, erectile function is impaired not so much by the increased blood pressure as by the associated stenotic arterial lesions. Focal stenosis of the common penile artery most often occurs in men who sustained blunt pelvic or perineal trauma (e.g., from bicycling accidents). Failure of the veins to close completely during an erection (veno-occlusive dysfunction) may occur in men with large venous channels that drain the corpora cavernosa. Many drugs are reported to cause erectile dysfunction, including antidepressant, antipsychotic, antiandrogen, and antihypertensive medications. Cigarette smoking can induce vasoconstriction and penile venous leakage because of its effects on cavernous smooth muscle and can double the risk of erectile dysfunction. Alcohol in small amounts may increase libido and improve erection. However, in large amounts it can cause central sedation, decreased libido, and transient erectile dysfunction.

Aging is known to increase the risk of erectile dysfunction. Many of the pathologic processes that contribute to erectile dysfunction, including diabetes, hyperlipidemia, vascular disease, and the long-term effects of cigarette smoking, are more common in older men. Age-related declines in testosterone may also play a role (andropause).

Diagnosis and Treatment. A diagnosis of erectile dysfunction requires careful history (medical, sexual, and psychosocial), physical examination, and laboratory tests aimed at determining what other tests are needed to rule out organic causes of the disorder. Because many medications, including prescribed, over-the-counter, and illicit drugs, can cause erectile dysfunction, a careful drug history is indicated.

Erectile dysfunction is now recognized as a marker for cardiovascular disease, and is now considered a component of the metabolic syndrome. The association between erectile dysfunction and the metabolic syndrome may be related to the underlying endothelial dysfunction seen in both conditions. A patient with erectile dysfunction should be thoroughly evaluated for coexisting vascular disease and type 2 diabetes mellitus. Any cardiovascular risk factors should be modified or treated (e.g., smoking, diabetes, hypertension, and hyperlipidemia).

Any treatment regimens should always take into account the partner’s attitude about the problem and the likely response to effective treatment. Treatment methods include psychosexual counseling, androgen replacement therapy, oral and intracavernous drug therapy, vacuum constriction devices, and surgical treatment. Among the commonly prescribed drugs are sildenafil, vardenafil, tadalafil, alprostadil, papaverine, and phentolamine. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) are selective inhibitors of phosphodiesterase type 5 (PDE-5), the enzyme that inactivates cGMP. This acts by facilitating corporal smooth muscle relaxation in response to sexual stimulation (see Fig. 52.4). The concomitant use of PDE-5 inhibitors and nitrates (used, e.g., in ischemic heart disease) is absolutely contraindicated because of the risk of profound hypotension. The PDE-5 inhibitors are taken orally. Alprostadil, a prostaglandin E1 analog, acts by producing relaxation of cavernous smooth muscle. It is either injected directly into the corpora cavernosa (with diffusion into the opposite cavernosa) or placed in the urethra as a minisuppository. Phentolamine (an α-adrenergic receptor antagonist) and papaverine (smooth muscle relaxant) are also administered by intracavernous injection.

Priapism

Priapism is an involuntary, prolonged (>4 hours), abnormal, and painful erection that continues beyond, or is unrelated to, sexual stimulation. Priapism is a true urologic emergency because the prolonged erection can result in ischemia and fibrosis of the erectile tissue with significant risk of subsequent impotence. Priapism can occur at any age, in the newborn as well as other age groups. Sickle cell disease or neoplasms are the most common cause in boys between 5 and 10 years of age. Priapism is caused by impaired blood flow in the corpora cavernosa of the penis. Priapism is classified as primary (idiopathic) or secondary to a disease or drug effect. Secondary causes include hematologic conditions such as leukemia, sickle cell disease, and thrombocytopenia; neurologic conditions such as stroke, spinal cord injury, and other central nervous system lesions; and renal failure. Males with sickle cell disease are frequently affected by either stuttering (lasting minutes to 3 to 4 hours and spontaneously resolving) or prolonged (lasting >3 to 4 hours and requiring medical intervention) priapism. The relative deoxygenation and stasis of cavernosal blood during erection is thought to
increase sickling. Various medications, such as antihypertensive drugs, anticoagulant drugs, antidepressant drugs, alcohol, and marijuana, can contribute to the development of priapism. Currently, intracavernous injection therapy for erectile dysfunction is one of the more common causes of priapism.

The diagnosis of priapism is usually based on clinical findings. Doppler studies of penile blood flow, penile ultrasonography, and computed tomography (CT) scans may be used to determine intrapelvic pathology.

Initial treatment measures include analgesics, sedation, and hydration. Urinary retention may necessitate catheterization. Local measures include ice packs and cold saline enemas, aspiration and irrigation of the corpus cavernosum with plain or heparinized saline, or instillation of α-adrenergic drugs. If less aggressive treatment does not produce detumescence, a temporary surgical shunt may be established between the corpus cavernosum and the corpus spongiosum.

Cancer of the Penis

The average age of men diagnosed with squamous cell cancer of the penis is 60 years. It is most common in uncircumcised men. Although relatively rare in developed countries (<0.5 of all cancers), it may account for 10% of all malignant lesions in areas such as Africa and South America. When it is diagnosed early, penile cancer is highly curable. The greatest hindrance to early diagnosis is a delay in seeking medical attention.

The cause of penile cancer is unknown. Several risk factors, including increasing age, poor hygiene, smoking, human papillomavirus (HPV) types 16 and 18 infections, ultraviolet radiation exposure, and immunodeficiency states, have been suggested. There is an association between penile cancer and poor genital hygiene and phimosis. One theory postulates that smegma accumulation under the phimotic foreskin may produce chronic inflammation, leading to carcinoma. The HPVs have been implicated in the genesis of several genital cancers, including cancer of the penis. Ultraviolet radiation is also thought to have a carcinogenic effect on the penis. Men who were treated for psoriasis with ultraviolet A radiation (i.e., PUVA) have had a reported increased incidence of genital squamous cell carcinomas. Immunodeficiency states (e.g., acquired immunodeficiency syndrome) may also play a role in the pathogenesis of penile cancer. Squamous cell carcinoma of the penis is thought to progress from an in situ lesion to an invasive carcinoma. Penile lesions with histologic features of carcinoma in situ require careful follow-up because of their potential to progress to invasive carcinoma.

Invasive carcinoma of the penis begins as a small lump or ulcer. If phimosis is present, there may be painful swelling, purulent drainage, or difficulty urinating. Palpable lymph nodes may be present in the inguinal region. Diagnosis is usually based on physical examination and biopsy results. Cavernosonography, urethroscopy, CT scans, and magnetic resonance imaging (MRI) may be used in the diagnostic workup.

Treatment options vary according to stage, size, location, and invasiveness of the tumor. Surgery remains the mainstay of treatment for invasive carcinoma. Superficial primary lesions that are freely movable, do not invade the corpora, and show no evidence of metastatic disease can be resected. Partial or total penectomy with appropriate lymph node dissection is indicated for invasive lesions.

Disorders of the penis can be congenital or acquired. Hypospadias and epispadias are congenital defects in which there is malpositioning of the urethral opening: it is located on the ventral surface in hypospadias and on the dorsal surface in epispadias. Phimosis is the condition in which the opening of the foreskin is too tight to permit retraction over the glans. Balanitis is an acute or chronic inflammation of the glans penis, and balanoposthitis is an inflammation of the glans and prepuce. Peyronie disease is characterized by the growth of a band of fibrous tissue on top of the penile shaft. Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It can be caused by psychogenic factors, organic disorders, or mixed psychogenic and organic conditions. Priapism is a prolonged, painful erection that can lead to thrombosis with ischemia and necrosis of penile tissue. Cancer of the penis accounts for less than 1% of male genital cancers in developed countries. Although the tumor is slow growing and highly curable when diagnosed early, the greatest hindrance to successful treatment is a delay in seeking medical attention.

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the cause, appearance, and significance of hydrocele, hematocoele, spermatocele, and varicocele.
- Describe the symptoms of epididymitis.
- State the cell types involved in seminoma, embryonal carcinoma, teratoma, and choriocarcinoma tumors of the testes.

The scrotum is a skin-covered pouch that contains the testes and their accessory organs. Defects of the scrotum and testes include cryptorchidism, disorders of the scrotal sac, vascular disorders, inflammation of the scrotum and testes, and neoplasms.

**Congenital and Acquired Disorders**

**Cryptorchidism**

Cryptorchidism, or undescended testes, occurs when one or both of the testes fail to move down into the scrotal sac. The condition is usually unilateral, but it may be bilateral in 30%...
of cases. \(^2\) The undescended testes may remain in the lower abdomen, at a point of descent in the inguinal canal, or in the upper scrotum (Fig. 52.5). \(^2\)

The incidence of cryptorchidism is directly related to birth weight and gestational age. Infants who are born prematurely or are small for gestational age have the highest incidence of the disorder. Approximately 30% of premature infants and 5% of full-term infants are born with undescended testicles. \(^2\) The cause of cryptorchidism in full-term infants is poorly understood. Most cases are idiopathic, but some may result from genetic or hormonal factors.

**Clinical Manifestations and Complications.** The major clinical manifestation of cryptorchidism is the absence of one or both testes from the scrotum. The testis either is not palpable or can be felt external to the inguinal ring. Spontaneous descent often occurs during the first 12 months of life. \(^2\)

In boys with cryptorchidism, histologic abnormalities of the testes reflect intrinsic defects in the testicle or adverse effects of the extrascrotal environment. There is a delay in germ cell development, changes in the spermatic tubules, and a reduced number of Leydig cells. These changes are progressive over time if the testes remain undescended.

The consequences of cryptorchidism include infertility, malignancy (20- to 40-fold greater risk), testicular torsion (10-fold increased risk), and the possible psychological effects of an empty scrotum. \(^2\) As a group, men with unilateral cryptorchidism usually have decreased sperm counts, poorer-quality sperm, and lower fertility rates than men whose testicles descend normally. Men with bilateral cryptorchidism have azoospermia. \(^2\) Indirect inguinal hernias usually accompany the undescended testis but are rarely symptomatic. Recognition of the condition and early treatment are important steps in preventing adverse consequences.

The increased risk of testicular cancer is not significantly affected by orchiopexy (the surgical placement and fixation of the testes in the scrotum), hormonal therapy, or late spontaneous descent after the age of 2 years. However, orchiopexy does allow for earlier detection of a testicular malignancy by positioning the testis in a more easily palpable location.

**Diagnosis and Treatment.** Diagnosis is based on careful examination of the genitalia in male infants. Undescended testes due to cryptorchidism should be differentiated from retractable testes that retract into the inguinal canal in response to an exaggerated cremaster muscle reflex. Retractable testes are usually palpable at birth but become nonpalpable later. They can be brought down with careful palpation in a warm room. Retractable testes usually assume a scrotal position during puberty.

Improved techniques for testicular localization include ultrasonography (i.e., visualization of the testes by recording the pulses of ultrasonic waves directed into the tissues), gonadal venography and arteriography (i.e., radiography of the veins and arteries of the testes after the injection of a contrast medium), and laparoscopy (i.e., examination of the interior of the abdomen using a visualization instrument). Adrenal hyperplasia in a genetic female should be considered in a phenotypically male infant with bilateral nonpalpable testes.

The treatment goals for boys with cryptorchidism include measures to enhance future fertility potential, placement of the gonad in a favorable place for cancer detection, and improved cosmetic appearance. Treatment modalities for children with unilateral or bilateral cryptorchidism include initial hormone therapy with human chorionic gonadotropin (hCG) or pulsatile GnRH, a hypothalamic hormone that stimulates production of the gonadotropic hormones (LH and FSH) by the anterior pituitary gland. For boys who do not respond to hormonal treatment, orchiopexy has proven effective.

Treatment of males with undescended testes should include lifelong follow-up, considering the sequelae of testicular cancer and infertility. Parents need to be aware of the potential issues of infertility and increased risk of testicular cancer. On reaching puberty, boys should be instructed on the necessity of testicular self-examination.

**Hydrocele**

The testes and epididymis are completely surrounded by the tunica vaginalis, a serous pouch derived from the peritoneum during fetal descent of the testes into the scrotum. The tunica vaginalis has an outer parietal layer and a deeper visceral layer that adheres to the dense fibrous covering of the testes, the tunica albuginea. A space exists between these two layers that typically contains a few milliliters of clear fluid. A hydrocele forms when excess fluid collects between the layers of the tunica vaginalis (Fig. 52.6C). \(^8\) It may be unilateral or bilateral and can develop as a primary congenital defect or as a secondary condition. Acute hydrocele may develop after local injury, testicular torsion, epididymitis or orchitis, gonorrhea, lymph obstruction, or germ cell testicular tumor, or as a side effect of radiation therapy. Chronic hydrocele is more common; fluid collects about the testis, and the mass grows gradually.

Most cases of hydrocele in male infants and children are caused by a patent processus vaginalis, which is continuous with the peritoneal cavity. There are usually reports that the mass increases in size during the day and decreases at night.
Chapter 52 Disorders of the Male Genitourinary System

The left side is more commonly affected because the left internal spermatic vein inserts into the left renal vein at a right angle, whereas the right spermatic vein usually enters the inferior vena cava. Incompetent valves are more common in the left internal spermatic veins, causing a reflux of blood back into the veins of the pampiniform plexus. The force of gravity resulting from the upright position also contributes to venous dilation. If the condition persists, there may be damage to the elastic fibers and hypertrophy of the vein walls, as occurs in formation of varicose veins in the leg. Sperm concentration and motility are decreased in men with varicocele.

Varicoceles are rarely found before puberty. Symptoms of varicocele include an abnormal feeling of heaviness in the left scrotum, although many varicoceles are asymptomatic. Usually, the varicocele is readily diagnosed on physical examination with the person in the standing and recumbent positions. Typically, the varicocele disappears in the lying position because of venous decompression into the renal vein. Scrotal palpation of a varicocele has been compared to feeling a “bag of worms.” Small varicoceles are sometimes difficult to identify. The Valsalva maneuver (i.e., forced expiration against a closed glottis) may be used to accentuate small varicosities. If the varicocele is present, retrograde blood flow to the scrotum can be detected by Doppler ultrasonography. Other diagnostic aids include radioisotope scanning and spermatic venography.

Treatment options include surgical ligation or sclerosis using a percutaneous transvenous catheter under fluoroscopic guidance. Both can be performed as outpatient procedures. The benefits of the percutaneous technique include a slightly lower recurrence rate and more rapid return to full physical activity. Aside from improving fertility, other reasons for surgery include relief of the sensation of “heaviness” and cosmetic improvement.

Testicular Torsion

Testicular torsion is a twisting of the spermatic cord that suspends the testis (Fig. 52.7). It is the most common acute scrotal disorder in the pediatric and young adult population occurring in 1 in 4000 males younger than 25 years. Varicocele can be divided into two distinct clinical entities, depending
on the level of spermatic cord involvement: extravaginal and intravaginal torsion.16

Extravaginal torsion, which occurs almost exclusively in neonates, is the less common form of testicular torsion. It occurs when the testicle and the fascial tunicae that surround it rotate around the spermatic cord at a level well above the tunica vaginalis. The torsion probably occurs during fetal or neonatal descent of the testes before the tunica adheres to the scrotal wall. At birth or shortly thereafter, a firm, smooth, painless scrotal mass is identified. The scrotal skin appears red, and some edema is present. Differential diagnosis is relatively easy because testicular tumors, epididymitis, and orchitis are exceedingly rare in neonates; a hydrocele is softer and can be transilluminated; and physical examination can exclude the presence of hernia. The use of surgical treatment (orchiopexy and orchietomy) is controversial.16

Intravaginal torsion is considerably more common than extravaginal torsion. It occurs when the testis rotates on its long axis in the tunica vaginalis. In most cases, congenital abnormalities of the tunica vaginalis or spermatic cord exist.16 The tunica vaginalis normally surrounds the testis and epididymis, allowing the testicle to rotate freely in the tunica. Although anomalies of suspension vary, the epididymal attachment may be loose enough to permit torsion between the testis and the epididymis. More commonly, the testis rotates about the distal spermatic cord. Because this abnormality is developmental, bilateral anomalies are common.

People with intravaginal torsion usually present in severe distress within hours of onset and often have nausea, vomiting, and tachycardia. The affected testis is large and tender, with pain radiating to the inguinal area. Extensive cremaster muscle contraction causes a thickening of the spermatic cord. Intravaginal testicular torsion is a true surgical emergency, and early recognition and treatment are necessary if the testicle is to be saved.

Testicular torsion must be differentiated from epididymitis, orchitis, and trauma to the testis. On physical examination, the testicle is often high in the scrotum and in an abnormal orientation. These changes are caused by the twisting and shortening of the spermatic cord. The degree of scrotal swelling and redness depends on the duration of symptoms. The testes are firm and tender. The cremasteric reflex, normally elicited by stroking the medial aspect of the thigh and observing testicular retraction, is frequently absent.17

**Infection and Inflammation**

**Epididymitis**

Epididymitis is an acute or chronic inflammation of the epididymis, the elongated cordlike structure that lies along the posterior border of the testis, whose function is the storage, transport, and maturation of spermatozoa. There are two major types of epididymitis: sexually transmitted infections associated with urethritis and primary nonsexually transmitted infections associated with urinary tract infections and prostatitis. Most cases of epididymitis are caused by bacterial pathogens.

In primary nonsexual infections, the pressure associated with voiding or physical strain may force pathogen-containing urine from the urethra or prostate up the ejaculatory duct and through the vas deferens and into the epididymis. Infections also may reach the epididymis through the lymphatics of the spermatic cord. In rare cases, organisms from other foci of infection reach the epididymis through the bloodstream. In prepubertal children, the disorder is usually associated with congenital urinary tract abnormalities and infection with gram-negative rods. In postpubertal males, several factors may predispose to development of epididymitis, including sexual activity, heavy physical exertion, and bicycle or motorcycle riding. Sexually transmitted acute epididymitis occurs mainly in young men without underlying genitourinary disease and is most commonly caused by _Chlamydia trachomatis_ and _Neisseria gonorrhoeae_. In men older than 35 years of age, epididymitis is often associated with _Escherichia coli_.

**Clinical Manifestations.** Epididymitis is characterized by unilateral pain and swelling, accompanied by erythema and edema of the overlying scrotal skin that develops over a period of 24 to 48 hours. Initially, the swelling and induration are limited to the epididymis. However, the distinction between the testis and epididymis becomes less evident as the inflammation progresses, and the testis and epididymis become one mass. In contrast to males with testicular torsion, males with epididymitis usually have a normal cremasteric reflex. There may be tenderness over the groin (spermatic cord) or in the lower abdomen. Fever and complaints of dysuria occur in approximately one half of cases. Whether urethral discharge is present depends on the organism causing the infection; it usually accompanies gonorrheal infections, is common in chlamydial infections, and is less common in infections caused by gram-negative organisms.

**Diagnosis and Treatment.** Laboratory findings usually reveal an elevated white blood cell count. Urinalysis and urine culture are important in the diagnosis of epididymitis, with bacteriuria...
and pyuria suggestive of the disorder; however, the urinalysis may be normal. The cause of epididymitis can be differentiated by Gram stain examination or culture of a midstream urine specimen or a urethral specimen. If the diagnosis remains uncertain, color Doppler ultrasonography may be useful, revealing increased blood flow to the affected testis.

Treatment during the acute phase includes bed rest, scrotal elevation and support, and antibiotics. Bed rest with scrotal support improves lymphatic drainage. Sexual activity or physical strain may exacerbate the infection and worsen the symptoms, and should be avoided. Since many men experience epididymitis due to chlamydia or gonorrhea it is important to ensure that the sexual partner is also screened and treated as necessary.

**Orchitis**

Orchitis is an infection of the testes. It can be precipitated by a primary infection in the genitourinary tract, or the infection can be spread to the testes through the bloodstream or the lymphatics. Epididymitis with subsequent infection of the testis is commonly related to genitourinary tract infections (cystitis, urethritis, prostatitis) that travel to the epididymis and testis through the vas deferens or the lymphatics of the spermatic cord. Orchitis can develop as a complication of a systemic infection, such as parotitis (i.e., mumps), scarlet fever, or pneumonia. Mumps orchitis is the most common complication of mumps infection in the postpubertal male, occurring in approximately 20% of men with mumps. Due to standard immunizations mumps orchitis is less common. The onset of mumps orchitis is sudden; it usually occurs approximately 3 to 4 days after the onset of the parotitis and is characterized by fever, painful enlargement of the testes, and small hemorrhages into the tunica albuginea. Unlike epididymitis, the urinary symptoms are absent. The symptoms usually run their course in 7 to 10 days. Microscopically, an acute inflammatory response is seen in the seminiferous tubules, with proliferation of neutrophils, lymphocytes, and histiocytes causing distention of the tubules. The residual effects seen after the acute phase include hyalinization of the seminiferous tubules and atrophy of the testes (seen in half of affected men). Spermatogenesis is irreversibly impaired in approximately 30% of testes damaged by mumps orchitis.

**Neoplasms**

Tumors can develop in the scrotum or the testes. Benign scrotal tumors are common and often do not require treatment. Carcinoma of the scrotum is rare and is usually associated with exposure to carcinogenic agents. Almost all solid tumors of the testes are malignant.

**Scrotal Cancer**

Cancer of the scrotum is linked to exposure to tar, soot, and oils. Most squamous cell cancers of the scrotum are linked to poor hygiene and chronic inflammation. Exposure to PUVA or HPV has also been associated with the disease. The mean age of presentation with the disease is 60 years, often preceded by 20 to 30 years of chronic irritation.

In the early stages, cancer of the scrotum may appear as a small tumor or wartlike growth that eventually ulcerates. The thin scrotal wall lacks the tissue reactivity needed to block the malignant process; more than one half of the cases seen involve metastasis to the lymph nodes. Because this tumor does not respond well to chemotherapy or irradiation, the treatment is generally surgery. Prognosis correlates with lymph node involvement.

**Testicular Cancer**

Testicular cancer accounts for 1% of all male cancers. It is relatively rare. A man’s risk of having testicular cancer over his lifetime is 1 in 270, while the risk of dying from the disease is 1 in 5000. With the exception of men with advanced metastatic disease at the time of presentation or those who relapse after primary chemotherapy, most men with these tumors are cured with available therapy. The prognosis and extent of treatment required for testicular cancer are related to the stage of the disease at the time of presentation.

**Etiology and Pathogenesis.** Although the cause of testicular cancer is unknown, there is a possible genetic link and a geographic risk to acquiring this type of cancer. The risk factors include cryptorchidism, genetic factors, and disorders of testicular development. The strongest association has been with cryptorchid testis. Genetic predisposition also appears to be important. Family clustering of the disorder has been described, although a well-defined pattern of inheritance has not been established. An increased incidence of testicular germ cell tumors, particularly seminomas, has been described in human immunodeficiency virus–infected men. Men with disorders of testicular development, including those with Klinefelter syndrome and testicular feminization, have a higher risk of germ cell tumors.

Approximately 90% of malignant tumors arising in the testis are germ cell tumors. Germ cell tumors can be classified as seminomas and nonseminomas based on their origin in primordial germ cells and their ability to differentiate in vivo. Because these tumors derive from germ cells in the testis, they are multipotential (able to differentiate into different tissue types) and often secrete polypeptide hormones or enzymes representing earlier stages of development.

Seminomas account for approximately 40% of germ cell tumors and are most frequent in the fourth decade of life. Seminomas are thought to arise from the seminiferous epithelium of the testes and are the type of germ cell tumor most likely to produce a uniform population of cells.

The nonseminoma tumors include embryonal carcinoma, teratoma, choriocarcinoma, and yolk cell carcinoma derivatives. Nonseminoma tumors usually contain more than one cell type and are less differentiated than seminomas. Embryonal carcinomas are the least differentiated of the tumors, with the totipotential capacity to differentiate into
other nonseminomatous cell types. Choriocarcinoma is a rare and highly malignant form of testicular cancer that is identical to tumors that arise in placental tissue. Yolk sac tumors mimic the embryonic yolk sac histologically. Teratomas are composed of somatic cell types from two or more germ-line layers (ectoderm, mesoderm, or endoderm). They are usually benign tumors in children. In adults, they can contain minute foci of cancer cells.

**Clinical Manifestations and Diagnosis.** Often the first sign of testicular cancer is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. This may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Pain may be experienced in the later stages as the tumor grows rapidly and hemorrhaging occurs. Testicular cancer can spread when the tumor may be barely palpable. Signs of metastatic spread include swelling of the lower extremities, back pain, neck mass, cough, hemoptysis, or dizziness.

The diagnosis of testicular cancer requires a thorough urologic history and physical examination. A painless testicular mass may be cancer. Conditions that produce an intrascrotal mass similar to testicular cancer include epididymitis, orchitis, hydrocele, or hematocyte. The examination for masses should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation. Testicular ultrasonography can be used to differentiate testicular masses. CT scans and MRI are used in assessing metastatic spread.

Tumor markers that measure protein antigens produced by malignant cells provide information about the existence of a tumor and the type of tumor present. These markers may detect tumor cells that are too small to be found on physical examination or radiographs. Two tumor markers are useful in evaluating the tumor response to therapy: α-fetoprotein, a glycoprotein that is normally present in fetal serum in large amounts and hCG, a hormone that is normally produced by the placenta in pregnant women. During embryonic development, the totipotential germ cells of the testes travel down normal differentiation pathways and produce different protein products. The reappearance of these protein markers in the adult suggests activity of undifferentiated cells in a testicular germ cell tumor.

The clinical staging (TNM classification) for testicular cancer is as follows: stage I, tumor confined to testes, epididymis, or spermatic cord; stage II, tumor spread to retroperitoneal lymph nodes below the diaphragm; and stage III, metastases outside the retroperitoneal nodes or above the diaphragm. Staging procedures include CT scans of the chest, abdomen, and pelvis; ultrasonography for detection of bulky inferior nodal metastases; and occasionally lymphangiography.

**Treatment.** The basic treatment of all testicular cancers includes orchiectomy, which is done at the time of diagnostic exploration. Surgical therapy is advantageous because it enables precise staging of the disease. Recommendations for further therapy (e.g., retroperitoneal lymph node dissection, chemotherapy, radiation therapy) are based on the pathologic findings from the surgical procedure.

Treatment after orchiectomy depends on the histologic characteristics of the tumor and the clinical stage of the disease. Seminomas are highly radiosensitive; the treatment of stage I or II seminoma is irradiation of the retroperitoneal and homolateral lymph nodes to the level of the diaphragm. Men with bulky retroperitoneal or distant metastases are often treated with multiagent chemotherapy. Men with nonseminomatous tumors are usually managed with observation, chemotherapy, or retroperitoneal lymph node dissection. Rigorous follow-up in all men with testicular cancer is necessary to detect recurrences. Testicular cancer is a disease in which even recurrence is highly treatable. With appropriate treatment, the prognosis for men with testicular cancer is excellent. Men with stage I and II disease do very well. Even men with more advanced disease have excellent chances for long-term survival.

Therapy for testicular cancer can have potentially adverse effects on sexual functioning. Men who have retroperitoneal lymph node dissection may experience retrograde ejaculation or failure to ejaculate because of severing of the sympathetic plexus. Infertility may result from retrograde ejaculation or the toxic effects of chemotherapy or radiation therapy. Sperm banking should be considered for men undergoing these treatments.

**IN SUMMARY**

Disorders of the scrotum and testes include cryptorchidism (i.e., undescended testes), hydrocele, hematocyte, spermocele, varicocele, and testicular torsion. Inflammatory conditions can involve the scrotal sac, epididymis, or testes. Tumors can arise in the scrotum or the testes. Scrotal cancers are usually associated with exposure to petroleum products such as tar, pitch, and soot. Testicular cancers account for 1% of all male cancers. With current treatment methods, a large percentage of men with these tumors can be cured.

**DISORDERS OF THE PROSTATE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the pathology and symptoms of acute bacterial prostatitis, chronic bacterial prostatitis, and chronic prostatitis/pelvic pain syndrome.
- Describe the urologic manifestations and treatment of benign prostatic hyperplasia.
The prostate is a firm, glandular structure that surrounds the urethra. It produces a thin, milky, alkaline secretion that aids sperm motility by helping to maintain an optimum pH. The contraction of the smooth muscle in the gland promotes semen expulsion during ejaculation.

**Infection and Inflammation**

Prostatitis refers to a variety of inflammatory disorders of the prostate gland, some bacterial and some not. It may occur spontaneously, as a result of catheterization or instrumentation, or secondary to other diseases of the male genitourinary system. There are four categories of prostatitis syndromes: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/pelvic pain syndrome, and asymptomatic inflammatory prostatitis. Men with asymptomatic inflammatory prostatitis have no subjective symptoms, and the disorder is detected incidentally on biopsy or examination of prostatic fluid.

**Acute Bacterial Prostatitis**

Acute bacterial prostatitis is often considered a subtype of urinary tract infection. The most likely etiology of acute bacterial prostatitis is an ascending urethral infection or reflux of infected urine into the prostatic ducts by *E. coli*. Gram-negative bacteria (*Proteus, Klebsiella, Pseudomonas, and Serratia* species) and enterococci are less frequent pathogens. Anaerobic and gram-positive bacteria are rarely a cause of acute prostatitis. The manifestations of acute bacterial prostatitis include fever and chills, malaise, frequent and urgent urination, and dysuria. Dull, aching perineal pain is often present. The urine may be cloudy and malodorous because of urinary tract infection. Rectal examination reveals a swollen, tender, warm prostate with scattered soft areas. Prostatic massage produces a thick discharge with white blood cells that grows large numbers of pathogens on culture.

Treatment of acute bacterial prostatitis depends on the severity of symptoms. It usually includes antibiotics, bed rest, adequate hydration, antipyretics, analgesics (preferably non-steroidal anti-inflammatory drugs) to alleviate pain, and stool softeners. Men who are extremely ill, such as those with sepsis, may require hospitalization. A suprapubic catheter may be indicated if voiding is difficult or painful.

Acute prostatitis usually responds to appropriate antimicrobial therapy chosen in accordance with the sensitivity of the causative agents in the urethral discharge. Depending on the urine culture results, antibiotic therapy is usually continued for at least 4 weeks. Because acute prostatitis is often associated with anatomic abnormalities, a thorough urologic examination is usually performed after treatment is completed.

A persistent fever indicates the need for further investigation for an additional site of infection. CT scans and transrectal ultrasonography of the prostate are useful in the diagnosis of prostatic abscesses.

**Chronic Bacterial Prostatitis**

In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is a subtle disorder that is difficult to treat. Men with the disorder typically have recurrent urinary tract infections with persistence of the same strain of pathogenic bacteria in prostatic fluid and urine. Organisms responsible for chronic bacterial prostatitis are usually the gram-negative enterobacteria. Infected prostatic calculi may develop and contribute to the chronic infection.

The symptoms of chronic prostatitis are variable and include frequent and urgent urination, dysuria, perineal discomfort, and low back pain. Occasionally, myalgia and arthralgia accompany the other symptoms. Secondary epididymitis is sometimes associated with the disorder. Many men experience relapsing lower or upper urinary tract infections because of recurrent invasion of the bladder by the prostatic bacteria. Bacteria may exist in the prostate gland even when the prostatic fluid is sterile. The most accurate method of establishing a diagnosis is by localizing cultures. This method is based on sequential collections of the first part of the voided urine (urethral specimen), midstream specimen (bladder specimen), the expressed prostatic secretion (obtained by prostatic massage), and the urine voided after prostatic massage. The last two specimens are considered prostatic urine. A positive expressed prostatic specimen establishes the diagnosis of bacterial prostatitis, excluding nonbacterial prostatitis.

Even after an accurate diagnosis has been established, treatment of chronic prostatitis is often very challenging. Unlike their action in the acutely inflamed prostate, antibacterial drugs penetrate poorly into the chronically inflamed prostate. Long-term therapy (3 to 4 months) with an appropriate low-dose oral antimicrobial agent is often used to treat the infection. Transurethral prostatectomy (TURP) has been used to treat men with refractory disease.

**Chronic Prostatitis/Chronic Pelvic Pain Syndrome**

Chronic prostatitis/pelvic pain syndrome is both the most common and least understood of the prostatitis syndromes. The category is divided into two types, inflammatory and noninflammatory, based on the presence of leukocytes in the prostatic fluid. The inflammatory type was previously referred to as nonbacterial prostatitis, and the noninflammatory type as prostatodynia.

**Inflammatory Prostatitis.** A large group of men with prostatitis have no bacteria in the urinary system, but yet have pain along the penis, testicles, and scrotum; painful ejaculation; low back pain; rectal pain along the inner thighs; urinary symptoms; decreased libido; and impotence. Men with nonbacterial prostatitis often have inflammation of the prostate with an elevated leukocyte count and abnormal inflammatory cells in their prostatic secretions. The cause of the disorder is unknown, and efforts to prove the presence of unusual pathogens (*e.g.*, mycoplasmas, *Chlamydia*, trichomonads, viruses) have been largely unsuccessful. It is thought that nonbacterial prostatitis may be an autoimmune disorder.

**Noninflammatory Prostatitis.** Men with noninflammatory prostatitis or prostatodynia have symptoms resembling those of nonbacterial prostatitis but have negative urine culture
results and no evidence of prostatic inflammation (i.e., normal leukocyte count). The cause of noninflammatory prostatitis is unknown, but because of the absence of inflammation, the search for the cause of symptoms has been directed toward extraprostatic sources. In some cases, there is an apparent functional obstruction of the bladder neck near the external urethral sphincter. During voiding this results in higher-than-normal pressures in the prostatic urethra that cause intraprostatic urine reflux and chemical irritation of the prostate by urine. In other cases, there is an apparent myalgia (i.e., muscle pain) associated with prolonged tension of the pelvic floor muscles.

**Treatment.** Treatment methods for chronic prostatitis/pelvic pain syndrome are highly variable and require further study. Antibiotic therapy is used when an occult infection is suspected. Treatment is often directed toward symptom control. Sitz baths and nonsteroidal anti-inflammatory drugs may provide some symptom relief. In men with irritative urination symptoms, anticholinergic agents (e.g., oxybutynin) or α-adrenergic blocking agents may be beneficial.

**Hyperplasia and Neoplasms**

**Benign Prostatic Hyperplasia**

Benign prostatic hyperplasia (BPH), or nodular prostatic hyperplasia, is an age-related, nonmalignant enlargement of the prostate gland (Fig. 52.8). It is characterized by the formation of large, discrete lesions in the periurethral region of the prostate rather than the peripheral zones, which are commonly affected by prostate cancer (Fig. 52.9). BPH is one of the most common diseases of aging men. It has been reported that more than 75% of men older than 80 years of age have BPH. It is uncommon for men less than 40 years of age to develop BPH.

**Etiology.** The exact cause of the BPH is unknown. Potential risk factors include age, family history, race, ethnicity, dietary fat and meat consumption, and hormonal factors. The incidence of BPH increases with advanced age and is highest in African Americans and lowest in native Japanese. Men with a family history of BPH are reported to have had larger prostates than those of control subjects, and higher rates of BPH were found in monozygotic twins than in dizygotic twins.

**Remember** Mr. Topers from the unit-opening case study? Mr. Topers had BPH for approximately 5 years and was just diagnosed with prostate cancer with a Gleason Score of Stage 3. He had risk factors for BPH, including the fact that he is an African American, he has a high BMI (still does at 26), and he is older at 57 years of age.

Both androgens (testosterone and dihydrotestosterone) and estrogens appear to contribute to the development of BPH. The prostate consists of a network of glandular elements embedded in smooth muscle and supporting tissue,
Pathophysiology and Clinical Manifestations. The anatomic location of the prostate at the bladder neck contributes to the pathophysiology and symptomatology of BPH. There are two prostatic components to the obstructive properties of BPH and development of lower urinary tract symptoms: dynamic and static.26 The static component of BPH is related to an increase in prostatic size and gives rise to symptoms such as a weak urinary stream, postvoid dribbling, frequency of urination, and nocturia. The dynamic component of BPH is related to prostatic smooth muscle tone. The \( \alpha_1 \)-adrenergic receptors are the main receptors for the smooth muscle component of the prostate. The recognition of the role of \( \alpha_1 \)-adrenergic receptors on neuromuscular function in the prostate is the basis for use of \( \alpha_1 \)-adrenergic receptor blockers in treating BPH. A third component, detrusor instability and impaired bladder contractility, may contribute to the symptoms of BPH independent of the outlet obstruction created by an enlarged prostate.26

Mr. Topers did experience both the dynamic and static symptoms of postvoid dribbling, frequency of urination, and nocturia and the dynamic symptoms related to decreased prostatic smooth muscle tone. He was also taking \( \alpha_1 \)-adrenergic receptor blockers to treat the BPH.

The clinical significance of BPH resides in its tendency to compress the urethra and cause partial or complete obstruction of urinary outflow. As the obstruction increases, acute retention may occur with overdistention of the bladder. The residual urine in the bladder causes increased frequency of urination and a constant desire to empty the bladder, which becomes worse at night. With marked bladder distention, overflow incontinence may occur with the slightest increase in intra-abdominal pressure.

Mr. Topers experienced the majority of the symptoms discussed above as his prostate gland increased in size and compressed the urethra to cause a partial obstruction of the urine flow. In fact, his urine flow was so compromised that his Uroflow test revealed a less than 7 mL/second flow.

Diagnosis. It is now thought that the single most important factor in the evaluation and treatment of BPH is the man’s own experiences related to the disorder. The American Urological Association Symptom Index (AUASI) consists of seven questions about symptoms regarding incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia.3 Each question is rated with a score of 0 (mild) to 7 (severe). A maximum score of 35 indicates severe symptoms. Total scores below 7 are considered mild; those between 8 and 20 moderate; and scores over 20 severe. A final question relates to quality of life due to urinary problems.

In 1994, the Agency for Health Care Policy and Research published clinical practice guidelines for management of BPH, which were updated by the American Urology Association in 2003. During the initial evaluation of men for a diagnosis of BPH, a history, physical examination, digital rectal examination, urinalysis, blood tests for prostate-specific antigen (PSA), and test for urine flow rate are carried out. Blood and urine analyses are used as adjuncts to determine BPH complications. Urinalysis is done to detect bacteria, white blood cells, or microscopic hematuria in the presence of infection and inflammation. The PSA test is used to screen for prostate cancer. These evaluation measures, along with the AUASI, are used to describe the extent of obstruction, determine if other diagnostic tests are needed, and establish the need for treatment.

Mr. Topers’ AUA Score has increased from between 1 and 2 to 6. He explains that the increased symptoms have negatively influenced his quality of life. His PSA has also had a significant spike from 7 ng/mL to 12 ng/mL within the last 6 months. Just having an increase in PSA does not warrant a cancer diagnosis by any means but his digital rectal exam (DRE) showed an increase in prostate size to +3 to +4. Mr. Topers expressed the fear that he may have prostate cancer.

The digital rectal examination is used to examine the external surface of the prostate. Enlargement of the prostate due to BPH usually produces a large, palpable prostate with a smooth, rubbery surface. Hardened areas of the prostate gland suggest cancer and should be sampled for biopsy. An enlarged prostate found during a digital rectal examination does not
always correlate with the degree of urinary obstruction. Some men can have greatly enlarged prostate glands with no urinary obstruction, but others may have severe symptoms without a palpable enlargement of the prostate.

Residual urine measurement may be made by ultrasonography or postvoiding catheterization for residual urine volume. Uroflowmetry provides an objective measure of urine flow rate. The patient is asked to void with a relatively full bladder (at least 150 mL) into a device that electronically measures the force of the stream and urine flow rate. A urinary flow rate of greater than 15 mL/second is considered normal, and less than 10 mL/second is indicative of obstruction.26

Transabdominal or transrectal diagnostic ultrasonography can be used to evaluate the kidneys, ureters, and bladder. Urethrocystoscopy is indicated in men with a history of hematuria, strictured disease, urethral injury, or prior lower urinary tract surgery. It is used to evaluate the length and diameter of the urethra, the size and configuration of the prostate, and bladder capacity. CT scans, MRI studies, and radionuclide scans are reserved for rare instances of tumor detection.

Treatment. Treatment of BPH is determined by the degree of symptoms that the condition produces and complications due to obstruction. When a man develops mild symptoms related to BPH, a “watchful waiting” stance often is taken. The condition does not always run a predictable course; it may remain stable or even improve.

Until the 1980s, surgery was the mainstay of treatment to alleviate urinary obstruction due to BPH. Currently, there is an emphasis on less invasive methods of treatment, including use of pharmacologic agents. However, when more severe signs of obstruction develop, surgical treatment is indicated to provide comfort and avoid serious kidney damage.

Pharmacologic management includes the use of 5α-reductase inhibitors and α1-adrenergic blocking drugs.26 The 5α-reductase inhibitors such as finasteride reduce prostate size by blocking the effect of androgens on the prostate. The presence of α-adrenergic receptors in the prostatic smooth muscle has prompted the use of α1-adrenergic blocking drugs (e.g., prazosin, terazosin) to relieve prostatic obstruction and increase urine flow. Combinations of 5α-reductase inhibitors and α1-adrenergic blocking agents seem to be more effective than either monotherapy.26

The surgical removal of an enlarged prostate can be accomplished by the transurethral, suprapubic, or perineal approach. Currently, TURP is the most commonly used technique.26 With this approach, an instrument is introduced through the urethra, and prostate tissue is removed using a resectoscope and electrocautery. Immediate complications of TURP include the inability to urinate, postoperative hemorrhage or clot retention, and urinary tract infection. Late complications of TURP include erectile dysfunction, incontinence, and bladder neck contractures. Retrograde ejaculation is another problem that may occur because of resection of bladder neck tissue.

Many new and experimental techniques have also been used to treat BPH (e.g., transurethral incision of the prostate [TUIP], laser surgery, transurethral vaporization, transurethral microwave therapy, transurethral needle ablation), and each has advantages and disadvantages when considered as an alternative treatment of BPH.

For men who have heart or lung disease or a condition that precludes major surgery, a stent may be used to widen and maintain the patency of the urethra. A stent is a device made of a tubular mesh that is inserted under local or regional anesthesia. Within several months, the lining of the urethra grows to cover the inside of the stent.

KEY POINTS

HYPERPLASIA AND CANCER OF THE PROSTATE

- The prostate gland surrounds the urethra and periurethral enlargement causes manifestations of urinary obstruction.
- BPH is an age-related enlargement of the prostate gland with formation of large, discrete lesions in the periurethral region of the prostate. These lesions compress the urethra and produce symptoms of dysuria or difficulty urinating.

Prostate Cancer

Prostate cancer is the most common nonskin cancer in the United States, and is third to lung and colorectal cancer as a cause of cancer-related death in U.S. men.26,27 The American Cancer Society estimates that during 2013, approximately 238,500 men in the United States will be diagnosed with prostate cancer, and 29,720 men will die of the disorder.27 The increase in diagnosed cases is thought to reflect earlier diagnosis because of the widespread use of PSA testing. The incidence of prostate cancer varies markedly from country to country and varies among races in the same country.27 African American and Caribbean men have the highest reported incidence for prostate cancer at all ages.27 Asians and Native American men have the lowest rate.27 Prostate cancer is also a disease of aging. The incidence increases rapidly after 50 years of age. In fact, more than 85% of all prostate cancers are diagnosed in men older than 65 years of age.27

Etiology and Pathophysiology. The precise cause of prostate cancer is unclear. As with other cancers, it appears that the development of prostate cancer is a multistep process involving genes that control cell differentiation and growth.27 Several risk factors, such as age, race, heredity, and environmental influences (e.g., a high-fat diet), are suspected of playing a role.27 Male hormone levels also play a role. There is insufficient evidence linking socioeconomic status, infectious agents, smoking, vasectomy, sexual behavior, or BPH to the pathogenesis of prostate cancer.27
The incidence of prostate cancer appears to be higher in relatives of men with prostate cancer. It has been estimated that men who have an affected first-degree relative (e.g., father, brother) and an affected second-degree relative (e.g., grandfather, uncle) have an eightfold increase in risk. It has been suggested that dietary patterns, including increased dietary fats from processed meats and dairy items, may alter the production of sex hormones and growth factors and increase the risk of prostate cancer. Supporting the role of dietary fats as a risk factor for prostate cancer has been the observation that the diet of Japanese men, who have a low rate of prostate cancer, is much lower in fat content than that of U.S. men, who have a much higher incidence.

Mr. Topers has a significant risk for prostate cancer given his family history, his obesity and his history of cigarette smoking.

In terms of hormonal influence, androgens are believed to play a role in the pathogenesis of prostate cancer. Evidence favoring a hormonal influence includes the presence of steroid receptors in the prostate, the requirement of sex hormones for normal growth and development of the prostate, and the fact that prostate cancer almost never develops in men who have been castrated. The response of prostate cancer to estrogen administration or androgen deprivation further supports a correlation between the disease and testosterone levels.

Prostatic adenocarcinomas, which account for 98% of all primary prostate cancers, are commonly multicentric and located in the peripheral zones of the prostate. The high frequency of invasion of the prostatic capsule by adenocarcinoma relates to its subcapsular location. Invasion of the urinary bladder is less frequent and occurs later in the clinical course. Metastasis to the lung reflects lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column, ribs, and pelvis, produce pain that often presents as a first sign of the disease.

Most men with early-stage prostate cancer are asymptomatic. The presence of symptoms often suggests locally advanced or metastatic disease. Depending on the size and location of prostate cancer at the time of diagnosis, there may be changes associated with the voiding pattern similar to those found in BPH. These include urgency, frequency, nocturia, hesitancy, dysuria, hematuria, or blood in the ejaculate. On digital rectal examination, the prostate can be nodular and fixed. Bone metastasis is often characterized by low back pain. Pathologic fractures can occur at the site of metastasis. Men with metastatic disease may experience weight loss, anemia, or shortness of breath.

Screening. Because early cancers of the prostate usually are asymptomatic, screening tests are important. The screening tests currently available are digital rectal examination, PSA testing, and transrectal ultrasonography. PSA is a glycoprotein secreted into the cytoplasm of benign and malignant prostatic cells that is not found in other normal tissues or tumors. However, a positive PSA test indicates only the possible presence of prostate cancer. It can also be positive in cases of BPH and prostatitis. In fact, every man who has an elevated PSA will not necessarily have prostate cancer nor will every man with a known prostate cancer diagnosis by biopsy have an elevated PSA. Measures to increase the specificity of PSA testing in terms of predicting prostate cancer are being developed and evaluated. For example, because PSA levels increase with age, age-specific ranges have been established. PSA velocity (a change of PSA level over time) and PSA density (i.e., PSA level/prostate volume as measured by rectal ultrasonography), kallikreins, and other molecular biomarkers are being studied to ascertain if they will be more effective predictors of indolent versus aggressive prostate cancer.

The American Cancer Society and the American Urological Association recommend that men 50 years of age or older should undergo annual measurement of PSA and digital rectal examination for early detection of prostate cancer. Men at high risk for prostate cancer, such as African Americans and those with a strong family history, should undergo annual screening even at an earlier age. However, some controversy regarding the widespread use of PSA for screening remains. Informed decision making regarding screening with PSA is warranted.

A new approach, transrectal ultrasonography, may detect cancers that are too small to be detected by physical examination. This method is not used for first-line detection because of its expense, but it may benefit men who are at high risk for development of prostate cancer.

Diagnosis. The diagnosis of prostate cancer is based on history and physical examination and confirmed through biopsy methods. Transrectal ultrasonography is used to guide a biopsy needle and document the exact location of the sampled tissue. It is also used for providing staging information. Newly developed small probes for transrectal MRI have been shown to be effective in detecting the presence of cancer in the prostate. Radiologic examination of the bones of the skull, ribs, spine, and pelvis can be used to reveal metastases, although radionuclide bone scans are more sensitive.

Staging. Cancer of the prostate, like other forms of cancer, is graded and staged. Prostatic adenocarcinoma is commonly classified using the Gleason grading system, which grades on a continuum of aggressiveness of prostate cancer with the lower range of 1 and 2 being less aggressive. As the Gleason score increases this indicates a higher aggressiveness of the prostate cancer. Primary-stage tumors (T1) are asymptomatic and discovered on histologic examination of prostatic tissue specimens; T2 tumors are palpable on digital examination but are confined to the prostate gland; T3 tumors have extended beyond the prostate; and T4 tumors have pushed beyond the prostate to involve adjacent structures (Fig. 52.10). Regional lymph node (N) and distant metastases (M) are described as Nx or Mx (cannot be assessed), N0 or M0 (not present), and N1 or M1 (present).
PSA levels are important in the staging and management of prostate cancer. In untreated cases, the level of PSA tends to correlate with the volume and stage of disease. A rising PSA after treatment is consistent with progressive disease, whether it is locally recurring or metastatic. Measurement of PSA is used to detect recurrence after total prostatectomy. Because the prostate is the source of PSA, levels should drop to zero after surgery; a rising PSA indicates recurring disease.

**Treatment.** Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations. Chemotherapy has shown limited effectiveness in the treatment of prostate cancer. For some, high-intensity focused ultrasound is used successfully. Treatment decisions are based on tumor grade and stage and on the age and health of the man.

Mr. Topers had a transrectal ultrasound and biopsy that revealed positive prostate cancer with a Gleason Staging Score of 3. This score indicates a relatively early diagnosis, so Mr. Topers has a good prognosis. He does not have metastasis (has a TNM stage of T2) and will undergo surgery, radiation, and hormonal manipulation immediately.

Expectant therapy (watchful waiting) may be used if the tumor is not producing symptoms, is expected to grow slowly, and is small and contained in one area of the prostate. This approach is particularly suited for men who are elderly or have other health problems.

Radical prostatectomy involves complete removal of the seminal vesicles, prostate, and ampullae of the vas deferens. Refinements in surgical techniques (“nerve-sparing” prostatectomy) have allowed maintenance of continence in most men and erectile function in selected cases. Radiation therapy can be delivered by a variety of techniques, including external-beam radiation therapy and transperineal implantation of radioisotopes (brachytherapy).

Metastatic disease is often treated with androgen deprivation therapy. Androgen deprivation may be induced at several levels along the pituitary–gonadal axis using a variety of methods or agents. Orchiectomy is often effective in reducing symptoms and extending survival. The GnRH analogs (e.g., leuprolide, triptorelin) block LH (and FSH) release from the pituitary and reduce testosterone levels. When given continuously (as opposed to pulsatile, which is the normal physiologic secretory rhythm) and in therapeutic doses, these drugs desensitize GnRH receptors in the pituitary, thereby preventing the release of LH. However, initially, because these agents are GnRH agonists, LH and FSH rise and cause testosterone levels to increase. This can be decreased by pretreatment with antiandrogens. The nonsteroidal antiandrogens (e.g., flutamide, bicalutamide) block the uptake and actions of androgens in the target tissues. Although testosterone is the main circulating androgen, the adrenal gland also secretes androgens. Complete androgen blockade can be achieved by blocking androgens of adrenal origin by combining an antiandrogen with a GnRH agent or orchiectomy. Inhibitors of adrenal androgen synthesis (i.e., ketoconazole and aminoglutethimide) may...
also be used for treating men with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular clotting. This is because these men need rapid decreases in their testosterone levels (i.e., ketoconazole can produce chemical castration within 24 hours). Palliative care includes adequate pain control and focal irradiation of symptomatic or unstable bone disease. In men with advanced prostate cancer, the bisphosphonates (e.g., pamidronate, zoledronate), which act mainly by inhibiting osteoclastic activity, have several potential uses in prostate cancer. These include (1) prevention of osteopenia that accompanies the use of androgen deprivation therapy; (2) prevention and delay of skeletal complications (e.g., the need for local radiation treatment, fractures) in patients with metastatic bone involvement; (3) palliation of bone pain; and (4) treatment of hypercalcemia of malignancy.

IN SUMMARY

The prostate is a firm, glandular structure that surrounds the urethra. Inflammation of the prostate occurs as an acute or a chronic process. Chronic prostatitis probably is the most common cause of relapsing urinary tract infections in men. BPH is a common disorder in men older than 50 years of age. Because the prostate encircles the urethra, BPH exerts its effect through obstruction of urinary outflow from the bladder. Treatment of BPH include laser and robotic surgery, prostatic stents, and pharmacologic treatment using 5α-reductase inhibitors such as finasteride, which reduce prostate size by blocking the effects of androgen on the prostate, and α₁-adrenergic receptor blockers, which inhibit contraction of prostatic smooth muscle.

Prostate cancer is the most common nonskin cancer in the United States and is third to lung cancer and colon/rectal cancer as a cause of cancer-related death in men. A recent increase in diagnosed cases is thought to reflect earlier diagnosis because of widespread use of PSA testing. The incidence of prostate cancer increases with age and is greater in African American men of all ages. Most prostate cancers are asymptomatic and are incidentally discovered on rectal examination. Screening for prostate cancer has become recognized as a method for early identification of prostate cancer. The American Cancer Society suggests that every man 50 years of age or older should have a digital rectal examination and PSA test done as part of his annual physical examination. Cancer of the prostate, like other forms of cancer, is graded according to the histologic characteristics of the tumor and staged clinically using the TNM system. Treatment, which is based on the extent of the disease, includes surgery, radiation therapy, and hormonal manipulation.

Structure and Function of the Female Reproductive System

Lisa C. Grossman

The female genitourinary system consists of internal paired ovaries, fallopian tubes, the uterus, vagina, external mons pubis, labia majora, labia minora, clitoris, urethra, and perineal body. Although the female urinary structures are anatomically separate from the genital structures, their anatomic proximity provides a means for cross-contamination and shared symptomatology between the two systems (Fig. 53.1). This chapter focuses on the internal and external genitalia. It includes a discussion of hormonal and physical changes that occur throughout the life cycle in response to the gonadotropic hormones. The reader is referred to a specialty text for a discussion of pregnancy.

After completing this section of the chapter, you should be able to meet the following objectives:

- Name the three layers of the uterus and describe their function.
- Cite the location of the ovaries in relation to the uterus, fallopian tubes, broad ligaments, and ovarian ligaments.
- State the function of endocervical secretions.

External Genitalia

The external genitalia are located at the base of the pelvis in the perineal area and include the mons pubis, labia majora, labia minora, clitoris, and perineal body. The urethra and anus, although not genital structures, are usually considered in a...
anteriorly at the base of the mons pubis and ending posteriorly at the anus. The labia majora are composed of folds of skin and fat and become covered with hair at the onset of puberty. Before puberty, the labia majora have a skin covering similar to that covering the abdomen. With sufficient hormonal stimulation, the labia of a mature woman close over the urethral and vaginal openings; this can change after childbirth or surgery.

The labia minora (singular, labium minus) are located between the labia majora. These delicate cutaneous structures are smaller than the labia majora and are composed of skin, fat, and some erectile tissue and are similar to the skin of the penis. Unlike the skin of the labia majora, that of the labia minora is hairless and usually light pink. The labia minora begin anteriorly at the hood of the clitoris and end posteriorly at the base of the vagina. During sexual arousal, the labia minora become distended with blood; with resolution, the labia throb and then return to normal size. The clitoris is located below the clitoral hood, or prepuce, which is formed by the joining of the two labia minora. The clitoris is made up of two erectile corpora cavernosa. The female clitoris is an erectile organ, rich in vascular and nervous supply. Analogous to the male penis, it is a highly sensitive organ that becomes distended during sexual stimulation.

The area between labia minora is called the vestibule and it is lined with squamous epithelium. Located in the vestibule are the urethral and vaginal openings, and the Bartholin lubricating glands, which are often referred to as the greater vestibular glands. The urethra, or urinary meatus, is the external opening of the internal urinary bladder. The urethra is located posterior to the clitoris and is usually closer to the vaginal opening than to the clitoris. The urethral opening is the site of the Skene glands, which have a lubricating function and are often referred to as the lesser vestibular glands. The vaginal orifice, commonly known as the introitus, is the opening between the external and internal genitalia. The size and shape of the opening are determined by

Discussion of the external genitalia. The external genitalia, also known collectively as the vulva, are diagrammed in Figure 53.2. The mons pubis is a rounded, skin-covered fat pad located anterior to the symphysis pubis. Puberty stimulates an increase in the amount of fat and the development of darker and coarser hair over the mons. Normal pubic hair distribution in the female follows an inverted triangle with the base centered over the mons. Hair color and texture varies from person to person and among racial groups. There is an abundance of sebaceous glands in the skin that can become infected owing to normal variations in glandular secretions or poor hygiene. The labia majora (singular, labium majus) are analogous to the male scrotum. These structures are the outermost lips of the vulva, beginning at the base of the mons pubis and ending posteriorly at the anus. The labia majora are composed of folds of skin and fat and become covered with hair at the onset of puberty. Before puberty, the labia majora have a skin covering similar to that covering the abdomen. With sufficient hormonal stimulation, the labia of a mature woman close over the urethral and vaginal openings; this can change after childbirth or surgery.

The labia minora (singular, labium minus) are located between the labia majora. These delicate cutaneous structures are smaller than the labia majora and are composed of skin, fat, and some erectile tissue and are similar to the skin of the penis. Unlike the skin of the labia majora, that of the labia minora is hairless and usually light pink. The labia minora begin anteriorly at the hood of the clitoris and end posteriorly at the base of the vagina. During sexual arousal, the labia minora become distended with blood; with resolution, the labia throb and then return to normal size. The clitoris is located below the clitoral hood, or prepuce, which is formed by the joining of the two labia minora. The clitoris is made up of two erectile corpora cavernosa. The female clitoris is an erectile organ, rich in vascular and nervous supply. Analogous to the male penis, it is a highly sensitive organ that becomes distended during sexual stimulation.

The area between labia minora is called the vestibule and it is lined with squamous epithelium. Located in the vestibule are the urethral and vaginal openings, and the Bartholin lubricating glands, which are often referred to as the greater vestibular glands. The urethra, or urinary meatus, is the external opening of the internal urinary bladder. The urethra is located posterior to the clitoris and is usually closer to the vaginal opening than to the clitoris. Chapter 53  Structure and Function of the Female Reproductive System 1367

Internal Genitalia

Vagina

Connecting the internal and external genitalia is a fibromuscular tube called the vagina. The vagina, which is essentially free of sensory nerve fibers, is located behind the urinary bladder and urethra and anterior to the rectum. It connects the vestibule to the cervix. The uterine cervix projects into the vagina at its upper end, forming recesses called fornices (Fig. 53.3). The vagina functions as a route for discharge of menses and other secretions. It also serves as an organ of sexual fulfillment and reproduction.

The membranous vaginal wall forms two longitudinal folds and several transverse folds, or rugae. The vagina is lined with mucus-secreting stratified squamous epithelial cells. Vaginal tissue is usually moist, with a pH maintained within the bacteriostatic range of 4.0 to 4.5. The epithelial cells of the vagina, like other tissues of the reproductive system, respond to changing levels of the ovarian sex hormones. Estrogen stimulates the proliferation and maturation of the vaginal mucosa. This results in a thickening of the vaginal mucosa and an increased glycogen content of the epithelial cells. The glycogen is fermented to lactic acid by the lactobacilli (i.e., Döderlein bacilli) that are part of the normal vaginal flora, accounting for the mildly acid pH of vaginal fluid. The vaginal ecology can be disrupted at many levels, rendering it susceptible to infection. Pregnancy and the use of

KEY POINTS

FEMALE REPRODUCTIVE STRUCTURES

- The external genitalia (labia majora, labia minora, clitoris, and vestibular glands) surround the openings of the urethra and vagina. Although the female urinary and genital structures are anatomically separate, their close proximity provides a means for cross-contamination and shared symptomatology.
- The internal genitalia of the female reproductive system include the ovaries, fallopian tubes, uterus, cervix, and vagina.

FIGURE 53.3  Female internal reproductive organs. This is a frontal view and illustrates the continuous opening from the vagina to the uterus and to the fallopian or uterine tubes. (From McConnell T. H., Hull K. L. (2011). Human form human function: Essentials of Anatomy & Physiology (p. 678, Figure 17-7B). Philadelphia, PA: Lippincott Williams & Wilkins.)
oral contraceptive agents increase the amount of estrogen in the system. Diabetes or a prediabetic state may increase the glycogen content of the cells.\(^4\) The use of systemic antibiotics may decrease the number of lactobacilli in the vagina.

Decreased estrogen stimulation after menopause causes the vaginal mucosa to become thin and dry, often resulting in dyspareunia (i.e., painful intercourse), atrophic vaginitis, and, occasionally, in vaginal bleeding. Estrogen levels can be estimated by means of vaginal scrapings obtained during a routine pelvic examination. The scrapings are used for a test, the maturation index, that examines the cellular structure and configuration of the vaginal epithelial cells.\(^5,6\) The maturation index determines the ratio of parabasal (least mature), intermediate, and superficial (most mature) cells. Typically, this index is 0-40-60 during the reproductive years.\(^6\) With diminished estrogen levels, there is a shift to the left, producing an index of 30-40-30 during the perimenopausal period and an index of 75-25-0 during the postmenopausal period.\(^6\)

**Uterus and Cervix**

The uterus is a thick-walled, muscular organ. This pear-shaped, hollow structure is located between the bladder and the rectum. The uterus can be divided into three parts: the portion above the insertion of the fallopian tubes, called the fundus; the lower constricted part, called the cervix; and the portion between the fundus and the cervix, called the body of the uterus. The uterus is supported on both sides by four sets of ligaments: the broad ligaments, which run laterally from the body of the uterus to the pelvic side walls; the round ligaments, which run from the fundus laterally into the mons; the uterosacral ligaments, which run from the uterocervical junction to the sacrum; and the cardinal or transverse cervical ligaments.

The wall of the uterus is composed of three layers: the perimetrium (also known as serosa), the myometrium, and the endometrium. The perimetrium is the outer serous covering that is derived from the abdominal peritoneum. This outer layer merges with the peritoneum that covers the broad ligaments. Anteriorly, the perimetrium is reflected over the bladder wall, forming the vesicouterine pouch. Posteriorly, it extends to form the cul-de-sac, or pouch of Douglas. Because of the proximity of the perimetrium to the urinary bladder, infection of the bladder can cause uterine symptoms, particularly during pregnancy.\(^1\)

The middle muscle layer, the myometrium, forms the major portion of the uterine wall. The inner fibers of the myometrium run in various directions, giving it an interwoven appearance. Contractions of these muscle fibers help to expel menstrual flow and the products of conception during miscarriage or childbirth. When pain accompanies the contractions associated with menses, it is called dysmenorrhea. The myometrium has an amazing ability to change length during pregnancy and labor to accommodate gestation.\(^1\)

The endometrium, the inner layer of the uterus, is made up of a basal and a superficial layer. The superficial layer is shed during menstruation and regenerated by cells of the basal layer. Ciliated cells promote the movement of tubal–uterine secretions out of the uterine cavity into the vagina.\(^1\)

The round cervix is the neck of the uterus that projects into the vagina. The cervix is a firm structure, composed of a connective tissue matrix of glands and muscular tissue elements that become soft and pliable under the influence of hormones produced during pregnancy. Glandular tissue provides a rich supply of protective mucus that changes in character and quantity during the menstrual cycle and during pregnancy. The cervix is richly supplied with blood from the uterine artery and can be a site of significant blood loss during delivery.

The opening of the cervix, the os, forms a pathway between the uterus and the vagina. The vaginal opening is called the cervical os (see Fig. 53.3). Secretions from the columnar epithelium of the endocervix protect the uterus from infection, alter receptivity to sperm, and form a mucoid “plug” during pregnancy. The endocervical canal provides a route for menstrual discharge and sperm entrance.

**Fallopian Tubes**

The fallopian tubes, or oviducts, are slender, cylindrical structures attached bilaterally to the uterus and supported by the upper folds of the broad ligament.\(^1,2\) The end of the fallopian tube nearest the ovary forms a funnel-like opening with fringed, finger-like projections, called fimbriae, that pick up the ovum after its release into the peritoneal cavity after ovulation (Fig. 53.4). The fallopian tubes are formed of smooth muscle and lined with a ciliated, mucus-producing epithelial layer. The beating of the cilia, along with contractile movements of the smooth muscle, propels the nonmotile ovum toward the uterus. If coitus has occurred recently, fertilization normally occurs in the middle to outer portion of the fallopian tube. Besides providing a passageway for ova and sperm, the fallopian tubes provide for drainage of tubal secretions into the uterus.\(^1\)

**Ovaries**

By the 3rd month of fetal life, the ovaries have fully developed and descended to their permanent pelvic position. Remnants of the primitive genital system provide lateral supporting attachments to the uterus. In the mature female, these supporting structures evolve into the round and suspensory ligaments. Remnants that do not evolve may form cysts, which may become symptomatic later in life.

Oogenesis is the process of generation of ova by mitotic division that begins at the 6th week of fetal life.\(^6\) These primitive germ cells ultimately provide the 1 to 2 million oocytes that are present in the ovaries at birth. At puberty, this number is reduced through cell death to approximately 200,000.\(^6\)

The neonate’s ovaries are smooth, pale, and elongated. As the child grows, the ovaries become shorter, thicker, and heavier before the onset of menarche, which is initiated by pituitary influence. The initial hormonal stimulus for this development is believed to come from ovarian rather than systemic estrogen.\(^1\) In the adult, the ovaries are flat, almond-shaped structures that are 3 to 5 cm long, 1.5 cm wide, and 1 cm thick.\(^1\) As the woman matures the ovaries shrink to approximately one fourth of the size as they were during reproductive years.\(^1\)

The ovaries are located on either side of the uterus below the fimbriated ends of the fallopian tubes.\(^6\) The ovaries are
attached to the posterior surface of the broad ligament and to the uterus by the ovarian ligament. They are covered with a thin layer of surface epithelium that is continuous with the lining of the peritoneum. The integrity of this covering is periodically broken at the time of ovulation.

The ovaries, like the male testes, have a dual function: they store the female germ cells, or ova, and produce the female sex hormones, estrogen and progesterone. Unlike the male gonads, which produce sperm throughout a man’s reproductive life, the female gonads contain a fixed number of ova at birth that diminishes throughout a woman’s life.

Structurally, the mature ovary is divided into a highly vascular inner medulla, which contains supporting connective tissue, and an outer cortex of stroma and epithelial follicles (i.e., vesicles), which contain the primary oocytes, or germ cells. After puberty, the pituitary gonadotropic hormones—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—stimulate the primordial follicles to develop into mature graafian follicles. The graafian follicle produces estrogen, which begins to stimulate the thickening of the endometrium in the uterus.

Although several follicles begin to develop during each ovulatory cycle, only one or two complete the entire developmental process and rupture to release a mature ovum. After ovulation, the follicle becomes luteinized. As the corpus luteum, it produces estrogen and progesterone to support the endometrium until conception occurs or the cycle begins again.

**IN SUMMARY**

The female reproductive system consists of internal paired ovaries, fallopian or uterine tubes, uterus, vagina, external mons pubis, labia majora, labia minora, clitoris, urethra, and perineal body. The genitourinary system as a whole serves sexual and reproductive functions throughout the life cycle. The uterus is a thick-walled, muscular organ. The wall of the uterus is composed of three layers: the outer perimetrium; the myometrium or muscle layer, which is continuous with the myometrium of the fallopian tubes and the vagina; and the inner lining or endometrium, which is continuous with the lining of the fallopian tubes and vagina. The gonads, or ovaries, which are internal in the female (unlike the testes in the male), have the dual function of storing the female germ cells, or ova, and producing the female sex hormones, estrogen and progesterone. Although several follicles begin to develop during each ovulatory cycle, only one or two complete the entire developmental process and rupture to release a mature ovum. After ovulation, the follicle becomes luteinized. As the corpus luteum, it produces estrogen and progesterone to support the endometrium until conception occurs or the cycle begins again.

**MENSTRUAL CYCLE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the feedback control of estrogen and progesterone levels by means of gonadotropin-releasing hormone, LH, FSH, and ovarian follicle function.
- Relate FSH and LH levels to the stages of follicle development and to estrogen and progesterone production.
- Discuss the risks and benefits of hormone replacement therapy in menopausal women.

---

**Figure 53.4** • Schematic drawing of female reproductive organs, showing (A) suspensory ligament of the ovary and the broad, uterosacral, and cardinal ligaments on the left, and (B) the path of the oocyte as it moves from the ovary into the fallopian (uterine) tube; the path of sperm is also shown, as is the usual site of fertilization.
Between menarche (i.e., first menstrual bleeding) and menopause (i.e., last menstrual bleeding), the female reproductive system undergoes cyclic changes called the *menstrual cycle*. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining. It is not necessary for a woman to ovulate to menstruate. Anovulatory cycles do occur, leading to irregular menses. The menstrual cycle produces changes in the breasts, uterus, skin, and ovaries. The maintenance of the cycle affects biologic and sociologic aspects of a woman’s life, including fertility, reproduction, sexuality, and femaleness.

**Hormonal Control of the Menstrual Cycle**

Normal menstrual function results from interactions among the central nervous system, hypothalamus, anterior pituitary, ovaries, and associated target tissues (Fig. 53.5). Although each part of the system is essential to normal function, the ovaries are primarily responsible for controlling the cyclic changes and the length of the menstrual cycle. In most women in the middle reproductive years, menstrual bleeding occurs every 28 to 30 days with a median length of 28 days. The average length of a menses cycle is 2 to 7 days. As women age and become perimenopausal their cycle shortens.

The hormonal control of the menstrual cycle is complex. For example, the biosynthesis of estrogens that occurs in adipose tissue may be a significant source of the hormone. There is evidence that a woman must have a minimum body weight and fat content in order for menarche to occur and for the menstrual cycle to be maintained. This is supported by the observation of amenorrhea in women with anorexia nervosa, chronic disease, and malnutrition and in those who are long-distance runners. In women with anorexia nervosa, gonadotropin and estradiol secretion, including LH
release and responsiveness to the hypothalamic gonadotropin-releasing hormone (GnRH), can revert to prepubertal levels. With resumption of weight gain and attainment of sufficient body mass, the normal hormonal pattern is usually reinstated. Obesity or significant weight gain is also associated with oligomenorrhea or amenorrhea and infertility, although the mechanism is not well understood.

**Hypothalamic and Pituitary Hormones**

FSH and LH from the anterior pituitary gland regulate growth, prepubertal maturation, the reproductive cycle, and sex hormone secretion in males and females (Fig. 53.6). Because these hormones promote the growth of cells in the ovaries and testes as a means of stimulating the production of sex hormones, they are called the *gonadotropic hormones*. GnRH from the hypothalamus stimulates the secretion of LH and FSH. In addition to LH and FSH, the anterior pituitary secretes a third hormone called *prolactin*. The primary function of prolactin is the stimulation of lactation in the postpartum period. During pregnancy, prolactin, along with other hormones such as estrogen, progesterone, insulin, and cortisol, contributes to breast development in preparation for lactation. Although prolactin does not appear to play a physiologic role in ovarian function, hyperprolactinemia leads to hypogonadism. This may include an initial shortening of the luteal phase with subsequent anovulation, oligomenorrhea or amenorrhea, and infertility. The hypothalamic control of prolactin secretion is primarily inhibitory, and dopamine is the most important inhibitory factor. Hyperprolactinemia may occur as an adverse effect of drug treatment using phenothiazine derivatives (*i.e.*, antipsychotic drugs that block dopamine receptors).  

**Ovarian Hormones**

The ovaries produce estrogens, progesterone, and androgens. Ovarian hormones are secreted in a cyclic pattern as a result of the interaction between the hypothalamic GnRH and the pituitary gonadotropic hormones FSH and LH. The steroid sex hormones enter cells by passive diffusion, bind to specific receptor proteins in the cytoplasm, and then move to the nucleus, where they bind to specific sites on the chromosomes. These hormones exert their effects through gene–hormone interactions that stimulate the synthesis of specific messenger ribonucleic acid (mRNA). In addition, estrogen appears to have the ability to influence cell activity through other nongenomic mechanisms. These nongenomic effects take place in cells that have no steroid receptors, possibly mediated by other membrane receptors. This may explain in part some of the nonreproductive effects of estrogen. An example of a nongenomic cardioprotective effect would be the antioxidant activity of estrogen in preventing endothelial injury that can lead to platelet adherence. The number of hormonal receptor sites on a cell is not fixed. Evidence suggests that they are constantly being removed and replaced. An increase or a decrease in the number of receptors can serve as a mechanism for regulating hormonal activity. For example, estrogen may induce the development of an increased number of estrogen receptors in some tissues and may stimulate the synthesis of progesterone receptors in others. In contrast, progesterone may cause a reduction in the number of estrogen and progesterone receptors.

There is a second type of estrogen receptor (ER) that is different in structure and tissue distribution, and expression from ER, helps to expand our understanding of the mechanism of action of estrogen in the body. ER appears to be an activator of estrogen response, whereas ER appears to modulate or inhibit the action of estrogen. Likewise, the progesterone receptor has two major forms (A and B), expressed by a single gene, but promoted differently in a complex system of transcription regulation.

**Estrogens.** Estrogens are a family of structurally related female sex hormones synthesized and secreted by cells in the ovaries and, in small amounts, by cells in the adrenal cortex. Androgens can be converted to estrogens peripherally, especially in fat tissue. Three estrogens occur naturally in humans: estrone (E), estradiol (E), and estriol (E). Of these, estradiol is the most biologically potent and the most abundantly secreted product of the ovary. Estrogens are secreted throughout the menstrual cycle. Two peaks occur: one before ovulation and one in the middle of the luteal phase. Estrogens are transported in the blood bound to specific plasma globulins.
Estrogens are necessary for normal female physical maturation. In concert with other hormones, estrogens provide for the reproductive processes of ovulation, implantation of the products of conception, pregnancy, parturition, and lactation by stimulating the development and maintaining the growth of the accessory organs. In the absence of androgens, estrogens stimulate the intrauterine development of the vagina, uterus, and uterine tubes from the embryonic Müllerian system. They also stimulate the stromal development and ductal growth of the breasts at puberty, are responsible for the accelerated pubertal skeletal growth phase and for closure of the epiphyses of the long bones, contribute to the growth of axillary and pubic hair, and alter the distribution of body fat to produce the typical female body contours, including the accumulation of body fat around the hips and breasts. Larger quantities of estrogen stimulate pigmentation of the skin in the nipple, areolar, and genital regions.

In addition to their effects on the growth of uterine muscle, estrogens play an important role in the development of the endometrial lining. During anovulatory cycles, continued exposure to estrogens for prolonged periods leads to abnormal hyperplasia of the endometrium and abnormal bleeding patterns. When estrogen production is poorly coordinated during the normal menstrual period, inappropriate bleeding and shedding of the endometrium can also occur.

Estrogens have a number of important extragenital metabolic effects. They are responsible for maintaining the normal structure of skin and blood vessels in women. Estrogens decrease the rate of bone resorption by antagonizing the effects of parathyroid hormone on bone. For this reason, osteoporosis is a common problem in estrogen-deficient postmenopausal women. In the liver, estrogens increase the synthesis of transport proteins for thyroxine, estrogen, testosterone, and other hormones. Estrogens also affect the composition of the plasma lipoproteins. They produce an increase in high-density lipoproteins (HDLs), a slight reduction in low-density lipoproteins (LDLs), and a reduction in cholesterol levels.

Estrogens have additional cardioprotective actions, including direct antiatherosclerotic effects on the arterial wall (augmentation of vasodilating and antiplatelet aggregation factors such as nitric oxide and prostacyclin), vasodilation through endothelium-independent mechanisms, antioxidant activity, reduction of levels of angiotensin-converting enzyme and renin, reduction of homocysteine levels, improvement of peripheral glucose metabolism with subsequent decreased circulating insulin levels, and direct effects on cardiac function (i.e., increased left ventricular diastolic filling and stroke volume output). Estrogens increase plasma triglyceride levels and enhance the coagulability of blood by effecting increased circulating levels of plasminogen and factors II, VII, IX, and X.

Estrogens appear to have both neurotropic and neuroprotective effects on cognitive function and memory. Observational studies indicate a decrease in cognitive function and dementia with women who have oophorectomy (surgical removal of the ovaries) prior to menopause. Estrogens promote dendritic branching and enhance presynaptic and postsynaptic signal transmission through increased production of neurotransmitters and receptors.

The estrogens cause moderate retention of sodium and water. Most women retain sodium and water and gain weight just before menstruation. This occurs because the estrogens facilitate the movement of intravascular fluids into the extracellular spaces, producing edema and increased sodium and water retention by the kidneys because of the decreased plasma volume. The actions of estrogens are summarized in Table 53.1.

**Progesterone.** Although the word progesterone refers to a substance that maintains pregnancy, progesterone is secreted as part of the normal menstrual cycle. The corpus luteum of the ovary secretes large amounts of progesterone after ovulation, and the adrenal cortex secretes small amounts. The hormone circulates in the blood attached to a specific plasma protein. It is metabolized in the liver and conjugated for excretion in the bile.

The local effects of progesterone on reproductive organs include the glandular development of the lobular and alveolar tissue of the breasts and the cyclic glandular development of the endometrium. Progesterone can also compete with aldosterone at the level of the renal tubule, causing a decrease in sodium reabsorption, with a resultant increase in secretion of aldosterone by the adrenal cortex, as occurs in pregnancy. Although the mechanism is uncertain, progesterone is responsible for the increase in basal body temperature that occurs with ovulation. Smooth muscle relaxation under the influence of progesterone plays an important role in maintaining pregnancy by decreasing uterine contractions, and is responsible for many of the common discomforts of pregnancy, such as edema, nausea, constipation, flatulence, and headaches. The increased progesterone present during pregnancy and the luteal phase of the menstrual cycle enhances the ventilatory response to carbon dioxide, leading to a measurable change in arterial and alveolar carbon dioxide (PCO₂) levels.

**Androgens.** The normal female also produces androgens along with estrogens and progesterone. Approximately 25% of these androgens are secreted from the ovaries, 25% from the adrenal cortex, and 50% from ovarian or adrenal precursors. In the female, androgens contribute to normal hair growth at puberty and may have other important metabolic effects.

**Eileen,** the subject of this chapter’s case study, has been diagnosed with polycystic ovarian syndrome (PCOS). As discussed in Chapter 54, the diagnosis of PCOS requires at least two of the three Rotterdam Criteria, 14, which are

1. Oligo- or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries
Chapter 53  Structure and Function of the Female Reproductive System

Ovarian Follicle Development and Ovulation

The tissues of the adult ovary can be conveniently divided into four compartments, or units: the stroma, or supporting tissue; the interstitial cells; the follicles; and the corpus luteum. The stroma is the connective tissue substance of the ovary in which the follicles are distributed. The interstitial cells are estrogen-secreting cells that resemble the Leydig cells, or interstitial cells, of the testes.

Beginning at puberty, a cyclic rise in the anterior pituitary hormones FSH and LH stimulates the development of several graafian, or mature, follicles. Follicles at all stages of development can be found in both ovaries, except in menopausal women (see Fig. 53.7). Most follicles exist as primary follicles, each of which consists of a round oocyte surrounded by a single layer of flattened, epithelium-derived granulosa cells and a basement membrane. The primary follicles constitute an inactive pool of follicles from which all the ovulating follicles develop. Under the influence of endocrine stimulation, 6 to 12 primary follicles develop into secondary follicles once every ovulatory cycle. During the development of the secondary follicle, the primary oocyte increases in size, and the granulosa cells proliferate to form a multilayered wall around it. During this time, a membrane called the zona pellucida develops and surrounds the oocyte and small pockets of fluid begin to appear between the granulosa cells. Blood vessels, however, do not penetrate the basement membrane; the granulosa cell layer remains avascular until after ovulation has occurred.

As the follicles mature, FSH stimulates the development of the cell layers. Cells from the surrounding stromal tissue align themselves to form a cellular wall called the theca. The cells of the theca become differentiated into two layers: an inner theca interna, which lies adjacent to the follicular cells, and an outer theca externa. As the follicle enlarges, a single large cavity, or antrum, is formed, and a portion of the granulosa cells and the oocyte are displaced to one side of the follicle by the fluid that accumulates. The secondary oocyte remains surrounded by a crown of granulosa cells, the corona radiata. As the follicle ripens, granulose cells produce ovarian estrogen. Selection of a dominant follicle occurs with the conversion to an estrogen microenvironment. The lesser follicles, although continuing to produce some estrogen, atrophy or become atretic. The dominant follicle accumulates a greater mass of granulosa cells, and the theca becomes richly vascular, giving the follicle a hyperemic appearance. High levels of estrogen exert a negative feedback effect on FSH, inhibiting multiple follicular development and causing an increase in LH levels. This represents the follicular stage of the menstrual cycle. As estrogen suppresses FSH, the actions of LH predominate, and

Women with PCOS often do not ovulate at all (anovulation) or ovulate infrequently (oligoovulation). A common sign of anovulation or oligoovulation is absent or infrequent menstrual bleeding (periods). Eileen thus meets this first criterion, since she cannot recall her last period. Eileen also meets the second criterion, since her elevated concentration of testosterone is a biochemical sign of hyperandrogenism (testosterone is an androgen), and her hirsutism and acne are clinical signs. The increased production of testosterone is thought to reflect excess LH production from the anterior pituitary.

Eileen, aged 19, presents to the local community health center desiring oral contraception. She states that she is sexually active and feels she needs protection. Her periods have been irregular since menarche at age 11, and she cannot remember the last time she had her period. Eileen has not been to a physician since she was about 13 years old. She does not know of any family members who have irregular periods, but her older sister has been trying to get pregnant for the last 4 years. She has a family history of type II diabetes mellitus, obesity, and hypertension. Her physical examination shows abdominal obesity, facial hirsutism, and acne. Given her large body habitus, the ovaries are difficult to palpate. A urine pregnancy test is negative. Her body mass index (BMI) is 29 kg/m², which is classified as overweight.

A fasting blood test reveals abnormally high concentrations of glucose, insulin, lipids, luteinizing hormone (LH), and total testosterone; a slightly elevated prolactin concentration; and a normal thyroid-stimulating hormone (TSH) concentration. The health care provider suspects that Eileen might have polycystic ovarian syndrome (PCOS) and refers her to a gynecologist for further evaluation. The gynecologist observes multiple bilateral ovarian cysts on transvaginal ultrasound and is able to rule out related disorders, leading to a conclusive diagnosis of PCOS. Eileen is prescribed metformin (an insulin-sensitizing drug) and combined oral contraceptives, referred to a dietician for a low-fat and low-calorie diet, and assigned to work with a personal trainer. Chapters 53 and 54 discuss Eileen’s case in more detail.

After ovulation, the follicle collapses, and the luteal stage of the menstrual cycle begins. Blood vessels and yellow lipochrome-bearing cells from the theca layer invade the granulose cells. A rapid accumulation of blood and fluid forms a mass called the corpus luteum. Leakage of this blood onto the peritoneal surface that surrounds the ovary is thought to contribute to the mittelscherz (“middle [or intermenstrual] pain”) of ovulation. During the luteal stage, progesterone is secreted from the corpus luteum. If fertilization does not take place, the corpus luteum atrophies and is replaced by white scar tissue called the corpus albicans. At this point, the hormonal support of the endometrium is withdrawn and menstruation occurs. In the event of fertilization, the trophoblastic cells in the blastocyst produce a hormone called human chorionic gonadotropin. This hormone prevents luteal regression. The corpus luteum remains functional for 7 to 10 weeks and provides hormonal support for pregnancy until the placenta is fully functional. Figure 53.7B shows the hormonal changes that occur during the development of the ovarian follicle and ovulation.
Endometrial Changes

The endometrium consists of two distinct layers, or zones, that are responsive to hormonal stimulation: a basal layer and a functional layer. The basal layer lies adjacent to the myometrium and is not sloughed during menstruation. The functional layer arises from the basal layer and undergoes proliferative changes and menstrual sloughing. It can be subdivided into two components: a thin, superficial, compact layer and a deeper spongiosa layer that makes up most of the secretory and fully developed endometrium. The endometrial cycle can be divided into three phases: the proliferative, or preovulatory, phase, during which the glands and stroma of the superficial layer grow rapidly under the influence of estrogen; the secretory, or postovulatory, phase, during which progesterone produces glandular dilation and active mucus secretion and the endometrium becomes highly vascular and edematous; and the menstrual phase, during which the superficial layer degenerates and sloughs off (see Fig. 53.5).

Cervical Mucus Changes

Cervical mucus is a complex, heterogeneous secretion produced by the glands of the endocervix. It is composed of 92% to 98% water and 1% inorganic salts, mainly sodium chloride. The mucus also contains simple sugars, polysaccharides, proteins, and glycoproteins. Its pH is usually alkaline, ranging from 6.5 to 9.0. Ferning or arborization refers to the characteristic microscopic pattern that results from the crystallization of the inorganic salts in the cervical mucus when it is dried. Its characteristics are strongly influenced by serum levels of estrogen and progesterone. Estrogen stimulates the production of large amounts of clear, watery mucus through which sperm can penetrate most easily. During ovulation cervical mucus is thin and stretchy. Spinnbarkeit is the property that allows cervical mucus to be stretched or drawn into a thread. Spinnbarkeit can be estimated by stretching a sample of cervical mucus between two glass slides and measuring the maximum length of the thread before it breaks. At midcycle, spinnbarkeit usually exceeds 10 cm. Progesterone, even in the presence of estrogen, reduces the secretion of mucus. During the luteal phase of the menstrual cycle, mucus is scant, viscous, and cellular.

Menopause

Menopause is the cessation of menstrual cycles. Like menarche, it is more of a process than a single event. Most women stop menstruating between 48 and 55 years of age. Perimenopause (the years immediately surrounding menopause) precedes menopause by approximately 4 years and is characterized by menstrual irregularity and other menopausal symptoms. Climacteric is a more encompassing term that refers to the entire transition to the nonreproductive period of life. Premature ovarian failure describes the approximately 1% of women who experience menopause before the age of 40 years. A woman who has not menstruated for a full year or who has a persistently elevated FSH level (>20 mIU/mL) is considered menopausal.

Functional Changes

Menopause results from the gradual cessation of ovarian function and the resultant diminished levels of estrogen. Although estrogens derived from the adrenal cortex continue to circulate in a woman’s body, they are insufficient to maintain the secondary sexual characteristics in the same manner as ovarian estrogens. As a result, body hair, skin elasticity, and subcutaneous fat decrease. The breasts become pendulous with a decrease in tissue mass, leaving only the ducts, fat, and connective tissue. The ovaries and uterus diminish in size; and the cervix and vagina become pale and friable. Vaginal pH increases; a pH greater than 4.5 is usually associated with estrogen deficiency. Problems that can arise as a result of urogenital atrophy include vaginal dryness, urinary stress incontinence, urgency, nocturia, vaginitis, and urinary tract infection (UTI). Women may find intercourse painful and traumatic, although some
type of vaginal lubrication may be helpful. Vaginal estrogen cream may be recommended for vaginal dryness and atrophy. It remains controversial as to the advantages and disadvantages of taking a small amount of transdermal (more likely a gel or spray) estrogen to decrease the vulvovaginal symptoms. Many believe the transdermal gel or spray is more effective than the patch and has less risk for health problems.

Systemically, a woman may experience significant vasomotor instability secondary to the decrease in estrogens and the relative increase in other hormones, including FSH, LH, GnRH, dehydroepiandrosterone, androstenedione, epinephrine, corticotropin, β-endorphin, growth hormone, and calcitonin gene-related peptide. This instability may give rise to “hot flashes,” palpitations, dizziness, and headaches as the blood vessels dilate. Despite the association with these biochemical changes, the underlying cause of hot flashes is unknown. Tremendous variation exists in the onset, frequency, severity, and length of time that women experience hot flashes. When they occur at night and are accompanied by significant perspiration, they are referred to as night sweats. Insomnia as well as frequent awakening because of vasomotor symptoms can lead to sleep deprivation. A woman may experience irritability, anxiety, and depression as a result of these uncontrollable and unpredictable events.

In addition to changes that closely follow the cessation of ovarian function, there are changes that over many years influence the health and well-being of postmenopausal women. Consequences of long-term estrogen deprivation include osteoporosis due to an imbalance in bone remodeling (i.e., bone resorption occurs at a faster rate than bone formation), and an increased risk for cardiovascular disease (atherosclerosis is accelerated), which is the leading cause of death for women after menopause. Other potential health threats, which reflect both aging and cessation of ovarian function, are loss of vision due to macular degeneration, and cognitive impairment.

**Hormone Therapy**

Over the past four to five decades, hormone therapy (HT) became increasingly prescribed for postmenopausal women. Initially, HT was used only for symptom management, and later for prevention of osteoporosis. During the 1990s, HT evolved to the status of replacement for a vital hormone lost because of vasomotor instability. The addition of progesterone (EPT) is standard because of the association between unopposed estrogen and the development of endometrial cancer. When used cyclically, HT may prevent endometrial hyperplasia, which is the underlying cause of hot flashes.

**Women’s Health Initiative and Other Studies.** With the current shift to evidence-based medicine, randomized control trials were undertaken to confirm the reported benefits of HT using an experimental model to demonstrate that the intervention (HT), and not other variables, was in fact responsible for the outcome. Several randomized control trials have now demonstrated that HT does not prevent and can increase the likelihood of a cardiovascular event in women with established heart disease. Other studies looking at the effect of HT on cognition and Alzheimer disease have failed to show benefit.

The Women’s Health Initiative (WHI) was planned as an 8- to 10-year nationwide research effort with an observational study component (93,700 women) and a multicenter, prospective, randomized, double-blind, placebo-controlled clinical trial component (68,000 women) to define the risks and benefits of HT. The WHI enrolled 161,809 mostly healthy postmenopausal women (50 to 79 years of age) into a set of clinical trials (trials of low-fat diet, calcium and vitamin D supplementation, and two parallel trials of postmenopausal HT).

The two parallel trials of HT were undertaken to determine whether estrogen plus progestin (CCEPT; for women with an intact uterus) or estrogen alone (ET; for women with prior hysterectomy) would reduce the incidence of cardiovascular disease and lead to any change in risk for breast or colorectal cancer in postmenopausal women. A total of 16,608 women with an intact uterus were enrolled in the estrogen plus progestin arm (CCEPT). The study was stopped prematurely in 2002 after 5.2 years of data analysis when it was determined that the risks of HT outweighed its benefits. The study found that the risk of breast cancer crossed the predetermined safety boundary and incidences of CHD, stroke, and venous thromboembolic
disease were all increased. On the positive side, there was a reduction in colorectal cancer and hip fractures among the women using HT. The ET-only clinical trial was also stopped prematurely, after 6.8 years. The ET-only study demonstrated no increased risk of breast cancer or heart disease, but there was a similar increased risk of stroke and venous thromboembolic disease.

Results from a 3-year follow-up study of women in the CCEPT arm of the WHI trial indicate that the increased cardiovascular risks observed at the time the intervention was stopped were not maintained, but a greater risk of fatal and nonfatal malignancies occurred (global risk index was 12% higher in women from the CCEPT group as compared with the placebo group). The follow-up study also found that the positive effects of CCEPT, such as decreased risk of colorectal cancer and hip fractures, also stopped when therapy ended.22

**Cardiovascular Risk.** Subsequent critical reassessment and subgroup analyses of the WHI, as well as findings from other studies, have led to a reevaluation of some of the conclusions that were made. A complete review of the literature surrounding HT is beyond the scope of this chapter. However, the following summary statements represent some of the current thinking.

First, the average age (63.7 years) and length of time since menopause (18 years) have been identified as indications that the women in WHI were already potentially predisposed to CHD and that the WHI may, in truth, have been a secondary prevention trial. Analyses of risk by age21 and time since menopause24 in the CCEPT trial reveal that the younger women (younger than 60 years of age) and those who started HT within 10 years of menopause demonstrated a trend toward lower rates of CHD. It has been hypothesized that HT, given during a “critical window” after menopause, may continue the cardioprotective actions provided by premenopausal levels of estrogen. However, when HT is started beyond this window period (when women may already have preexisting subclinical atherosclerosis), it may stimulate inflammatory cytokines that predispose to atherosclerotic plaque rupture and development of symptomatic CHD.25 The majority (70%) of the women in the WHI were in the age group that could be expected to have subclinical changes at the start of the study and therefore would be less likely to benefit from HT.

Second, data from the Nurses’ Health Study suggest that women starting HT near the onset of menopause had a significantly reduced risk (30%) of CHD.

Third, a meta-analysis26 showed a 32% decrease in CHD in younger postmenopausal women. Although there was a reported initial increase in incidence of CHD during the first year in older postmenopausal women (those who started HT after age 60 years), there was a reduced incidence after 2 years. It is still a matter of debate whether the presence of the daily progestin contributed to the higher levels of CHD in the CCEPT group compared with the ET group.

The increased risk of venous thromboembolism does appear to be consistently associated with the use of HT. The absolute risk is low, appears to be greatest in the first 2 years of HT use, and declines thereafter. Women with a history of venous thromboembolism or who have a predisposition to clot formation as a result of coagulation defects such as factor V Leiden are generally advised to avoid the use of HT.

**Breast Cancer Risk.** The association with breast cancer has long been the other area of concern with HT. In studies reporting estimated risks of breast cancer associated with HT, most of the confidence intervals cross the relative risk of 1 and therefore are not statistically significant.27 The WHI added to the breast cancer concern by reporting a 26% increased risk of invasive breast cancer in the women using CCEPT.28 Results from a 3-year WHI follow-up study revealed that the breast cancer risk of women who stopped taking CCEPT continued at a rate similar to that observed during the intervention.22 The use of ET alone did not increase breast cancer risk in the WHI, but it did appear to increase the need for additional follow-up mammograms due to the added density of the breasts in women using estrogen HT.29

An update from the Nurses’ Health Study showed no increased risk of invasive breast cancer with estrogen HT until 20 years of use.30 In contrast, another large European study recruited over 1 million women aged 50 to 64 years and analyzed the 80% who were postmenopausal for breast cancer incidence (2.6 years average follow-up) and mortality (4.1 years average follow-up). Approximately half the women had used HT at some time. Results of this observational study revealed increased risk among current users of HT. The largest increase in risk was associated with CCEPT, was slightly less with ET, and declined after discontinuation and returned to baseline within 5 years.31

Current thinking postulates that these studies may, in fact, constitute detection studies rather than incidence studies, because it is known that breast cancer cells can be present in the body for 8 to 10 years before the cancer can be detected by any currently available means. Estrogen may accelerate the growth of these cells to a point where the cancer can then be detected, which may explain why some studies show a positive correlation between estrogen and breast cancer and others do not. In this case, the increase in breast cancer detection may in fact be a positive outcome because it can be discovered while the cancer is still curable. At present there is insufficient evidence to support estrogen as the cause (initiator) of breast cancer.32 In fact, studies conducted to determine if women with a history of breast cancer who experienced some of the aggravating symptoms of menopause could take HT safely do not have clear answers.34 Some physicians feel that if the woman is aware of the possible risks of breast cancer or other health problems that can be the result of HT and want to eradicate the symptoms of menopause, they should be able to take HT.34 Thus, a more reasonable approach may involve identifying predisposing factors for breast cancer and finding better ways for early detection. This would assist women in assessing their own risk–benefit ratio, taking into account their individual circumstances, when making decisions about HT.
Hip Fracture and Other Risks. The release of data from the other two clinical trials within the WHI (low-fat dietary patterns, calcium and vitamin D supplementation) has challenged conventional wisdom in other areas. The use of calcium (1000 mg/day) plus vitamin D (200 IU/day) was shown to result in a small but significant improvement in hip bone density, but failed to reduce the risk of hip fractures. The Institute of Medicine (2010) recommends that all adults take 600 IU/day to maintain healthy bones but could not make any causal relationships with taking vitamin D and any other health outcomes.

Final Analysis: Current Recommendations for HT. Although the average age of menopause has not changed substantially since 1900, life expectancy has increased dramatically. Today, the average woman will live almost one third of her life after menopause. Menopause now represents only the end of reproductive capability. Estrogen’s role in many other bodily functions has been well documented, but its replacement after the ovary ceases production has become highly controversial. Although the U.S. Preventive Services Task Force has recommended against the routine use of HT for preventing chronic conditions in general, statements from the North American Menopause Society (NAMS), the American Society for Reproductive Medicine (ASRM), the American College of Obstetricians and Gynecologists (ACOG), and the National Institutes of Health (NIH) State-of-the-Science Conference Statement on Management of Menopause-Related Symptoms all indicate that estrogen is the most consistently effective therapy for treating menopausal symptoms. Use of HT in younger, recently menopausal women appears less likely to result in the increased risks reported in the WHI and Heart and Estrogen/Progestin Replacement Study (HERS), which studied predominantly older, asymptomatic women who were on average 10 or more years beyond menopause.

Current recommendations for HT, in light of the findings of the WHI and other clinical trials, are as follows:

- Avoid HT for primary or secondary prevention of CHD
- Develop an individual risk profile for every woman contemplating HT and provide information regarding known risks
- Use HT only in those women who require relief from menopausal symptoms that affect quality of life
- Consider lower-than-standard doses and alternative routes of administration
- Limit the use of HT to the shortest duration consistent with goals, benefits, and risks of treatment for each woman
- Consider alternative therapies if the woman is not symptomatic because of the potential risks associated with HT products that are FDA-approved for the prevention of postmenopausal osteoporosis

Due to the mixed results of the WHI, there has been increased interest in alternative methods for management of postmenopausal symptoms, specifically vasomotor symptoms.

IN SUMMARY

Between menarche and menopause, the female reproductive system undergoes cyclic changes called the menstrual cycle. The normal menstrual cycle results from complex interactions among the hypothalamus, which produces GnRH; the anterior pituitary gland, which synthesizes and releases FSH, LH, and prolactin; the ovaries, which synthesize and release estrogens, progesterone, and androgens; and associated target tissues, such as the endometrium and the vaginal mucosa. Although each component of the system is essential for normal functioning, the ovarian hormones are largely responsible for controlling the cyclic changes and length of the menstrual cycle.

Estrogens are necessary for normal female physical maturation, for growth of ovarian follicles, generation of a climate that is favorable to fertilization and implantation of the ovum, and for promoting the development of the endometrium in the event of pregnancy. Estrogens also have a number of extragenital effects, including prevention of bone resorption and regulation of the composition of cholesterol-carrying lipoproteins (HDL and LDL) in the blood. The functions of progesterone include the glandular development of the lobular and alveolar tissue of the breasts, the cyclic glandular development of the endometrium, and maintenance of pregnancy. Androgens contribute to hair distribution in the female and may have important metabolic effects.

Menopause is the cessation of menstrual cycles. Systemically, a woman may experience significant vasomotor instability and “hot flashes” secondary to the decrease in estrogens and the relative increase in other hormones, including FSH, LH, GnRH, dehydroepiandrosterone, and androstenedione. The long-term effects of estrogen deprivation include osteoporosis due to an imbalance in bone remodeling (i.e., bone resorption occurs at a faster rate than bone formation) and an increased risk for cardiovascular disease (atherosclerosis is accelerated), which is the leading cause of death in women after menopause. HT, which was regarded as a hormone replacement therapy for postmenopausal women during the late 20th century, has come under scrutiny as a result of the WHI study, which indicates that CCEPT (continuous combined estrogen and progestin)
commonly called “breasts” are two parts of a single anatomic breast. This contiguous nature of breast tissue is important in health and illness. Men and women alike are born with rudimentary breast tissue, with the ducts lined with epithelium. In women, the pituitary release of FSH, LH, and prolactin at puberty stimulates the ovary to produce and release estrogen. This estrogen stimulates the growth and proliferation of the ductile system. With the onset of ovulatory cycles, progesterone release stimulates the growth and development of ductile and alveolar secretory epithelium. By adolescence, the breasts have developed characteristic fat deposition patterns and contours.

Structurally, the breast consists of fat, fibrous connective tissue, and glandular tissue. The superficial fibrous connective tissue is attached to the skin, a fact that is important in the visual observation of skin movement over the breast during breast self-examination. The breast mass is supported by the fascia of the pectoralis major and minor muscles and by the fibrous connective tissue of the breast. Fibrous tissue ligaments, called Cooper ligaments, extend from the outer boundaries of the breast to the nipple area in a radial manner, like the spokes on a wheel (see Fig. 53.9). These ligaments further support the breast and form septa that divide the breast into about 20 lobes. Each lobe consists of grapelike clusters—alveoli or glands—that are interconnected by ducts. The alveoli are lined with secretory cells capable of producing milk or fluid under the proper hormonal conditions (Fig. 53.9). The route of descent of milk and other breast secretions is from alveoli to duct, to intralobular duct, to lactiferous duct and reservoir, to nipple. Breast milk is produced secondary to complex hormonal changes associated with pregnancy. Fluid is produced and reabsorbed during the menstrual cycle. The breasts respond to the cyclic changes in the menstrual cycle with fullness and discomfort.

The nipple is made up of epithelial, glandular, erectile, and nervous tissue. Areolar tissue surrounds the nipple and is recognized as the darker, smooth skin between the nipple and the breast. The small bumps or projections on the areolar surface known as Montgomery tubercles are sebaceous glands.
During lactation, milk is secreted by alveolar cells, which are under the influence of the anterior pituitary hormone prolactin. Milk ejection from the ductile system occurs in response to the release of oxytocin from the posterior pituitary. The suckling of the infant provides the stimulus for milk ejection. Suckling produces feedback to the hypothalamus, stimulating the release of oxytocin from the posterior pituitary. Oxytocin causes contraction of the myoepithelial cells lining the alveoli and ejection of milk into the ductal system. A woman may have breast leakage for 3 months to 1 year after the termination of breast-feeding as breast tissue and hormones regress to the nonlactating state. Overzealous breast stimulation with or without pregnancy can likewise cause breast leakage.

It is important to follow safe guidelines for drug use, including optimal dosing, when a woman is pregnant or lactating because many drugs cross the placenta and enter breast milk. There is controversy over how much vitamin D is best for pregnant women. Pregnant and lactating women need to follow the current guidelines regarding maternal vitamin D status in order to prevent possible maternal and fetal adverse events since the amount of vitamin D needs to be individualized for each pregnant woman.

**IN SUMMARY**

The breast is a complex structure of variable size, consistency, and composition. Although anatomically distinct, the breasts are functionally related to the female genitourinary system in that they respond to cyclic changes in sex hormones and produce milk for infant nourishment.

Disorders of the female genitourinary system have widespread effects on physical and psychological function, including general health status, sexuality, and reproductive potential. The reproductive structures are located close to other pelvic structures, particularly those of the urinary system, and disorders of the reproductive system may affect urinary function. This chapter focuses on infection and inflammation, benign conditions, and neoplasms (benign and malignant) of the female reproductive structures; disorders of pelvic support and uterine position; and alterations in menstruation. An overview of infertility is also included.
Disorders of the External Genitalia

Diseases of the external genitalia are similar to those that affect hair-bearing skin elsewhere in the body. Most skin cysts, nevi, and malignant neoplasms can occur on the skin of the external genitalia as well as on the skin in other parts of the body. The vulva (composed of the mons pubis, labia majora and minora, clitoris, and vestibule) is particularly prone to skin infections because it is constantly exposed to secretions and moisture. Nonspecific vulvitis is particularly common in women with diabetes, chronic kidney disease, blood dyscrasias, and malnutrition.

Bartholin Gland Cyst and Abscess

A Bartholin gland cyst is a fluid-filled sac that results from occlusion of the duct system in the Bartholin gland (Fig. 54.1). If the cyst becomes infected, an abscess may develop in the gland and is commonly caused by staphylococcal, chlamydial, and anaerobic infections. Acute symptoms are usually the result of infection and include pain, tenderness, and dyspareunia. The treatment of symptomatic cysts consists of the administration of appropriate antibiotics, local application of moist heat, and incision and drainage. A Word catheter may be inserted to continue to drain the cyst for a few weeks. Frequently reoccurring cysts that are large enough to cause blockage of the introitus may require surgical intervention. Because the Bartholin glands usually shrink during menopause, a vulvar growth in postmenopausal women is suspicious and should be evaluated for malignancy.

Non-neoplastic Epithelial Disorders

The term non-neoplastic epithelial disorders refers to non-malignant atrophic and hyperplastic changes of the vulvar skin and mucosa that can develop at any age and can progress to malignancy. Depending on clinical and histologic characteristics, the lesions can be categorized as lichen simplex chronicus, lichen sclerosus, or lichen planus. These precursor lesions can progress to differentiated vulvar intraepithelial neoplasia (VIN) or VIN simplex. There is evidence that VIN, invasive squamous cell carcinoma, and lichen sclerosus have the identical p53 gene mutation. Vulvar carcinoma is rare.

Lichen simplex chronicus presents as thickened, gray-white plaques with an irregular surface. Presumed to be a response of the genital skin to some type of irritant, this diagnosis is used only when human papillomavirus (HPV) infection, fungal infections, or other known causative conditions have been ruled out. Vulvar pruritus is the most common presenting complaint. Treatment is aimed at reducing itching and preventing further irritation to the skin.

Lichen sclerosus is an inflammatory disease of the vulva characterized by plakelike areas that may progress to parchment-thin epithelium with focal areas of ecchymosis and superficial ulceration secondary to scratching. Atrophy and contracture of the vulvar tissues with eventual stenosis of the introitus are common when this condition becomes chronic. Itching is common and dyspareunia is frequent. The condition develops insidiously and has a high risk associated with developing vulvar malignancy.

Lichen sclerosis is also seen with autoimmune disorders such as thyroiditis and vitiligo. Current treatment measures for lichen sclerosus favor the use of potent topical corticosteroids. Lichen sclerosus frequently recurs, and lifetime maintenance therapy may be required. Hyperplastic areas that occur in the field of lichen sclerosus may be sites of malignant change and warrant close follow-up and possible biopsy.

Lichen planus is thought to have an autoimmune component and is more rarely seen. There are three types of lichen planus including erosive, which is the most common, papulosal, and hypertrophic. Generally a mild topical steroid is the treatment.

After completing this section of the chapter, you should be able to meet the following objectives:

• Discuss the abnormalities associated with Bartholin cyst, non-neoplastic epithelial disorders, vulvodynia, and cancer of the vulva.
• Describe the conditions that predispose to vaginal infections and the methods used to prevent and treat these infections.

Vulvodynia

Vulvodynia is a multifactorial chronic pain disorder previously referred to as vulvar pain syndrome or burning vulva syndrome. The International Society for the Study of Vulvovaginal Disorders (ISSVD) defines it as a condition characterized by vulvar irritation and rawness in the absence of relevant visible findings or a clinically identifiable, neurological disorder. Approximately, 16% of females in the United States have been diagnosed with this syndrome and many more women experience the symptoms but are never diagnosed. Vulvodynia is further classified as localized or generalized, and as to whether it is provoked, unprovoked, or of mixed origin.

Localized Vulvodynia. Localized vulvodynia or vestibulodynia, formerly referred to as vulvar vestibulitis syndrome, is characterized by pain at onset of intercourse (i.e., insertional dyspareunia), localized point tenderness near the vaginal opening, and sensitivity to tampon placement. The pain can be primary (present from first contact) or secondary (developing after a period of comfortable sexual relations). The etiology is unknown, but the problem may evolve from chronic vulvar inflammation or trauma. Nerve fibers that supply the vestibular epithelium may become highly sensitized and trigger an abnormal response from neurons in the dorsal horn of the spinal cord. Surgical vestibulectomy may be necessary for symptom relief when medical management fails. There is no specific etiology of vestibulodynia and there is no one effective treatment with high evidence of efficacy.

Generalized Vulvodynia. Generalized vulvodynia, involves severe, constant, widespread burning that interferes with daily activities. No abnormalities are found on examination, but there is diffuse and variable hypersensitivity and altered sensation to light touch. The quality of this unprovoked pain shares many of the features of other neuropathic pain disorders, particularly complex regional pain syndrome or pudendal neuralgia. Although the cause of the neuropathic pain is unknown, it has been suggested that it may result from myofascial restrictions affecting the sacral and pelvic floor nerves. Surface electromyography-assisted pelvic floor muscle rehabilitation has been shown to be an effective primary therapy or adjunct to medical or surgical therapy for generalized vulvodynia.

There are many proposed triggers for vulvodynia, including chronic recurrent vaginal infections; chemical irritation or drug effects, especially prolonged use of topical steroid creams; the irritating effects of elevated urinary levels of calcium oxalate; and immunoglobulin A deficiency or other disorders of immune regulation.

Careful history taking and physical assessment are essential for differential diagnosis and treatment. Vulvodynia is a diagnosis of exclusion after ruling out infections, such as candidiasis and genital herpes; inflammatory conditions, such as lichen simplex chronicus and lichen sclerosus; vulvar cancer; or neurologic disorders, such as herpes neuralgia or spinal nerve compression, as causes for the pain.

Treatment for this chronic, often debilitating problem is aimed at symptom relief, is frequently long term, and often needs to be managed from a multidimensional, chronic pain perspective. Regimens can include long-term vaginal or oral antifungal therapy, avoidance of potential irritants, sitz baths with baking soda, emollients such as vitamin E or vegetable oil for lubrication, anesthetic or steroid ointments, capsaicin cream (topical analgesic), physical therapy, and surgery. Oral medications, including tricyclic antidepressants, other antidepressants (e.g., selective serotonin receptor uptake inhibitors [SSRIs]), or gabapentin (an antiepileptic drug), are often used to treat the neuropathic pain associated with vulvodynia. Because this condition can cause strain in sexual, family, and work relationships, psychosocial support often is needed.

Cancer of the Vulva

Estimates of carcinoma of the vulva for 2011 in the United States are approximately 4,340 new cases per year with 940 predicted deaths. There is a lifetime risk of 1 in 387 women being diagnosed with vulvar carcinoma at sometime in their life. Vulvar cancer accounts for about 3% of all of the female genital malignancies occurring in women 60 years of age or older.

In terms of etiology, pathogenesis, and clinical presentation, vulvar carcinoma can be divided into two general groups. The first group is associated with VIN, a precursor lesion of squamous cell carcinoma. One third to one half of VIN cases appear to be caused by the cancer-promoting potential of certain strains (subtype 16) of HPV that are sexually transmitted and are associated with the type of vulvar cancer found in younger women (i.e., younger than 40 years of age). VIN lesions may take many forms. They may be singular or multicentric, macular or papular, red or white and plaque like. Microscopically, VIN presents as a proliferative process, characterized by epithelial cells with atypical nuclei, increased mitosis, and lack of surface differentiation. The risk of progression to invasive cancer increases in older women and in women with suppressed immune function.

The second form of vulvar cancer, which is seen more often in older women, is generally preceded by vulvar non-neoplastic disorders such as chronic vulvar irritation or lichen sclerosus. The etiology of this group of vulvar cancers is unclear, but they are not typically associated with HPV. Neoplastic changes may arise from lichen sclerosus lesions or hyperplasia, leading directly to malignancy.

The initial lesion of squamous cell vulvar carcinoma may appear as an inconspicuous thickening of the skin, a small raised area or lump, or an ulceration that fails to heal. It may be single or multiple and vary in color from white to velvety red or black. The lesions may resemble eczema or dermatitis and may produce few symptoms other than pruritus, local discomfort, and exudation. The lesion may become secondarily infected, causing pain and discomfort. The malignant lesion gradually spreads superficially or as a deep furrow involving all of one labial side. Because there are many lymph channels around the vulva, the cancer metastasizes freely to the regional lymph nodes. The most common extension is to the superficial…
inguinal, and then to deep femoral, inguinal, and pelvic lymph nodes. The system developed by the 2009 International Federation of Gynecology and Obstetrics grades vulvar cancer using four stages based on where it has spread.

Early diagnosis is important in the treatment of vulvar carcinoma. Because malignant lesions can vary in appearance and commonly are mistaken for other conditions, biopsy and treatment often are delayed. Treatment is primarily wide surgical excision of the lesion for noninvasive cancer and radical excision or vulvectomy with node resection for invasive cancer. Postoperative groin and pelvic radiation is recommended when groin lymph nodes are involved.

**Disorders of the Vagina**

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Normal estrogen levels maintain a thick, protective squamous epithelium that contains glycogen. The vaginal flora consists of various bacteria mostly from the lactobacillus genus that metabolize glycogen, and in the process produce the lactic acid that normally maintains the vaginal pH of 3.8 to 4.5. Disruptions in these environmental conditions, such as changes in the normal flora by antibiotic use, predispose to infection.

**Vaginitis**

Vaginitis represents an inflammation of the vagina that is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. Pain often occurs with urination and sexual intercourse. Chemical irritants, foreign bodies, or infectious agents may cause vaginitis. The causes of vaginitis differ in various age-groups. In premenarchal girls, most vaginal infections have nonspecific causes, such as poor hygiene, intestinal parasites, or the presence of foreign bodies. *Candida albicans*, *Trichomonas vaginalis*, and bacterial vaginosis are the most common causes of vaginitis in the childbearing years, and some of these organisms can be transmitted sexually.

In postmenopausal women, atrophic vaginitis is the most common form. Atrophic vaginitis is an inflammation of the vagina that occurs after menopause or removal of the ovaries (causing estrogen deficiency). Estrogen deficiency results in a lack of regenerative growth of the vaginal epithelium, rendering these tissues more susceptible to infection and irritation. These changes lead to a decrease in the vaginal flora, causing vaginal secretions to become less acidic. The symptoms of atrophic vaginitis include itching, burning, and painful intercourse. Extreme symptoms can sometimes be reversed by local application of estrogen cream.

Every woman normally experiences vaginal discharge during the menstrual cycle, but it should not cause burning, itching, or have an unpleasant odor. These symptoms suggest inflammation or infection. Because these symptoms are common to the different types of vaginitis, precise identification of the organism is essential for proper treatment. A careful history should include information about systemic disease conditions, the use of drugs such as antibiotics that foster the growth of yeast, dietary habits, stress, and other factors that alter the resistance of vaginal tissue to infections. A physical examination usually is done to evaluate the nature of the discharge and its effects on the genital structures. Microscopic examination of a saline wet-mount smear (prepared by placing a sample of vaginal mucus in one or two drops of normal saline) is the primary means of identifying the organism responsible for the infection. In order to identify candidiasis, potassium hydroxide (KOH) is used with the wet mount instead of the saline. Culture methods may be needed when the organism is not apparent on the wet-mount preparation.

The prevention and treatment of vaginal infections depend on proper health habits and accurate diagnosis and treatment of ongoing infections. It is important for women to see their primary care providers regarding any problem they may be experiencing in order for the earliest possible diagnosis to be made. Unfortunately, only approximately 10% of all women see their women’s health provider for vaginitis.

**Cancer of the Vagina**

Primary cancers of the vagina are extremely rare, accounting for approximately 1% of all cancers of the female reproductive system. Like vulvar carcinoma, carcinoma of the vagina is largely a disease of older women. Most women are 60 years of age or older at the time of diagnosis. The exception to that is the clear cell adenocarcinoma associated with diethylstilbestrol (DES) exposure in utero which is still, although rarely, seen in offspring of women who were treated with DES. Vaginal cancers may result from local extension of cervical cancer, from exposure to sexually transmitted HPV, or, rarely, from local irritation such as occurs with prolonged use of a pessary.

Squamous cell carcinomas begin in the epithelium and progress over many years from precancerous lesions called *vaginal intraepithelial neoplasia* (VAIN), 65% to 80% of which contain HPV. The most common symptom of vaginal carcinoma is abnormal bleeding. Other symptoms include an abnormal vaginal discharge, a palpable mass, or dyspareunia. Most women with preinvasive vaginal carcinoma are asymptomatic, with the cancer being discovered during a routine pelvic examination. The anatomic proximity of the vagina to other pelvic structures (urethra, bladder, and rectum) permits early spread to these areas. Therefore, the majority of vaginal cancer, about 80%, is due to metastasis.

Since most preinvasive and early invasive cancers are silent, the use of the vaginal cytology (Papanicolaou [Pap] smear) is the most effective way to detect vaginal cancer. Women who have had a hysterectomy performed for reproductive cancer should continue to have vaginal cytologic studies after surgery. However, women who have had no positive Pap smears, a hysterectomy for benign disease, and had their cervix removed will not need a Pap smear. Diagnosis of vaginal cancer requires biopsy of suspect lesions or areas.

Treatment of vaginal cancer must take into consideration the type of cancer, the size, location, and spread of the lesion, and the woman’s age. Local excision, laser vaporization, or a
loop electrode excision procedure (LEEP) can be considered as treatment with stage 0 squamous cell cancers. Radical surgery and radiation therapy are both curative with more advanced cancers. When there is upper vaginal involvement, radical surgery may be required. This includes a total hysterectomy, pelvic lymph node dissection, and partial vaginectomy. The ovaries usually are preserved unless they are diseased. Extensive lesions and those located in the middle or lower vaginal area usually are treated by radiation therapy, which can be intracavitary, interstitial, or external beam. The prognosis depends on the stage of the disease, involvement of lymph nodes, and the degree of mitotic activity of the tumor.

IN SUMMARY

The surface of the vulva is affected by disorders that affect skin on other parts of the body. Bartholin cysts are the result of occluded ducts in Bartholin glands. They often are painful and can become infected. Non-neoplastic epithelial disorders are characterized by thinning or hyperplastic thickening of vulvar tissues. Vulvodynia is a chronic vulvar pain syndrome with several classifications and variable treatment results. Cancer of the vulva, which accounts for 4% of all female genitourinary cancers, is associated with HPV infections in younger women and lichen sclerosus in older women.

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Disruptions in these normal environmental conditions predispose to vaginal infections. Vaginitis or inflammation of the vagina is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. It may be caused by chemical irritants, foreign bodies, or infectious agents. Primary cancers of the vagina are relatively uncommon, accounting for about 1% of all cancers of the female reproductive system. Daughters of women treated with DES to prevent miscarriage are at increased risk for development of adenocarcinoma of the vagina.

Disorders of the Uterine Cervix

The cervix is composed of two distinct types of tissue. The exocervix, or visible portion, is covered with stratified squamous epithelium, which also lines the vagina.1 The endocervix is the canal that leads to the endometrial cavity. It is lined with columnar epithelium that contains large, branched mucus-secreting glands.1 During each menstrual cycle, the cervical glands undergo important functional changes related to the transport of spermatozoa within the cervical canal. The amount and properties of the mucus secreted by the gland cells vary during the menstrual cycle under the influence of the ovarian hormones. Blockage of the mucosal glands results in trapping of mucus in the deeper glands, leading to the formation of dilated cysts in the cervix called nabothian cysts. These are benign cysts that require no treatment unless they become so numerous that they cause cervical enlargement.17

The junction of the squamous epithelium of the exocervix and mucus-secreting columnar epithelium of the endocervix (i.e., squamocolumnar junction) appears at various locations on the cervix at different points in a woman’s life (Fig. 54.2).17 During periods of high estrogen production, particularly menarche, and the first pregnancy, the cervix everts or turns outward, exposing the columnar epithelium to the vaginal environment. The combination of estrogen and low vaginal pH leads to a gradual transformation from columnar to squamous epithelium—a process called metaplasia. This area of continuous change, or process of repair, is called the transformation zone.17

The transformation zone is a critical area for the development of cervical cancer. During metaplasia, the newly developed squamous epithelial cells are vulnerable to development of dysplasia and genetic change if exposed to cancer-producing agents. Dysplasia means disordered growth or development of the cells. Although initially a reversible cell change, untreated dysplasia can develop into carcinoma.20 The transformation zone is the area of the cervix that must be sampled to have

DISORDERS OF THE CERVIX AND UTERUS

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the importance of the cervical transformation zone in the pathogenesis of cervical cancer.
- Describe the development of cervical cancer from the appearance of atypical cells to the development of invasive cervical cancer and relate to the importance of the Pap smear in early detection of cervical cancer.
- Compare the pathology and manifestations of endometriosis and adenomyosis.

FIGURE 54.2  Location of the squamocolumnar junction (transformation zone) in menarchial, menstruating, menopausal, and postmenopausal women. (A, menarchial; B, menstruating; C, menopausal; D, postmenopausal.)
Polyps are the most common lesions of the cervix. They can be found in women of all ages, but their incidence is higher during the reproductive years. Polyps are soft, velvety, red lesions; they usually are pedunculated and often are found protruding through the cervical os. They usually develop as a result of inflammatory hyperplasia of the endocervical mucosa. Polyps typically are asymptomatic, but may be associated with postcoital bleeding. Most are benign, but they should be removed and examined by a pathologist to exclude the possibility of malignant change.

Cancer of the Cervix
Cervical cancer is readily detected and, if detected early, is the most easily cured of all the cancers of the female reproductive system. According to the American Cancer Society, an estimated 12,710 new cases of invasive cervical cancer will be diagnosed in the United States in 2011, with approximately 4290 deaths predicted from cervical cancer during the same period. By comparison, there were four times as many new cases of cervical carcinoma in situ (i.e., precancerous lesion) diagnosed, indicating that a large number of potentially invasive cancers are cured by early detection and effective treatment.

Risk Factors. Risk factors for cervical cancer include early age at first intercourse, multiple sexual partners, smoking, and a history of sexually transmitted infections (STIs). Human papilloma virus (HPV) is a double stranded DNA virus that is a STI that is linked to inducing changes in cells. Specific strains, HPV type 16 and HPV type 18, have been associated with cervical cancer. Other HPV types that are linked with cervical cancer include HPV types 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68. Other factors such as smoking, nutrition, and coexisting sexual infections such as C. trachomatis, herpes simplex virus type 2, and HIV may play a contributing role in determining whether a woman with HPV infection develops cervical cancer.

Preventing Cervical Cancer. The HPV vaccine has decreased the risk of cervical cancer by 97%. Gardisil is one type of HPV vaccine to prevent infection with the HPV subtypes 16, 18, 6, and 11. This vaccine has been approved for girls and boys between 9 and 26 years of age (prior to them becoming sexually active) to prevent HPV 6 and HPV 11 genital warts. The vaccine targets the two strains of HPV (HPV 16 and 18) responsible for 70% of cervical cancer, and the two most common benign strains (HPV 6 and 11), which account for up to 90% of genital warts. Clinical studies have confirmed that the vaccine appears safe and effective in inducing a sustained immunity response to HPV. The other FDA approved HPV vaccine is Cervarix, which is recommended to be given to girls between 10 and 25 years of age prior to becoming sexually active.

Pathogenesis. One of the most important advances in the early diagnosis and treatment of cancer of the cervix was made possible by the observation that this cancer arises from precancerous lesions that begin with the development of atypical cervical cells. Atypical cells differ from normal cervical squamous epithelium. There are changes in the nuclear and cytoplasmic parts of the cell and more variation in cell size and shape (i.e., dysplasia). These precancerous changes represent a continuum of morphologic changes with indistinct boundaries that may gradually progress to cancer in situ and then to invasive cancer, or they may spontaneously regress.

A system of grading devised to describe the histopathological findings of dysplastic changes of cancer precursors uses the term cervical intraepithelial neoplasia (CIN). This term describes premalignant changes in the epithelial tissue. CIN is categorized as:

- CIN I (dysplasia or atypical changes in the cervical epithelium)
- CIN II (moderate dysplasia)
- CIN III (severe dysplasia).

Diagnosis. As discussed earlier, these abnormal cells can be detected on a PAP smear, which would then lead to a colposcopy to be done to look for abnormal lesions on the cervix. Biopsies are taken of these potential abnormal lesions or areas of increased vascularity, as well as a curettage of the endocervical canal that may not be fully seen on colposcopy, and sent to pathology. The abnormal PAP smear finding of low-grade squamous intraepithelial lesion (LSIL) is often CIN I or a condyloma on biopsy, while high-grade squamous intraepithelial lesion (HSIL) on a PAP smear is more likely CIN II or CIN III.
hysteroscopy, or, ultimately, a cone biopsy if the abnormality cannot be located or identified through other means.18,28 Before the availability of colposcopy, many women with abnormal Pap smear results required surgical cone biopsy for further evaluation. Cone biopsy involves the removal of a cone-shaped wedge of cervix, including the entire transformation zone and at least 50% of the endocervical canal. Postoperative hemorrhage, infection, cervical stenosis, infertility, and incompetent cervix are possible sequelae that warrant avoidance of this procedure unless it is truly necessary. LEEP (loop electrosurgical excision procedure) has taken the place of cone biopsies in most situations and is now the first-line management for CIN II/III.18 This outpatient procedure allows for the simultaneous diagnosis and treatment of dysplastic lesions found on colposcopy. It uses a thin, rigid, wire loop electrode attached to a generator that blends high-frequency, low-voltage current for cutting and a modulated higher voltage for coagulation.

It has been estimated that approximately 20% of women with intraepithelial lesions have normal Pap smear results, indicating that care must be taken to obtain an adequate smear from the transformation zone that includes endocervical cells and to ensure the cytologic examination is done by a competent laboratory.18,22,27 The presence of normal endometrial cells in a cervical cytologic sample during the luteal phase of the menstrual cycle or during the postmenopausal period has been associated with endometrial disease and warrants further evaluation with endometrial biopsy. This demonstrates that shedding of even normal cells at an inappropriate time may indicate disease. Because adenocarcinoma of the cervix is being detected more frequently, especially in women younger than 35 years of age, a Pap smear result of atypical glandular cells warrants further evaluation by endocervical or endometrial curettage, hysteroscopy, or, ultimately, a cone biopsy if the abnormality cannot be located or identified through other means.18,28

Before the availability of colposcopy, many women with abnormal Pap smear results required surgical cone biopsy for further evaluation. Cone biopsy involves the removal of a cone-shaped wedge of cervix, including the entire transformation zone and at least 50% of the endocervical canal. Postoperative hemorrhage, infection, cervical stenosis, infertility, and incompetent cervix are possible sequelae that warrant avoidance of this procedure unless it is truly necessary. LEEP (loop electrosurgical excision procedure) has taken the place of cone biopsies in most situations and is now the first-line management for CIN II/III.18 This outpatient procedure allows for the simultaneous diagnosis and treatment of dysplastic lesions found on colposcopy. It uses a thin, rigid, wire loop electrode attached to a generator that blends high-frequency, low-voltage current for cutting and a modulated higher voltage for coagulation.
In skilled hands, this wire can remove the entire transformation zone, providing adequate treatment for the lesion while obtaining a specimen for further histologic evaluation.

**Clinical Manifestations and Treatment.** In its early stages, cervical cancer often manifests as a poorly defined lesion of the endocervix. Frequently, women with cervical cancer present with abnormal vaginal bleeding, spotting, and discharge. Although bleeding may assume any course, it is reported most frequently after intercourse. Women with more advanced disease may present with pelvic or back pain that may radiate down the leg, hematuria, fistulas (rectovaginal or vesicovaginal), or evidence of metastatic disease to supraclavicular or inguinal lymph node areas.

Early treatment of cervical cancer involves removal of the lesion by one of various techniques. Biopsy or local cautery may be therapeutic in and of itself. Electrocautery, cryosurgery, or carbon dioxide laser therapy may be used to treat moderate to severe dysplasia that is limited to the exocervix (i.e., squamosocolumnar junction clearly visible). Therapeutic conization becomes necessary if the lesion extends into the endocervical canal and can be done surgically or with LEEP in the physician’s office.

Depending on the stage of involvement of the cervix, invasive cancer is treated with radiation therapy, surgery, or both. External-beam irradiation and intracavitary irradiation or brachytherapy (i.e., insertion of radioactive materials into the body) can be used in the treatment of cervical cancer. Intracavitary radiation provides direct access to the central lesion and increases the tolerance of the cervix and surrounding tissues, permitting curative levels of radiation to be used. External-beam radiation eliminates metastatic disease in pelvic lymph nodes and other structures, as well as shrinks the cervical lesion to optimize the effects of intracavitary radiation. Surgery can include trachelectomy (removal of the cervix) in women with early stage cancer desiring fertility, radical hysterectomy (includes uterus, cervix, parametria, and upper portion of the vagina) with pelvic lymph node dissection, or pelvic exenteration (i.e., removal of all pelvic organs, including the bladder, rectum, vulva, and vagina).

**Disorders of the Uterus**

Common disorders of the uterus include endometritis, endometriosis, and endometrial cancer. Additionally, there is a high frequency of leiomyomas, which include uterine fibroid tumors that are benign neoplasms occurring in many women at some time during their life and adenomyosis, which is uterine thickening due to tissue from the endometrium being displaced in the outer muscular wall of the uterus.

**Endometritis**

The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix normally forms a barrier to ascending infections. Endometritis is inflammation of the endometrium. Acute endometritis can occur as a result of an abortion or after delivery of a newborn when the cervical barrier is compromised. Prophylactic antibiotics are given before and after an abortion to prevent this. There is an increased risk of endometritis after delivery of a newborn if the woman had chorioamnionitis during labor, had a cesarean section, or needed manual or instrumented removal of the placenta. Treatment includes antibiotics, and in cases where there are retained products of conception or placenta, a curettage may be necessary.

Chronic inflammation of the endometrium can occur with pelvic inflammatory disease (PID), after instrumentation of the uterus (e.g., after endometrial biopsy or intrauterine device [IUD] insertion), and with unrecognized retained products of conception after delivery or abortion. The presence of plasma cells (which are not present in the normal endometrium) is required for diagnosis. The clinical picture is variable, but often includes mild to severe uterine tenderness, fever, malaise and foul-smelling discharge. Treatment involves oral or intravenous antibiotic therapy, depending on the severity of the condition.

**Endometriosis**

Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus. It is a progressively inflammatory chronic disease, leading to implants, scarring, adhesions, and ovarian cysts called endometriomas. The sites where endometriosis may occur include the ovaries, posterior broad ligaments, uterosacral ligaments, pouch of Douglas (cul-de-sac), pelvis, vagina, vulva, perineum, or intestines (Fig. 54.4).

**Etiology and Pathogenesis.** The cause of endometriosis is unknown. There appears to have been an increase in its incidence in developed Western countries during the past four to five decades. Approximately, 10% of premenopausal women have some degree of endometriosis, causing infertility and chronic pain. Evidence supports that approximately 50% of infertile women have some degree of endometriosis.

Several theories attempt to explain the origin of the dispersed endometrial lesions that occur in women with endometriosis. One theory, the regurgitation/implantation theory, proposes that menstrual blood containing fragments of endometrium is forced upward through the fallopian tubes into the peritoneal cavity. Retrograde menstruation is not an uncommon phenomenon, and it is unknown why endometrial cells implant and grow in some women but not in others. A second theory, the metaplastic theory, proposes that dormant, immature cellular elements, spread over a wide area during embryonic development, persist into adult life and then differentiate into endometrial tissue. Another theory, the vascular or lymphatic theory, suggests that the endometrial tissue may metastasize through the lymphatics or vascular system. Genetic and immune factors also have been studied as contributing factors to the development of endometriosis.

**Clinical Manifestations.** Endometriosis usually becomes apparent in the reproductive years when ovarian hormones stimulate the lesions in the same way as normal endometrium.
Treatment modalities fall into three categories: pain relief, endometrial suppression, and surgery. In young women, simple observation and analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs]) may be sufficient treatment. The use of hormones to induce physiologic amenorrhea is based on the observation that pregnancy and menopause afford pain relief by inducing atrophy of the endometrial tissue. This can be accomplished through administration of oral contraceptive pills or continuous progestogen agents (medroxyprogesterone acetate [oral or depot injection] or the levonorgestrel intrauterine system). Danazol (a synthetic androgen) is less commonly used now given the increased side effect profile. In women with severe endometriosis, long-acting gonadotropin-releasing hormone

The lesions then become proliferative, then secretory, and finally undergo menstrual breakdown. Bleeding into the surrounding structures can cause pain and the development of significant pelvic adhesions. Symptoms tend to be strongest premenstrually, subsiding after cessation of menstruation. Pelvic pain is the most common presenting symptom. Other symptoms include back pain, dyspareunia, and pain on defecation and micturition. Endometriosis is associated with infertility because of adhesions that distort the pelvic anatomy and cause impaired ovum release and transport.

The gross pathologic changes that occur in endometriosis differ with location and duration. In the ovary, the endometrial tissue may form cysts known as endometriomas. These cysts are filled with old blood resembling chocolate syrup, for which they are sometimes referred to as chocolate cysts. Rupture of these cysts can cause peritonitis and adhesions. Elsewhere in the pelvis, the tissue may take the form of small hemorrhagic lesions that may be in a variety of colors, but mostly appearing as red-blue nodules (Fig. 54.5). Some lesions may be surrounded by scar tissue.

**Diagnosis and Treatment.** Endometriosis may be difficult to diagnose because its symptoms mimic those of other pelvic disorders and the severity of the symptoms does not always reflect the extent of the disease. Unfortunately, there are no serum markers or noninvasive tests that screen for endometriosis.\(^3^6\) Definitive diagnosis can be accomplished only through laparoscopy and then confirmed with histological testing.\(^3^6\) This minimally invasive surgery allows direct visualization of pelvic organs to determine the presence and extent of endometrial lesions. Imaging techniques, including ultrasonography and magnetic resonance imaging (MRI), are useful tools in evaluating endometriomas and deep endometriosis.\(^3^2\)

**FIGURE 54.4** • Common locations of endometriosis in the pelvis and abdomen.

Adenomyosis typically is found in multiparous women. It is a benign condition involving endometrial glands and stroma found within the myometrium, interspersed between the smooth muscle fibers. In contrast to endometriosis, which usually is a problem of young, infertile women, adenomyosis typically is found in multiparous women. It is thought that events associated with repeated pregnancies, deliveries, and uterine involution may cause the endometrium to be displaced throughout the myometrium. However, there is no known cause. Adenomyosis frequently coexists with uterine myomas or endometrial hyperplasia. The diagnosis of adenomyosis often occurs as an incidental finding in a uterus removed for symptoms suggestive of myoma or hyperplasia. Heavy, painful periods with clots and painful intercourse are common complaints of women with adenomyosis. Although in the past the diagnosis was made primarily through careful history and the pelvic examination findings of an enlarged, boggy uterus, MRI is now considered the diagnostic tool for confirming this condition. Conservative medical therapy using oral contraceptives and NSAIDs is the first choice for treatment. However, women with severe adenomyosis will ultimately require a hysterectomy (with preservation of the ovaries in premenopausal women) for full resolution of symptoms.

Endometrial Cancer

Endometrial cancer is the most common cancer found in the female pelvis, occurring more than twice as often as cervical cancer. Most cases of endometrial cancer are adenocarcinomas, with 2% being sarcomas. In 2011, the American Cancer Society estimated that approximately 46,000 women were diagnosed with endometrial cancer and 8,100 died of the disorder. Endometrial cancer occurs more frequently in older women (peak ages of 55 to 65 years), with only 8% occurring in women younger than 45 years of age.

Although the proportion of cases of endometrial cancer with a background of familial risk is low, 2%-to-5% of endometrial cancer can develop as part of a hereditary cancer syndrome. Women with a family history of hereditary nonpolyposis colorectal cancer (also known as Lynch syndrome) may have an inherited disorder in DNA mismatch repair genes that predisposes to cancers, including colorectal and endometrial. This autosomal dominant disease carries a 40%-to-60% risk of developing endometrial cancer.

Pathogenesis. In terms of potential pathogenesis, two general groups of endometrial cancer can be identified. The first develops on a background of prolonged estrogen stimulation and endometrial hyperplasia, whereas the second is less commonly associated with hyperestrogenism and endometrial hyperplasia.

Most endometrial cancers (about 85%) are moderately well-differentiated adenocarcinomas that develop on a background of endometrial hyperplasia. These tumors, also known as type 1 endometrial cancers, are typically hormone sensitive, low grade, and have a favorable prognosis. They are associated with long-duration unopposed estrogen stimulation and tend to be well differentiated, mimicking normal endometrial glands in histologic appearance, or display altered differentiation (mucinous, tubal, squamous differentiation).

The endometrium undergoes structural modification and cellular changes in response to fluctuations in estrogen and progesterone levels that occur during the menstrual cycle. Prolonged unopposed estrogen stimulation leads to endometrial hyperplasia, which increases the chance of development of atypical hyperplasia and eventually type 1 endometrial cancer. Although the molecular basis for this process is still unknown, anovulatory cycles, disorders of estrogen metabolism, unopposed estrogen therapy, estrogen-secreting granulosa cell tumor, and obesity are all known to increase the risk of endometrial cancer.

Ovulatory dysfunction that causes infertiltiy at any age or occurs with declining ovarian function in perimenopausal women also can result in unopposed estrogen and increase the risk of endometrial cancer. A sharp rise in endometrial cancer was seen in the 1970s among middle-aged women who had received unopposed estrogen therapy (i.e., estrogen therapy without progesterone) for menopausal symptoms. It was later determined that it was not the estrogen exposure that increased the risk of cancer, but that the hormone was administered without progesterone. It is the presence of progesterone in the second half of the menstrual cycle that matures the endometrium, and the withdrawal of progesterone ultimately results in endometrial sloughing. Long-term unopposed estrogen exposure without periodic addition of progesterone allows for continued endometrial growth and hyperplasia, which increases the chance of development of atypical cells. Hyperplasia usually regresses after treatment with cyclic progesterone. Sequential oral contraceptives (estrogen alone for 15 days followed by 7 days of...
combined estrogen and progestin) were withdrawn from the market in the 1970s because of potential risk of endometrial hyperplasia. In contrast, combination oral contraceptives (estrogen and progestin in each pill) effectively prevent hyperplasia and decrease the risk of cancer by 50%. Tamoxifen, a drug that blocks estrogen receptor sites and is used in treatment of breast cancer, exerts a weak estrogenic effect on the endometrium and represents another exogenous risk factor for endometrial cancer.

Diabetes mellitus, hypertension, and polycystic ovary syndrome are conditions that alter estrogen metabolism and elevate estrogen levels. Excessive fat consumption and being overweight are important risk factors for endometrial cancer. In premenopausal women, overweight causes insulin resistance, ovarian androgen excess, anovulation, and chronic progesterone deficiency. In postmenopausal women, estrogens are synthesized in body fats from adrenal and ovarian androgen precursors. Because of its effect on insulin-like growth factor-1 (IGF-1) and its binding protein, obesity can be a risk factor even when circulating levels of estrogen are normal. Estrogen receptor transcriptional activity can be induced by IGF-1 signaling even in the absence of estrogen.

**Remember** Eileen, the 19-year-old woman who presented for contraception? Eileen has multiple risk factors for the development of endometrial cancer. For instance, she is overweight and has a family history of hypertension. She also is in danger of developing type 2 diabetes mellitus, based on her family history and elevated blood levels of both glucose and insulin. Overweight, hypertension, and diabetes mellitus are all risk factors that can be addressed by weight loss. Eileen needs to decrease her risk of endometrial cancer by losing some weight and changing to a low-fat diet.

A second subset of endometrial cancers (about 10%) are high-grade tumors with a tendency to recur, even in early stages. These tumors, also known as type 2 endometrial cancers, are not estrogen driven, typically occur in women who acquire the disease at a somewhat older age, and are mostly associated with endometrial atrophy rather than hyperplasia. Overall, this type of endometrial cancer usually has a poorer prognosis than that associated with prolonged estrogen stimulation and endometrial hyperplasia.

**Clinical Manifestations.** The major symptom of endometrial hyperplasia or overt endometrial cancer is abnormal, painless bleeding. In menstruating women, this takes the form of bleeding between periods or excessive, prolonged menstrual flow. In postmenopausal women, any bleeding is abnormal and warrants investigation. Abnormal bleeding is an early warning sign of the disease, and because endometrial cancer tends to be slow growing in its early stages, the chances of cure are good if prompt medical care is sought. Later signs of endometrial cancer may include cramping, pelvic discomfort, postcoital bleeding, lower abdominal pressure, and enlarged lymph nodes.

**Diagnosis and Treatment.** Although the Pap smear can identify a small percentage of endometrial cancers, it is not a good screening test for this type of gynecologic cancer. Endometrial biopsy (tissue sample obtained in an office procedure by direct aspiration of the endometrial cavity) is far more accurate. Dilation and curettage (D&C), which consists of dilating the cervix and scraping the uterine cavity, is the definitive procedure for diagnosis because it provides a more thorough evaluation. Transvaginal ultrasonography (TVS) used to measure the endometrial thickness is being evaluated as an initial test for postmenopausal bleeding because it is less invasive than endometrial biopsy and less costly than D&C when biopsy is not possible.

The prognosis for endometrial cancer depends on the clinical stage of the disease when it is discovered and its histologic grade and type. Surgery and radiation therapy are the most successful methods of treatment for endometrial cancer. When used alone, radiation therapy has a 20% lower cure rate than surgery for stage I disease. It may be the best option, however, in women who are not good surgical candidates. Total abdominal hysterectomy with bilateral salpingo-oophorectomy plus sampling of regional lymph nodes and peritoneal washings for cytologic evaluation of occult disease is the treatment of choice whenever possible. Postoperative radiation therapy may be added in cases of advanced disease for more complete treatment and to prevent recurrence or metastasis, although the benefits of this as adjuvant therapy are still controversial. The 5-year relative survival rates of early-diagnosed endometrial cancers are 96%. The survival rate for all endometrial cancers (those diagnosed early and late stage) is 83%.

**Leiomyomas**

Uterine leiomyomas (commonly called fibroids) are benign neoplasms of smooth muscle origin. These are the most common form of pelvic tumor and are believed to occur in one of every four or five women older than 35 years of age. They are seen more often and their rate of growth is more rapid in black women than in white women. Leiomyomas usually develop as submucosal, subserosal, or intramural tumors in the corpus of the uterus (Fig. 54.6). Intramural fibroids are embedded in the myometrium. They are the most common type of fibroid, and present as a symmetric enlargement of the nonpregnant uterus. Subserosal tumors are located beneath the perimetrium of the uterus. These tumors are recognized as irregular projections on the uterine surface. They may become pedunculated, displacing or impinging on other genitourinary structures and causing hydroureter or bladder problems. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types.

Leiomyomas are asymptomatic approximately half of the time and may be discovered during a routine pelvic examination, or they may cause menorrhagia (excessive menstrual bleeding), anemia, urinary frequency, rectal pressure/constipation, abdominal distention, and, infrequently pain. Their rate of growth is variable, but they may increase in size during pregnancy or with exogenous estrogen stimulation (i.e., oral
contraceptives or menopausal estrogen replacement therapy). Interference with pregnancy is rare unless the tumor is submucosal and interferes with implantation or obstructs the cervical outlet. These tumors may outgrow their blood supply, become infarcted, and undergo degenerative changes.

Most leiomyomas regress with menopause, but if bleeding, pressure on the bladder, pain, or other problems persist, hysterectomy may be required. Myomectomy (removal of just the tumors) can be done to preserve the uterus for future childbearing. Cesarean section is recommended if the uterine cavity is entered during myomectomy. Hypothalamic GnRH agonists (e.g., leuprolide) may be used to suppress leiomyoma growth before surgery. Data suggests uterine artery embolization is a nonsurgical therapy that has demonstrated short-term advantages, but generated higher frequency of reintervention over surgery.41

**IN SUMMARY**

Disorders of the cervix and uterus include inflammatory conditions (*i.e.*, cervicitis and endometritis), cancer (*i.e.*, cervical and endometrial cancer), endometriosis, and leiomyomas. Cervicitis is an acute or chronic inflammation of the cervix. Acute cervicitis may result from the direct infection of the cervix or may be secondary to a vaginal or uterine infection. It may be caused by a variety of infectious agents. Chronic cervicitis represents a low-grade inflammatory process resulting from trauma or nonspecific infectious agents. Cervical cancer arises from precursor lesions that can be detected on a Pap smear, and, if detected early, is the most easily cured of all the cancers of the female reproductive system. Evidence suggests a causal link between HPV infection and cervical cancer. Vaccines against several strains of the HPV are available and show promise for the prevention of cervical cancer.

Endometriosis represents an ill-defined inflammation or infection of the endometrium that produces variable symptoms. Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus, particularly in dependent parts of the pelvis and in the ovaries. It causes dysmenorrhea, dyspareunia, and infertility. Adenomyosis is the condition in which endometrial glands and stroma are found in the myometrium, interspersed between the smooth muscle fibers. Endometrial cancer is the most common cancer found in the female pelvis, occurring more than twice as often as cervical cancer. Prolonged estrogen stimulation with hyperplasia of the endometrium has been identified as a major risk factor for endometrial cancer.

Leiomyomas are benign uterine wall neoplasms of smooth muscle origin. They can develop in the corpus of the uterus and can be submucosal, subserosal, or intramural. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types.
Factors that predispose women to the development of PID include an age of 16 to 24 years, nulliparity, history of multiple sexual partners, and previous history of PID. Although the use of an IUD has been associated with a three- to fivefold increased risk for development of PID, studies have shown that women with only one sexual partner who are at low risk of acquiring STIs have no significant risk for development of PID from using an IUD.

**Clinical Manifestations**

The symptoms of PID include lower abdominal pain, which may start just after a menstrual period; dyspareunia; back pain; purulent cervical discharge; and the presence of adnexal tenderness and exquisitely painful cervix on bimanual pelvic examination. Fever (>101°F), increased erythrocyte sedimentation rate, and an elevated white blood cell count (>10,000 cells/mL) commonly are seen, even though the woman may not appear acutely ill. Elevated C-reactive protein levels equate with inflammation and can be used as another diagnostic tool.

**Diagnosis and Treatment**

Laparoscopy, which allows for direct visualization of the ovaries, fallopian tubes, and uterus, is one of the most specific procedures for diagnosing PID, but is costly and carries the inherent risks of surgery and anesthesia. Minimal criteria for a presumptive diagnosis of PID require the presence of lower abdominal pain, adnexal tenderness, and cervical motion tenderness on bimanual examination with no other apparent cause.

Outpatient antibiotic therapy is usually sufficient. However, treatment may involve hospitalization with intravenous

**Pelvic Inflammatory Disease**

PID is a polymicrobial infection of the upper reproductive tract (uterus, fallopian tubes, or ovaries) associated with the sexually transmitted organisms such as *N. gonorrhoeae* or *C. trachomatis* as well as endogenous organisms, including anaerobes, such as *Haemophilus influenzae*, enteric gram-negative rods, and streptococci. The organisms ascend through the endocervical canal to the endometrial cavity, and then to the tubes and ovaries. The endocervical canal is slightly dilated during menstruation, allowing bacteria to gain entrance to the uterus and other pelvic structures. After entering the upper reproductive tract, the organisms multiply rapidly in the favorable environment of the sloughing endometrium and ascend to the fallopian tube (Fig. 54.7).

**FIGURE 54.7** Pelvic inflammatory disease. Microbial agents enter through the vagina and ascend to involve the uterus, fallopian tubes, and pelvic structures.
administration of antibiotics in some cases. Antibiotic regimens should be selected according to STI treatment guidelines, which are published every 4 years by the Centers for Disease Control and Prevention (CDC). Treatment is aimed at preventing complications, which can include pelvic adhesions, infertility, ectopic pregnancy, chronic abdominal pain, and tubo-ovarian abscesses. Accurate diagnosis and appropriate antibiotic therapy may decrease the severity and frequency of PID sequelae. The CDC recommends empiric treatment with a presumptive diagnosis of PID, while waiting for confirmation by culture or other definitive test results.

**Ectopic Pregnancy**

Although pregnancy is not discussed in detail in this text, it is reasonable to mention ectopic pregnancy because it represents a true gynecologic emergency and should be considered when a woman of reproductive age presents with the complaint of pelvic pain. Ectopic pregnancy occurs when a fertilized ovum implants outside the uterine cavity, the most common site being the fallopian tube (Fig. 54.8). Updated estimates for ectopic pregnancy incidence rates are difficult to determine because many women are now treated on an outpatient basis, so data from hospital discharge records are no longer representative of the scope of the problem. Although ectopic pregnancy is the leading cause of maternal mortality in the first trimester, the death rate has steadily declined as a result of improved diagnostic methods.

The cause of ectopic pregnancy is delayed ovum transport, which may result from decreased tubal motility or distorted tubal anatomy (i.e., narrowed lumen, convolutions, or diverticula). Risk factors most strongly associated with ectopic pregnancy include previous tubal surgery, tubal ligation or reversal, previous ectopic pregnancy, and a tubal lesion or abnormality. Smoking, current IUD use, history of PID or therapeutic abortion, and the use of fertility drugs to induce ovulation have also been associated with an increased risk for ectopic pregnancy.

**Clinical Manifestations**

The site of implantation in the tube (e.g., isthmus, ampulla) may determine the onset of symptoms and the timing of diagnosis. As the tubal pregnancy progresses, the surrounding tissue is stretched. The pregnancy eventually outgrows its blood supply, at which point the pregnancy terminates or the tube itself ruptures because it can no longer contain the growing pregnancy.

Symptoms can include lower abdominal discomfort—diffuse or localized to one side—that progresses to severe pain caused by rupture, spotting, syncope, referred shoulder pain from bleeding into the abdominal cavity, and amenorrhea. Physical examination usually reveals adnexal tenderness; an adnexal mass is found in only about half of cases. Although rarely used today, culdocentesis (needle aspiration from the cul-de-sac) may reveal blood if rupture has occurred.

**Diagnosis and Treatment**

Diagnostic tests for ectopic pregnancy include a urine pregnancy test, ultrasonography, and β-human chorionic gonadotropin (hCG; a hormone produced by placental cells) levels. Serial hCG tests may detect lower than expected hCG rise. Transvaginal ultrasonographic studies after 5 weeks gestation may demonstrate an empty uterine cavity or presence of the gestational sac outside the uterus. In a comparison of various protocols for diagnosing ectopic pregnancy, ultrasonography followed by serial hCG levels was found to yield the best results. Definitive diagnosis may require laparoscopy. Differential diagnosis for this type of pelvic pain includes ruptured ovarian cyst, threatened or incomplete abortion, PID, acute appendicitis, and degenerating fibroid.

Treatment is aimed at resolving the problem with minimal morbidity and protecting future fertility where possible. Advances in detection now make it possible to treat early ectopic pregnancies medically with methotrexate to stop the pregnancy followed by serial hCG to be assured the ectopic pregnancy has been effectively treated. Surgical removal of the pregnancy is required when it is unlikely medical management will be effective (e.g., large ectopic pregnancy, presence of a fetal heart beat, noncompliance of the client), rupture is imminent or has already occurred, or when the woman is hemodynamically unstable. Laparoscopic treatment of ectopic pregnancy is well tolerated and more cost effective than laparotomy because of shorter convalescence and the reduced need for postoperative analgesia. Laparotomy, which involves an open incision into the abdominopelvic cavity, becomes necessary when there is uncontrolled internal bleeding, when the ectopic site cannot be visualized through the laparoscope, or when the surgeon is not trained in operative laparoscopy.

Methotrexate (an antimetabolite used in treatment of chronic inflammatory diseases and cancer) has been successfully used to eliminate residual ectopic pregnancy tissue after laparoscopy. More recently, it has been used as a primary treatment in cases where the pregnancy is diagnosed early and tubal rupture has not occurred, or when the pregnancy is not in a common location, such as when the pregnancy occurs in the cornua of the uterus or the cervix. This folic acid antagonist interferes...
with DNA and ribonucleic acid (RNA) synthesis, thus inhibiting
the growth of trophoblastic cells at the placental implantation
site. Adverse effects can include bone marrow depression, tran-
sient elevation of liver enzymes, anemia, and stomatitis.

Cancer of the Fallopian Tube
Although a common site of metastases, primary cancer of the fallopian tube is rare, accounting for less than 1% of all female genital tract cancers. Fewer than 3,000 cases have been reported worldwide. Most primary tubal cancers are papillary adenocarcinomas, and these tumors develop bilaterally in 30% of women with advanced disease.

Symptoms are uncommon, but intermittent serosanguine-
ous vaginal discharge, abnormal vaginal bleeding, and colicky
low abdominal pain have been reported. An adnexal mass may
be present. However, the preoperative diagnosis in most cases is
leiomyoma or ovarian tumor. Management is similar to that for
ovarian cancer and usually includes total hysterectomy, bilat-
eral salpingo-oophorectomy, and pelvic lymph node dissection.

Ovarian Cysts and Tumors
The ovaries have a dual function: they produce germ cells, or
ova, and they synthesize the female sex hormones. Disorders
of the ovaries frequently cause menstrual and fertility prob-
lems. Benign conditions of the ovaries can present as primary
lesions of the ovarian structures or as secondary disorders
related to hypothalamic, pituitary, or adrenal dysfunction.

Ovarian Cysts
Cysts are the most common form of ovarian tumor. Many are
benign. A follicular cyst is one that results from occlusion of
the duct of the follicle. Each month, several follicles begin to
develop and are blighted at various stages of development.
These follicles form cavities that fill with fluid, producing a
cyst. The dominant follicle normally ruptures to release the egg
(i.e., ovulation), but occasionally persists and continues grow-
ing. Likewise, a luteal cyst is a persistent cystic enlargement
of the corpus luteum that is formed after ovulation and does
not regress in the absence of pregnancy. Functional cysts are
asymptomatic unless there is substantial enlargement or bleed-
ing into the cyst. This can cause considerable discomfort or a
dull, aching sensation on the affected side. These cysts usually
regress spontaneously. Occasionally, a cyst may become twisted
or may rupture into the intra-abdominal cavity (Fig. 54.9).

Polycystic Ovary Syndrome
Polycystic ovary syndrome (PCOS) is a common endocrine
disorder affecting 5% to 10% of women of reproductive age,
and is a frequent source of chronic anovulation. The diagnosis
of PCOS is made after other endocrine diseases are ruled out
and the patient has some of the following symptoms:

- Oligomenorrhea (irregular infrequent periods)
- Signs of hyperandrogenism (acne, excess body hair
  [hirsutism])
- Elevated testosterone levels on blood testing
- Polycystic appearing ovaries in which there are numer-
  ous small cysts at the periphery of the ovary

Etiology and Pathogenesis. About 50% of women who are
diagnosed with PCOS are obese. Hyperinsulinemia and insu-
lin resistance are thought to play a role in the pathogenesis of
the disorder.

Remember Eileen, who was worked up for
PCOS. Her periods have been irregular (oligomen-
orrea) since age 11. She shows multiple signs of
hyperandrogenism, including hirsutism and acne, and she
has elevated blood levels of testosterone. Finally, the ultra-
sound reveals bilateral polycystic ovaries. Eileen thus meets
all of the criteria for PCOS, once related disorders are ruled
out. Eileen also has increased blood levels of both insulin
glucose, indicating that she is experiencing insulin
resistance, and she is overweight. Eileen’s hyperinsu-
linemia and insulin resistance are probably involved in the
development of her disease.

The precise etiology of PCOS is still being debated, but it is
probably multifactorial. A possible genetic basis has been sug-
gested with an autosomal dominant mode of inheritance. There
is increasing evidence that the disorder may begin before ado-
lescence and that many of the manifestations of PCOS begin to
make their appearance at that time. Because many of the symp-
toms common to PCOS, such as excess hair, acne, and obesity,
can be detrimental to a teenage girl’s health and self-esteem, early
detection and treatment of PCOS in adolescents is essential.
Unfortunately, Eileen was just diagnosed with PCOS at 19 years of age. Her irregular periods since menarche (age 11) suggest that she may have suffered from this disorder throughout her adolescence. Since PCOS is hereditary, Eileen’s younger female siblings and cousins should be evaluated for PCOS so that, if positive, they can benefit from early treatment and avoid some of the systemic pathologic problems experienced by Eileen.

Although this syndrome has been the subject of considerable research, the underlying mechanisms remain unclear. Chronic anovulation is thought to be the underlying cause of the amenorrhea or irregular menses and enlarged, “polycystic” ovaries associated with this condition. Most women with PCOS have elevated luteinizing hormone (LH) levels with normal estrogen and follicle-stimulating hormone (FSH) production. Elevated levels of circulating total testosterone, free testosterone, and dehydroepiandrosterone sulfate (DHEAS) are not uncommon, and these women occasionally have hyperprolactinemia or hypothyroidism. Persistent anovulation results in an estrogen environment that alters the hypothalamic release of GnRH with a resultant increase in LH secretion and suppression of FSH release by the pituitary gland. This altered LH/FSH ratio often is used as a diagnostic criterion for this condition, but it is not universally present. Although the presence of some FSH allows for new follicular development, full maturation is not attained, and ovulation does not occur. The elevated LH level results in increased androgen production, which in turn prevents normal follicular development and contributes to the vicious cycle of anovulation.45

Eileen cannot remember her last menstrual period, and she has hirsutism and acne. These problems are caused, at least partially, by excess testosterone activity (hyperandrogenism). Eileen’s hyperandrogenism results from excess LH production.

The association between hyperandrogenism and hyperinsulinemia is now well recognized.45–48 It has been shown that the cause of hyperinsulinemia is insulin resistance. The frequency and degree of hyperinsulinemia in women with PCOS is often amplified by the presence of obesity. Insulin may cause hyperandrogenism in several ways, although the exact mechanism has not been well defined. It has been shown that the ovary possesses insulin receptors and there is evidence that insulin may act directly on the ovary.47

In addition to its clinical manifestations, long-term health problems including cardiovascular disease and diabetes have been linked to PCOS. There is also concern that women with PCOS who are anovulatory do not produce progesterone. Although there is a reported association with breast, endometrial, and ovarian cancer, PCOS has not been conclusively shown to be an independent risk factor for any of these malignancies.

Diagnosis and Treatment. The diagnosis of PCOS can be suspected from the clinical presentation. Although there is no consensus as to which tests should be used, laboratory evaluation to exclude hyperprolactinemia, late-onset adrenal hyperplasia, and androgen-secreting tumors of the ovary and adrenal gland is commonly done. Although a fasting blood glucose, 2-hour oral glucose tolerance test, and insulin levels are often measured to evaluate for hyperinsulinemia, this testing is not required prior to treatment as insulin resistance is almost universal in women with PCOS. Confirmation with ultrasonography of the ovaries is often done, but not required.46

The overall goal of treatment should be directed toward symptom relief, prevention of potential malignant endometrial sequelae, and reduction in risk for development of diabetes and cardiovascular disease. The preferred and most effective treatment for PCOS is lifestyle modification. Weight loss may be beneficial in restoring normal ovulation when obesity is present. Although numerous medications and protocols are available, the choice depends on the manifestations that are most bothersome to the woman and her stage in reproductive life. Combined oral contraceptive agents ameliorate menstrual irregularities and improve hirsutism and acne.

Metformin, an insulin-sensitizing drug, used with or without ovulation-inducing medications, is emerging as an important component of PCOS treatment.49 In addition to expected improvements in insulin sensitivity and glucose metabolism, it has been associated with reductions in androgen and LH levels and is highly effective in restoring normal menstrual regularity and ovulatory cycles.

When fertility is desired, PCOS usually is treated by the administration of the hypothalamic–pituitary–stimulating drug clomiphene citrate or injectable gonadotropins to induce ovulation. These drugs must be used carefully because they can induce extreme enlargement of the ovaries.

Benign and Functioning/Endocrine Active Ovarian Tumors

Ovarian tumors are extremely common with most being benign. Ovarian tumors can arise from any of the ovarian tissue types—serosal epithelium, germ cell layers, or gonadal stroma tissue48 (Fig. 54.10).

Serous and mucinous cystadenomas are the most common benign ovarian neoplasms. Endometriomas are the “chocolate cysts” that develop secondary to ovarian endometriosis. Ovarian fibromas are connective tissue tumors composed of fibrocytes and collagen. They range in size from 6 to 20 cm. Cystic teratomas, or dermoid cysts, are derived
Treatment for all ovarian tumors is surgical excision. Ovarian tissue that is not affected by the tumor can be left intact if frozen-section analysis does not reveal malignancy. When ovarian tumors are very large, as is frequently the case with serous or mucinous cystadenomas, the entire ovary must be removed.

Ovarian Cancer
Ovarian cancer is the second most common female genitourinary cancer and the most lethal. The rate of ovarian cancer has decreased. However, in 2007, there were still an estimated 20,749 new cases of ovarian cancer in the United States, with 14,621 deaths. Ovarian cancer is difficult to diagnose, and up to 75% of women have metastatic disease before the time of discovery.

Risk Factors. The most significant risk factor for ovarian cancer appears to be ovulatory age—the length of time during a woman’s life when her ovarian cycle is not suppressed by

pregnancy, lactation, or oral contraceptive use. The incidence of ovarian cancer is much lower in countries where women bear numerous children. Family history also is a significant risk factor for ovarian cancer. Women with two or more first- or second-degree relatives who have had site-specific ovarian cancer have up to a 50% risk for development of the disease. There are two other types of inherited risk for ovarian cancer: breast-ovarian cancer syndrome, where both breast and ovarian cancer occur among first- and second-degree relatives, and family cancer syndrome or Lynch syndrome II (a subtype of hereditary nonpolyposis colon cancer), in which male or female relatives have a history of colorectal, endometrial, ovarian, pancreatic, or other types of cancer. The breast cancer susceptibility genes, BRCA1 and BRCA2, which are tumor suppressor genes, are incriminated in approximately 8%-to-10% of hereditary ovarian cancers despite being identified as “breast cancer genes.” Susceptibility to ovarian cancer is transmitted as an autosomal dominant characteristic. Therefore, a mutated gene from either parent is sufficient to cause the problem. A high-fat Western diet and use of powders containing talc in the genital area are other factors that have been linked to the development of ovarian cancer.

Prevention. Chemoprevention strategies that have been suggested include long-term oral contraceptive use, NSAIDs, acetaminophen, or retinoids (analogs of vitamin A). Each of these agents acts in slightly different ways. The NSAIDs are thought to exert their protective effects through growth inhibition and increased apoptosis (programmed cell death) of ovarian cancer cell lines. The structure of acetaminophen bears a similarity to the sex hormones, suggesting a potential sex steroid–antagonist property. Support for the use of retinoids comes from experimental data in which retinoic acid was shown to induce the differentiation of cultured ovarian cancer cells. Additional clinical trials are needed to support the effectiveness of these chemoprevention agents. Surgical strategies that have reduced the risk of developing ovarian cancer include prophylactic removal of both fallopian tubes and ovaries.

Types of Ovarian Cancer. Cancer of the ovary is a complex neoplasm because of the diversity of tissue types that originate in the ovary. As a result of this diversity, there are several types of ovarian cancers. Malignant neoplasms of the ovary can be divided into three categories: epithelial tumors, germ cell tumors, and gonadal stromal tumors (see Fig. 54.10). Epithelial tumors account for approximately 90% of cases.

Clinical Manifestations. The different types of ovarian cancers display various degrees of virulence, depending on the type of tumor and degree of differentiation involved. A well-differentiated cancer of the ovary may have produced symptoms for many months and still be found to be operable at the time of surgery. A poorly differentiated tumor may have been clinically evident for only a few days but be found to be widespread and inoperable. Often, no correlation exists between the duration of symptoms and the extent of the disease.

Ovarian cancer is often diagnosed at an advanced stage because many symptoms are nonspecific and therefore difficult to distinguish from other problems presenting to a primary care provider. Symptoms that are believed to have a strong correlation to ovarian cancer include abdominal or pelvic pain, increased abdominal size or bloating, and difficulty eating or feeling full quickly after ingesting food. Because these gastrointestinal manifestations can occur for a variety of reasons, many women self-treat with antacids and other remedies for a time before seeking treatment, and health care providers may dismiss the woman’s complaints as being caused by other conditions, further delaying diagnosis and treatment. Recent onset (<12 months) and frequent occurrence (>12 times per month) of these symptoms should increase the index of suspicion for ovarian cancer and suggest the need for further evaluation. It is not fully understood why the initial symptoms of ovarian cancer are manifested as gastrointestinal disturbances. It is thought that biochemical changes in the peritoneal fluids may irritate the bowel or that pain originating in the ovary may be referred to the abdomen and be interpreted as a gastrointestinal disturbance. Clinically evident ascites (i.e., fluid in the peritoneal cavity) is seen in approximately one fourth of women with malignant ovarian tumors and is associated with a worse prognosis.

Diagnosis and Treatment. No good screening tests or other early methods of detection exist for ovarian cancer. The serum tumor marker CA-125 is a cell surface antigen. Its level is elevated in 80% to 90% of women with stage II to IV nonmucinous ovarian epithelial cancers. The result is negative, however, for as many as 50% of women with stage I disease. In a postmenopausal woman with a pelvic mass, an elevated CA-125 has a positive predictive value of greater than 70% for cancer. It also can be used in monitoring therapy and recurrences when preoperative levels have been elevated. Despite its role in diagnostic evaluation and follow-up, CA-125 is not cancer or tissue specific for ovarian cancer. Levels also are elevated in the presence of endometriosis, uterine fibroids, pregnancy, liver disease, and other benign conditions and with cancers of the endometrium, cervix, fallopian tube, and pancreas. Because it lacks sensitivity and specificity, CA-125 has limited value as a single screening test.

TVS has been used to evaluate ovarian masses for malignant potential. Although TVS has demonstrated high sensitivity and specificity as a screening tool, cost precludes its use as universal screening method. Molecular biologic studies have identified tumor suppressor genes that may play a role in the cause of ovarian cancer. Further evaluation in this area is ongoing and may eventually lead to identification of appropriate screening techniques for ovarian cancer.

When ovarian cancer is suspected, surgical evaluation is required for diagnosis, complete and accurate staging, and cytoreduction and debulking procedures to reduce the size of the tumor. The most common surgery involves removal of the uterus, fallopian tubes, ovaries, and omentum. The liver, diaphragm, retroperitoneal and aortic lymph nodes,
and peritoneal surface are examined and biopsies are taken as needed. Cytologic washings are done to test for cancerous cells in the peritoneal fluid. Women with very early cancer who may wish to become pregnant will sometimes have only the affected ovary removed. Recommendations regarding treatment beyond surgery and prognosis depend on the stage of the disease. The lack of accurate screening tools and the resistant nature of ovarian cancers significantly affect the success of treatment and survival.

**IN SUMMARY**

PID is an inflammation of the upper reproductive tract that involves the uterus (endometritis), fallopian tubes (salpingitis), or ovaries (oophoritis). It is most commonly caused by *N. gonorrhoeae* or *C. trachomatis*. Accurate diagnosis and appropriate antibiotic therapy are aimed at preventing complications such as pelvic adhesions, infertility, ectopic pregnancy, chronic abdominal pain, and tubo-ovarian abscesses.

Ectopic pregnancy occurs when a fertilized ovum implants outside the uterine cavity; the most common site is the fallopian tube. Causes of ectopic pregnancy are delayed ovum transport resulting from complications of PID, therapeutic abortion, tubal ligation or tubal reversal, previous ectopic pregnancy, or other conditions such as use of fertility drugs to induce ovulation. It represents a true gynecologic emergency, often necessitating surgical intervention. Cancer of the fallopian tube is rare; the diagnosis is difficult, and the condition usually is well advanced when diagnosed.

Disorders of the ovaries include benign cysts, functioning ovarian tumors, and cancer of the ovary; they usually are asymptomatic unless there is substantial enlargement or bleeding into the cyst, or the cyst becomes twisted or ruptured. PCOS is characterized by anovulation with varying degrees of menstrual irregularity and infertility; hyperandrogenism with hirsutism, acne, male pattern of hair loss, and obesity; polycystic ovaries; and hyperinsulinemia with insulin resistance. Benign ovarian tumors consist of endometriomas (chocolate cysts that develop secondary to ovarian endometriosis), ovarian fibromas (connective tissue tumors composed of fibrocytes and collagen), and cystic teratomas or dermoid cysts (germ cell tumors composed of various combinations of ectodermal, mesodermal, and endodermal elements). Functioning ovarian tumors may be benign or malignant and are of three types: estrogen secreting, androgen secreting, and mixed estrogen–androgen secreting. Cancer of the ovary is the second most common female gynecotitary cancer and the most lethal. It can be divided into three categories: epithelial tumors, germ cell tumors, and gonadal stromal tumors. There are no effective screening methods for ovarian cancer, and often the disease is well advanced at the time of diagnosis.
FIGURE 54.11 • (A) Normal support of the uterus and vagina, (B) cystocele, (C) rectocele, and (D) uterine prolapse.

FIGURE 54.12 • Muscles of the pelvic floor (female perineum).
the urethra, rectum, and vagina cause an inherent weakness in the pelvic diaphragm. Congenital or acquired weakness of the pelvic diaphragm results in widening of these openings, particularly the vagina, with the possible herniation of pelvic viscera through the pelvic floor (i.e., prolapse).

Relaxation of the pelvic outlet usually comes about because of overstretching of the perineal supporting tissues during pregnancy and childbirth. Although the tissues are stretched only during these times, there may be no difficulty until later in life, such as in the fifth or sixth decade, when further loss of elasticity and muscle tone occurs. Even in a woman who has not borne children, the combination of aging and postmenopausal changes may give rise to problems related to relaxation of the pelvic support structures. The three most common conditions associated with this relaxation are cystocele, rectocele, and uterine prolapse. These may occur separately or together.

Cystocele
Cystocele is a herniation of the bladder into the vagina. It occurs when the normal muscle support for the bladder is weakened, and the bladder sags below the uterus. This causes the anterior vaginal wall to stretch and bulge downward, allowing the bladder to herniate into the vagina due to the force of gravity and pressures from coughing, lifting, or straining at stool (see Fig. 54.11B). The symptoms of cystocele include an annoying bearing-down sensation, difficulty in emptying the bladder, frequency and urgency of urination, and cystitis. Stress incontinence may occur at times of increased abdominal pressure, such as during squatting, straining, coughing, sneezing, laughing, or lifting.

Rectocele and Enterocele
Rectocele is the herniation of the rectum into the vagina. It occurs when the posterior vaginal wall and underlying rectum bulge forward, ultimately protruding through the introitus as the pelvic floor and perineal muscles are weakened. The symptoms include discomfort because of the protrusion of the rectum and difficulty in defecation (see Fig. 54.11C). Digital pressure (i.e., splinting) on the bulging posterior wall of the vagina may become necessary for defecation. The area between the uterosacral ligaments just posterior to the cervix may weaken and form a hernial sac into which the small bowel protrudes when the woman is standing. This defect, called an enterocele, may extend into the rectovaginal septum. It may be congenital or acquired through birth trauma. Enterocele can be asymptomatic or cause a dull, dragging sensation and, occasionally, low backache.

Uterine Prolapse
Uterine prolapse is the bulging of the uterus into the vagina that occurs when the primary supportive ligaments (i.e., cardinal ligaments) are stretched (Fig. 54.11D). Prolapse is ranked as first, second, or third degree, depending on how far the uterus protrudes through the introitus. First-degree prolapse shows some descent, but the cervix has not reached the introitus. In second-degree prolapse, the cervix or part of the uterus has passed through the introitus. The entire uterus protrudes through the vaginal opening in third-degree prolapse (i.e., procidentia).

The symptoms associated with uterine prolapse result from irritation of the exposed mucous membranes of the cervix and vagina and the discomfort of the protruding mass. Sometimes, the woman has incontinence along with discomfort from the pelvic floor prolapse. Evidence suggests there may be a connection with decreased collagen metabolism caused by defects in either collagen Type I or Type III. Prolapse often is accompanied by perineal relaxation, cystocele, or rectocele. Like cystocele, rectocele, and enterocele, it occurs most commonly in multiparous women because childbirth is accompanied by injuries to pelvic structures and uterine ligaments. It also may result from pelvic tumors and neurologic conditions, such as spina bifida and diabetic neuropathy, which interrupt the innervation of pelvic muscles. Generally, it is a benign condition but problems can arise with infection, obstruction, and skin irritation, sometimes leading to skin breakdown.

A pessary may be inserted to hold the uterus in place and may stave off surgical intervention in women who want to have children or in older women for whom the surgery may pose a significant health risk. A newer conservative approach to treatment involves use of a space-occupying device (Colpexin sphere) to elevate the prolapse while performing pelvic floor muscle contractions.

Treatment of Pelvic Support Disorders
Kegel exercises, which strengthen the pubococcygeus muscle, may be helpful in cases of mild cystocele or rectocele (or after surgical repair to help maintain the improved function).

However, most of the disorders of pelvic relaxation will eventually require surgical correction. Most commonly, surgery is elective and deferred until after the childbearing years, so only one repair will be necessary. Additionally, the symptoms associated with the disorders often are not severe enough to warrant surgical correction, so the risk/benefit ratio needs to carefully be considered. In other cases, the stress of surgery is contraindicated because of other physical disorders. This is particularly true of older women, in whom many of these disorders occur and other nonsurgical interventions may be successful.

There are a number of surgical procedures for the conditions that result from relaxation of pelvic support structures. Removal of the uterus through the vagina (vaginal hysterectomy) with appropriate repair of the vaginal wall (colporrhaphy) is often done when uterine prolapse is accompanied by cystocele or rectocele. A vesicourethral suspension may be done to alleviate the symptoms of stress incontinence. Repair may involve abdominal hysterectomy along with anteroposterior repair.

Variations in Uterine Position
Variations in the position of the uterus are common. Some variations are innocuous. Others, which may be the result of weakness and relaxation of the perineum, give rise to various problems that compromise the structural integrity of the pelvic floor, particularly after childbirth.
The uterus usually is flexed approximately 45 degrees anteriorly, with the cervix positioned posteriorly and downward in the anteverted position. When the woman is standing, the angle of the uterus is such that it lies practically horizontal, resting lightly on the bladder.

Asymptomatic, normal variations in the axis of the uterus in relation to the cervix and physiologic displacements that arise after pregnancy or with pathology of the cul-de-sac include anteflexion, retroflexion, and retroversion (Fig. 54.13). An anteflexed uterus is flexed forward on itself. Retroflexion is flexion backward at the isthmus. Retroversion describes the condition in which the uterus inclines posteriorly while the cervix remains tilted forward. Simple retroversion of the uterus is the most common displacement, found in 30% of normal women. It usually is a congenital condition caused by a short anterior vaginal wall and relaxed uterosacral ligaments; together, these force the uterus to fall back into the cul-de-sac. Retroversion also can follow certain diseases, such as endometriosis and PID, which produce fibrous tissue adherence with retraction of the fundus posteriorly. Large leiomyomas also may cause the uterus to move into a posterior position. Dyspareunia with deep penetration or low back pain with menses can also be associated with retroversion.

Alterations in pelvic support frequently occur because of weaknesses and relaxation of the pelvic floor and perineum. Cystocele and rectocele involve herniation of the bladder or rectum into the vagina. Uterine prolapse occurs when the uterus bulges into the vagina. Pelvic relaxation disorders typically result from overstrecthing of the perineal supporting muscles during pregnancy and childbirth. The loss of elasticity in these structures that is a normal accompaniment of aging contributes to these problems. Variations in uterine position include anteflexion, retroflexion, and retroversion. These disorders, which often are innocuous, can be the result of a congenital shortness of the vaginal wall, development of fibrous adhesions secondary to endometriosis or PID, or displacement caused by large uterine leiomyomas.

### Dysfunctional Menstrual Cycles

Although unexplained uterine bleeding can occur for many reasons, such as pregnancy, abortion, bleeding disorders, and neoplasms, the most frequent cause in the nonpregnant woman is what is commonly called dysfunctional menstrual cycles or bleeding. Dysfunctional cycles may take the form of amenorrhea (absence of menstruation), hypomenorrhea (scanty menstruation), oligomenorrhea (infrequent menstruation, periods more than 35 days apart), polymenorrhea (frequent menstruation, periods less than 21 days apart), menorrhagia (excessive menstruation), or metrorrhagia (bleeding between periods). Menometrorrhagia is heavy bleeding during and between menstrual periods.

### Etiology and Pathogenesis

Dysfunctional menstrual cycles are related to alterations in the hormones that support normal cyclic endometrial changes. Estrogen deprivation causes retrogression of a previously built-up endometrium and bleeding. Such bleeding often is irregular in amount and duration, with the flow varying with the time and degree of estrogen stimulation and with the degree of estrogen withdrawal. A lack of progesterone can cause abnormal menstrual bleeding. In its absence, estrogen induces development of a much thicker endometrial layer with a richer blood supply. The absence of progesterone results from the failure of any of the developing ovarian follicles to mature to the point of ovulation, with the subsequent formation of the corpus luteum and production and secretion of progesterone.

Periodic bleeding episodes alternating with amenorrhea are caused by variations in the number of functioning ovarian

---

**IN SUMMARY**

Alterations in pelvic support frequently occur because of weaknesses and relaxation of the pelvic floor and perineum. Cystocele and rectocele involve herniation of the bladder or rectum into the vagina. Uterine prolapse occurs when the uterus bulges into the vagina. Pelvic relaxation disorders typically result from overstrecthing of the perineal supporting muscles during pregnancy and childbirth. The loss of elasticity in these structures that is a normal accompaniment of aging contributes to these problems. Variations in uterine position include anteflexion, retroflexion, and retroversion. These disorders, which often are innocuous, can be the result of a congenital shortness of the vaginal wall, development of fibrous adhesions secondary to endometriosis or PID, or displacement caused by large uterine leiomyomas.
follicles present. If sufficient follicles are present and active and if new follicles assume functional capacity, high levels of estrogen develop, causing the endometrium to proliferate for weeks or even months. In time, estrogen withdrawal and bleeding develop. This can occur for two reasons: an absolute estrogen deficiency may develop when several follicles simultaneously degenerate, or a relative deficiency may develop as the needs of the enlarged endometrial tissue mass exceed the capabilities of the existing follicles, even though estrogen levels remain constant. Estrogen and progesterone deficiencies are associated with the absence of ovulation, hence the term anovulatory bleeding. Because the vasoconstriction and myometrial contractions that normally accompany menstruation are caused by progesterone, anovulatory bleeding seldom is accompanied by cramps, and the flow frequently is heavy. Anovulatory cycles are common among adolescents during the first several years after menarche, when ovarian function is becoming established, among perimenopausal women whose ovarian function is beginning to decline, and, commonly, in obese women with PCOS.

Dysfunctional menstrual cycles can originate as a primary disorder of the ovaries or as a secondary deficit in ovarian function related to hypothalamic–pituitary stimulation. The latter can be initiated by emotional stress, marked variation in weight (i.e., sudden gain or loss), or nonspecific endocrine or metabolic disturbances. Nonhormonal causes of irregular menstrual bleeding include endometrial polyps, submucosal myoma (i.e., fibroid), bleeding disorder (e.g., von Willebrand disease, platelet dysfunction), infection, endometrial cancer, and pregnancy.

Treatment

The treatment of dysfunctional bleeding depends on what is identified as the probable cause. The minimum evaluation should include a detailed history with emphasis on bleeding pattern and a physical examination. Endocrine studies (e.g., FSH/LH ratio, prolactin, testosterone, DHEAS levels), β-hCG pregnancy test, ultrasonography of the endometrium, endometrial biopsy, D&C with or without hysteroscopy, and progesterone withdrawal tests may be needed for diagnosis. Nonhormonal causes generally require surgical intervention. D&C can be therapeutic as well as diagnostic. Endometrial ablation (thinning or elimination of the basal layer of the endometrium from which the monthly buildup generates) has become a primary treatment strategy for heavy bleeding. It can be accomplished using heat, cold, microwave, chemicals, or radiofrequency energy sources. If nonhormonal problems have been excluded and alterations in hormone levels are the primary cause, treatment may include the use of oral contraceptives, cyclic progesterone therapy, or long-acting progesterone via injection or an IUD.

Amenorrhea

There are two types of amenorrhea: primary and secondary. Primary amenorrhea is the failure to menstruate by 15 years of age, or by 13 years of age if failure to menstruate is accompanied by absence of secondary sex characteristics. Secondary amenorrhea is the cessation of menses for at least 6 months in a woman who has established normal menstrual cycles.

Etiology

Primary amenorrhea usually is caused by gonadal dysgenesis, congenital müllerian agenesis, testicular feminization, or a hypothalamic–pituitary–ovarian axis disorder. Causes of secondary amenorrhea include pregnancy; ovarian, pituitary, or hypothalamic dysfunction; intrauterine adhesions; infections (e.g., tuberculosis, syphilis); pituitary tumor; anorexia nervosa; or strenuous physical exercise, which can alter the critical body fat–muscle ratio needed for menses to occur.

Diagnosis and Treatment

Diagnostic evaluation resembles that for dysfunctional uterine bleeding, with the possible addition of a computed tomographic scan or MRI to exclude a pituitary tumor. Treatment is based on correcting the underlying cause and inducing menstruation with cyclic progesterone or combined estrogen–progesterone regimens.

Dysmenorrhea

Dysmenorrhea is pain or discomfort with menstruation. Although not usually a serious medical problem, it causes some degree of monthly disability for a significant number of women. There are two forms of dysmenorrhea: primary and secondary. Primary dysmenorrhea is menstrual pain that is not associated with a physical abnormality or pathologic process. It usually occurs with ovulatory menstruation beginning 6 months to 2 years after menarche. Symptoms may begin 1 to 2 days before menses, peak on the first day of flow, and subside within several hours to several days. Severe dysmenorrhea may be associated with systemic symptoms such as headache, nausea, vomiting, diarrhea, fatigue, irritability, dizziness, and syncope. The pain typically is described as dull, lower abdominal aching or cramping, spasmodic or colicky in nature, often radiating to the lower back, labia majora, or upper thighs.

Secondary dysmenorrhea is menstrual pain caused by specific organic conditions, such as endometriosis, uterine fibroids, adenomyosis, pelvic adhesions, IUDs, or PID. Laparoscopy often is required for diagnosis of secondary dysmenorrhea if medication for primary dysmenorrhea is ineffective.

Treatment for primary dysmenorrhea is directed at symptom control. Although analgesic agents such as aspirin and
acetaminophen may relieve minor uterine cramping or low back pain, prostaglandin synthetase inhibitors (e.g., ibuprofen, naproxen, meneamic acid, indomethacin) are more specific for dysmenorrhea and the treatment of choice if contraception is not desired. Ovulation suppression and symptomatic relief of dysmenorrhea can be instituted simultaneously with the use of oral contraceptives. Relief of secondary dysmenorrhea depends on identifying the cause of the problem. Medical or surgical intervention may be needed to eliminate the problem.

Premenstrual Symptom Disorders

According to surveys, 80% of women experience some type of premenstrual emotional or physical changes. In addition, 20% of the adult female population indicate that these mild to moderate monthly symptoms cause some difficulty, sometimes enough difficulty to present for medical assistance in treating.60 Exactly how many of these women have symptoms that are severe enough to warrant treatment is unknown due to the multiple symptoms associated with PMS.51

There exists a spectrum of premenstrual symptom disorders, ranging from mild to severe. These disorders include:

- **Premenstrual moliina (mild)**
- **Premenstrual syndrome (PMS)**, which is characterized by mild to moderate physical and psychological symptoms limited to 3 to 14 days preceding menstruation and relieved by onset of the menses
- **Premenstrual dysphoric disorder (PMDD)**, which is the most severe form of premenstrual distress and generally is associated with mood disorders.

The incidence of PMS seems to increase with age. It is less common in women in their teens and twenties. Most of the women seeking help for the problem are in their mid-thirties. The disorder is not culturally distinct; it affects both Westerners and non-Westerners. There is some dispute about whether PMS occurs more frequently in women who have had children or in those who have not.

Etiology

Although the causes of PMS are poorly documented, they probably are multifactorial. Like dysmenorrhea, it is only recently that PMS has been recognized as a bona fide disorder rather than merely a psychosomatic illness. There has been a tendency to link the disorder with endocrine imbalances such as hyperprolactinemia, estrogen excess, and alteration in the estrogen–progesterone ratio. Prolactin concentration affects sodium and water retention, is higher in the luteal phase than in the follicular phase, and can be increased by estrogens, stress, hypoglycemia, pregnancy, and oral contraceptives. Estrogens stimulate anxiety and nervous tension, and increased progesterone levels may produce depression. The role of hormonal factors in the cause of PMS is supported by two well-established phenomena. First, women who have undergone a hysterectomy but not an oophorectomy may have cyclic symptoms that resemble PMS. Second, PMS symptoms are rare in postmenopausal women. Research has failed, however, to confirm these theories.

Other hypotheses suggest that increased aldosterone may contribute to symptoms associated with fluid retention (e.g., headache, bloating, breast tenderness, weight gain); that pyridoxine (vitamin B6) deficiency may lead to estrogen excess or decreased production of the neurotransmitters dopamine and serotonin, which may contribute to PMS symptoms; or that decreased prostaglandin E concentrations can lead to abnormal sensitivity to prolactin, with associated fluid retention, irritability, and depression. In addition, increased appetite, binge eating, fatigue, and depression have been associated with altered endorphin activity and subclinical hypoglycemia. Learned beliefs about menstruation may also contribute to the development of PMS or at least affect the woman’s response to the symptoms.

The most recent theory to emerge suggests a relationship between normal gonadal fluctuations and central neurotransmitter activity, particularly serotonin. There is confusion as to whether decreased levels of serotonin are present during the luteal phase, and only susceptible women respond with varying degrees of premenstrual symptoms, or if women with PMDD have a neurotransmitter abnormality.50-63

Clinical Manifestations

Physical symptoms of PMS include painful and swollen breasts, bloating, abdominal pain, headache, and backache. Psychologically, there may be depression, anxiety, irritability, and behavioral changes. In some cases, there are puzzling alterations in motor function, such as clumsiness and altered handwriting. Women with PMS may report one or several symptoms, with symptoms varying from woman to woman and from month to month in the same woman.61,62 Signs and symptoms associated with this disorder are summarized in Table 54.1. PMS can significantly affect a woman’s ability to perform at normal levels.

Diagnosis

A complete history and physical examination are necessary to exclude other physical causes of the symptoms. Depending on the symptom pattern, blood studies, including thyroid hormones, glucose, and prolactin assays, may be done. Psychosocial evaluation is helpful to exclude emotional illness that is merely exacerbated premenstrually. The American College of Obstetricians and Gynecologists (ACOG) published clinical management guidelines for PMS that included diagnostic criteria similar to what the American Psychiatric Association did for PMDD in the DSM-IV.64 Diagnosis focuses on identification of symptoms by means of a daily calendar on which the woman records her symptoms for 2 to 3 consecutive months. Although validated tools are available for recording symptoms, any calendar used for this purpose should include information regarding specific symptoms, severity, timing in relation to the menstrual cycle, and baseline level of symptoms in the follicular phase.64 PMDD is a psychiatric diagnosis that has been developed to distinguish those women whose symptoms are severe enough to interfere significantly with activities of daily living. It requires prospective symptom charting, and a minimum of 5 of the 11 symptom groups as described in the fourth edition of the Diagnostic and
Statistical Manual of Mental Disorders (DSM-IV) to establish a diagnosis of PMDD. Presence of a single symptom is sufficient for the diagnosis of PMS.64

**Treatment**

Management of PMS/PMDD has been largely symptomatic and includes education and support directed toward lifestyle changes for women with mild symptoms. Treatment includes diuretics to reduce fluid retention, analgesics for pain, and anxiolytic drugs to treat mood changes. An integrated program of personal assessment by diary, regular exercise, avoidance of caffeine, and a diet low in simple sugars and high in lean proteins is often beneficial. Additional therapeutic regimens that have been used include vitamin or mineral supplements (particularly pyridoxine, vitamin E, and magnesium), evening primrose oil (which contains linoleic acid, a precursor of prostaglandin E1), natural progesterone supplements, low-dose oral monophasic contraceptives, GnRH agonists, bromocriptine for prolactin suppression, danazol (a synthetic androgen), and spironolactone (an aldosterone antagonist and inhibitor of adrenal androgen synthesis).65 Although a body of knowledge has evolved that offers a variety of therapeutic choices, few treatments have been adequately evaluated in randomized, controlled clinical trials. The SSRI antidepressants, however, have demonstrated significant improvement in overall symptoms compared with placebo, whether used continuously or only in the luteal phase, and are recommended by ACOG as first-line therapy for severe PMS or PMDD.64,65

### IN SUMMARY

Menstrual disorders include dysfunctional menstrual cycles, dysmenorrhea, and PMS. Dysfunctional menstrual cycles, which involve amenorrhea, oligomenorrhea, metrorrhagia, or menorrhagia, occur when the hormonal support of the endometrium is altered. Estrogen deprivation causes retrogression of a previously built-up endometrium and bleeding. A lack of progesterone can cause abnormal menstrual bleeding; in its absence, estrogen induces development of a much thicker endometrial layer with a richer blood supply. The absence of progesterone results from the failure of any of the developing ovarian follicles to mature to the point of ovulation, with subsequent formation of the corpus luteum and production of progesterone.

Dysmenorrhea is characterized by pain or discomfort during menses. It can occur as a primary or secondary disorder. Primary dysmenorrhea is not associated with other disorders and begins soon after menarche. Secondary dysmenorrhea is caused by a specific organic condition, such as endometriosis or pelvic adhesions. It occurs in women with previously painless menses.

Premenstrual symptom disorders represent a spectrum from molimina, which is present to some degree in most ovulatory women, to PMS and PMDD. PMS represents a cluster of physical and psychological symptoms that precede menstruation by 1 to 2 weeks. PMDD describes the most severe, disabling form of PMS. The true incidence and nature of PMS has been recognized only recently, and its cause and methods for treatment are still under study.

### DISORDERS OF THE BREAST

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe changes in breast function that occur with galactorrhea, mastitis, and ductal ectasia.
- Describe the methods used in the diagnosis and treatment of breast cancer.

Most breast disease may be described as either benign or cancerous. Breast tissue is never static; the breast is constantly...
responding to changes in hormonal, nutritional, psychological, and environmental stimuli that cause continual cellular changes. Benign breast conditions are nonprogressive. However, some forms of benign disease increase the risk of malignant disease. In light of this, strict adherence to a dichotomy of benign versus malignant disease may not always be appropriate. However, is useful for the sake of simplicity and clarity.

**Galactorrhea**

*Galactorrhea* is the secretion of breast milk in a nonlactating breast. Galactorrhea may result from vigorous nipple stimulation, exogenous hormones, internal hormonal imbalance, or local chest infection or trauma. A pituitary tumor, such as a prolactinoma, may produce large amounts of prolactin and cause galactorrhea. Galactorrhea occurs in men and women and usually is benign. Observation may be continued for several months before diagnostic hormonal screening. Spontaneous leaking from the breast (occurring without any type of stimulation) is pathologic and warrants a complete workup.66

**Mastitis**

Mastitis is inflammation of the breast. It most frequently occurs during lactation but may also result from other conditions. In the lactating woman, inflammation results from an ascending infection that travels from the nipple to the ductile structures. The most common organisms isolated are *Staphylococcus*. The offending organisms originate from the suckling infant’s nasopharynx or the mother’s hands. During the early weeks of nursing, the breast is particularly vulnerable to bacterial invasion because of minor cracks and fissures that occur with vigorous suckling. Infection and inflammation cause obstruction of the ductile system. The breast area becomes hard, inflamed, and tender if not treated early. Without treatment, the area becomes walled off and may abscess, requiring incision and drainage. It is advisable for the mother to continue breast-feeding during antibiotic therapy to prevent this.

Mastitis is not confined to the postpartum period; it can occur as a result of hormonal fluctuations, tumors, trauma, or skin infection. Cyclical inflammation of the breast occurs most frequently in adolescents, who commonly have fluctuating hormone levels. Tumors may cause mastitis secondary to skin involvement or lymphatic obstruction. Local trauma or infection may develop into mastitis because of ductal blockage of trapped blood, cellular debris, or the extension of superficial inflammation. Treatment for mastitis symptoms includes application of heat or cold, excision, aspiration, mild analgesics, antibiotics, and a supportive brassiere or breast binder.

**Ductal Disorders**

Ductal ectasia manifests in older women as a spontaneous, intermittent, usually unilateral, grayish-green nipple discharge. Palpation of the breast increases the discharge. Ectasia occurs during or after menopause and is symptomatically associated with burning, itching, pain, and a pulling sensation of the nipple and areola. The disease results in inflammation of the ducts and subsequent thickening. The treatment requires removal of the involved ductal mass.

Intraductal papillomas are benign epithelial tissue tumors that range in size from 2 mm to 5 cm. Papillomas usually manifest with a bloody nipple discharge. The tumor may be palpated in the areolar area. *Galactography*, a radiograph taken after dye is injected into the affected duct, is used for diagnosis. The papilloma is probed through the nipple, and the involved duct is removed.

**Fibroadenoma and Fibrocystic Changes**

Fibroadenomas are seen in premenopausal women, most commonly in the third and fourth decades. The clinical findings include a firm, rubbery, sharply defined round mass. On palpation, the mass “slides” between the fingers and is easily movable. These masses usually are singular; only 15% are multiple or bilateral. Fibroadenomas are asymptomatic and usually found by accident. They are not thought to be precancerous. Treatment involves simple excision.

*Fibrocystic changes* are the most frequent lesion of the breast. These changes are most common in women between 20 and 50 years of age and are rare in postmenopausal women not receiving hormone replacement. Fibrocystic changes usually present as nodular (i.e., “shotty”), granular breast masses that are more prominent and painful during the luteal or progesterone-dominant portion of the menstrual cycle. Discomfort ranges from heaviness to exquisite tenderness, depending on the degree of vascular engorgement and cystic distention.

Fibrocystic changes encompass a wide variety of lesions and breast changes. Microscopically, fibrocystic changes refer to a constellation of morphologic changes manifested by (1) microscopic cysts, (2) apocrine metaplasia, (3) mild epithelial hyperplasia, and (4) increase in fibrous stroma. Although fibrocystic changes have been thought to increase the risk of breast cancer, only certain variants in which proliferation of the epithelial components is demonstrated represent a true risk. Presence of large cysts and proliferative epithelial lesions with atypia are more common in women who are at increased risk for invasive breast cancer. The nonproliferative form of fibrocystic changes, which does not carry an increased risk for development of cancer, is more common.

Diagnosis of fibrocystic changes is made by physical examination, mammography, ultrasonography, and biopsy (i.e., aspiration or tissue sample). The use of mammography for diagnosis in high-risk groups of women younger than 35 years of age on a routine basis remains controversial. Mammography may be helpful in establishing the diagnosis, but increased breast tissue density in women with fibrocystic changes may make an abnormal or cancerous mass difficult to discern among the other structures and requires MRI. Ultrasonography is useful in differentiating a cystic from a solid mass. Because a mass caused by fibrocystic changes may be indistinguishable from carcinoma on the basis of
clinical findings, suspect lesions should undergo biopsy. Fine-needle aspiration may be used, but if a suspect mass that was nonmalignant on cytologic examination does not resolve over several months, it should be removed surgically. Any discrete mass or lump on the breast should be viewed as possible carcinoma, and cancer should be excluded before instituting the conservative measures used to treat fibrocystic changes.

Treatment for fibrocystic changes is usually symptomatic. Mild analgesics (e.g., aspirin, acetaminophen, or NSAIDs), and local application of heat or cold may be used for pain relief. Prominent or persistent cysts may be aspirated and any fluid obtained sent to the laboratory for cytologic analysis.

Breast Cancer

Cancer of the breast is the most common female cancer. One in eight women in the United States will have breast cancer in her lifetime. In 2011, invasive breast cancer affected an estimated 230,480 American women and killed an estimated 39,520 women. Although the breast cancer mortality rate has shown a slight decline, it is second only to lung cancer as a cause of cancer-related deaths in women. An additional 57,650 American women were diagnosed with cancer in situ or precancer. Incidence rates for carcinoma in situ have increased dramatically since the mid-1970s because of recommendations regarding mammography screening. Death rates have decreased, particularly in women younger than 50 years of age. The decline in the breast cancer mortality rate since 1989 is due to earlier diagnosis through screening programs and increased awareness, as well as improvements in cancer treatments.

Risk Factors

Risk factors for breast cancer include sex, increasing age, personal or family history of breast cancer (i.e., at highest risk are those with multiple affected first-order relatives), history of benign breast disease (i.e., primary “atypical” hyperplasia), and hormonal influences that promote breast maturation and may increase the chance of cell mutation (i.e., early menarche, late menopause, no term pregnancies or first child after 30 years of age, and no breast feeding). Modifiable risk factors include obesity (particularly after menopause), physical inactivity, and alcohol intake greater than one drink per day. However, most women with breast cancer have no identifiable risk factors.

Approximately, 5% to 10% of all breast cancers are hereditary, with genetic mutations causing up to 80% of breast cancers in women younger than 50 years of age. Two breast cancer susceptibility genes—BRCA1 on chromosome 17 and BRCA2 on chromosome 13—may account for most inherited forms of breast cancer. BRCA1 is known to be involved in tumor suppression. A woman with known mutations in BRCA1 has a lifetime risk of 60% to 85% for breast cancer and an increased risk of ovarian cancer. BRCA2 is another susceptibility gene that carries an elevated cancer risk similar to that with BRCA1. Guidelines have been established for when genetic counseling and testing should be offered. Breast cancer risk reduction options available to known carriers of BRCA1 and BRCA2 mutations include surveillance, chemoprevention, and surgery. Breast evaluation using MRI is generally preferred over standard mammography for these women because of its enhanced sensitivity and lack of radiation exposure, which may be safer for them. Prophylactic surgery, in the form of bilateral mastectomy, bilateral oophorectomy, or both, has been shown to decrease the risk of developing cancer. These controversial surgeries can have physical and psychological side effects that warrant careful consideration before proceeding. The use of aromatase inhibitors for prevention of breast cancer in women with + BRCA1 and/or 2 gene mutations is dependent on the type of breast cancer.

Detection

Cancer of the breast may manifest clinically as a mass, a puckering, nipple retraction, or unusual discharge. Many cancers are found by women themselves—sometimes when only a thickening or subtle change in breast contour is noticed. The variety of symptoms and potential for self-discovery underscore the need for all women to have an awareness of what their normal breast appearance and texture are like. The American Cancer Society has dropped its recommendation that all women perform regular, systematic self-examination. Research has indicated that most women who discover their own cancer do so outside of a scheduled breast self-examination (BSE). American Cancer Society screening guidelines now place primary emphasis for breast cancer diagnosis on mammography and the clinical breast examination, while encouraging women in the area of self-awareness. Premenopausal women who do perform BSE should conduct the examination right after menses. This time is most appropriate in relation to cyclic breast changes that occur in response to fluctuations in hormone levels. Postmenopausal women and women who have had a hysterectomy can perform the examination any day of the month. Examination may be done in the shower or bath or at bedtime. The most important aspect of BSE is to devise a systematic, convenient, and consistent method of examination. Women should have a clinical examination by a trained health professional at least every 3 years between 20 and 40 years of age, and annually after 40 years of age.

Mammography is the only effective screening technique for the early detection of clinically inapparent lesions. A generally slow-growing form of cancer, breast cancer may have been present for 2 to 9 years before it reaches 1 cm, the smallest mass normally detected by palpation. Mammography can disclose lesions as small as 1 mm and the clustering of calcifications that may warrant biopsy to exclude cancer. Mammography has a sensitivity of 80% to 90% for the detection of breast cancer even when performed by the most capable institutions. Therefore, even if the mammogram is negative a palpable mass requires further evaluation. Approximately, 40% of breast cancers can be detected only by palpation and another 40% only by mammography. The most comprehensive approach to screening is a combination of individual self-awareness, clinical breast evaluation by a health professional, and mammography.
Diagnosis and Classification

Procedures used in the diagnosis of breast cancer include physical examination, mammography, ultrasonography, percutaneous needle aspiration, stereotactic needle biopsy (i.e., core biopsy), and excisional biopsy. Figure 54.14 illustrates the appearance of breast cancer on mammography. Breast cancer often manifests as a solitary, painless, firm, fixed lesion with poorly defined borders. It can be found anywhere in the breast but is most common in the upper outer quadrant. Because of the variability in presentation, any suspect change in breast tissue warrants further investigation. The diagnostic use of mammography enables additional definition of the clinically suspect area (e.g., appearance, character, calcification). Placement of a wire marker under radiographic guidance can ensure accurate surgical biopsy of nonpalpable suspect areas. Ultrasonography is useful as a diagnostic adjunct to differentiate cystic from solid tissue in women with nonspecific thickening.

Fine-needle aspiration is a simple in-office procedure that can be performed repeatedly in multiple sites and with minimal discomfort. It can be accomplished by stabilizing a palpable mass between two fingers or in conjunction with handheld sonography to define cystic masses or fibrocystic changes and to provide specimens for cytologic examination. Fine-needle aspiration can identify the presence of malignant cells, but it cannot differentiate in situ from infiltrating cancer. Stereotactic needle biopsy is an outpatient procedure done with the guidance of a mammography machine. After the lesion is localized radiologically, a large-bore needle is mechanically thrust quickly into the area, removing a core of tissue. Discomfort is similar to that with ear piercing, and even when multiple cores are obtained, healing occurs quite rapidly. Cells are available for histologic evaluation with 96% accuracy in detecting cancer. This procedure is less costly than excisional biopsy. However, excisional biopsy to remove the entire lump provides the only definitive diagnosis of breast cancer, and often is therapeutic without additional surgery. MRI, positron emission tomography (PET), and computer-based or digital mammography are available as additional diagnostic modalities for breast cancer, and may be recommended to supplement conventional mammography in women with radiographically dense breasts or a strong family history of cancer, or who are known carriers of BRCA1 or BRCA2.72

Tumors are classified histologically according to tissue characteristics and staged clinically according to tumor size, nodal involvement, and presence of metastasis. It is recommended that estrogen and progesterone receptor analysis be performed on surgical specimens. Information about the presence or absence of estrogen and progesterone receptors can be used in predicting tumor responsiveness to hormonal manipulation. High levels of both receptors improve the prognosis and increase the likelihood of remission.

Treatment

The treatment methods for breast cancer include surgery, chemotherapy, radiation therapy, and hormonal manipulation. Radical mastectomy (i.e., removal of the entire breast, underlying muscles, and all axillary nodes) rarely is used today as a primary surgical therapy unless breast cancer is advanced at the time of diagnosis. Modified surgical techniques (i.e., mastectomy plus axillary dissection or lumpectomy for breast conservation) accompanied by chemotherapy or radiation therapy have achieved outcomes comparable with those obtained with radical surgical methods and constitute the preferred treatment methods.

The prognosis is related more to the extent of nodal involvement than to the extent of breast involvement. Greater nodal involvement requires more aggressive postsurgical treatment, and many cancer specialists believe that a diagnosis of breast cancer is not complete until dissection and testing of the axillary lymph nodes has been accomplished. A newer technique for evaluating lymph node involvement is a sentinel lymph node (SLN) biopsy. A radioactive substance or dye is injected into the region of the tumor. In theory, the dye is carried to the first (sentinel) node to receive lymph from the tumor.18 This would therefore be the node most likely to contain cancer cells if the cancer has spread. If the sentinel node biopsy is positive, more nodes are removed. If it is negative, further lymph node evaluation may not be needed.

Systemic therapy refers to the administration of chemotherapy, biologic therapy, or hormonal therapy. Neoadjuvant therapy is given before surgery to shrink the tumor and make surgical removal more effective. Adjuvant therapy is given after surgery to women with and without detectable metastatic disease. The goal of this therapy depends on nodal involvement, menopausal status, and hormone receptor status. Systemic adjuvant therapy...
Biologic therapy, using the drug trastuzumab (Herceptin), is used to stop the growth of breast tumors that express the HER2/neu receptor on their cell surface. The HER2/neu receptor binds an epidermal growth factor that contributes to cancer cell growth. Trastuzumab is a recombinant DNA-derived monoclonal antibody that binds to the HER2/neu receptor.

Hormone therapy is used to block the effects of estrogen on the growth of breast cancer cells. Tamoxifen is a nonsteroidal antiestrogen that binds to estrogen receptors and blocks the effects of estrogens on the growth of malignant cells in the breast. Decreased cancer recurrence, decreased mortality rates, and increased 5-year survival rates have been found in women with estrogen receptor–positive tissue samples who have been treated with Tamoxifen. Aromatase inhibitors block the enzyme that converts androstenedione and testosterone to estrogen in the peripheral tissues. This reduces the circulating estrogen levels in postmenopausal women and is becoming the most effective adjuvant therapy for women with early-stage breast cancer. Autologous bone marrow transplantation and peripheral stem cell transplantation are experimental therapies that may be used for treatment of advanced disease or in women at increased risk for recurrence.

**Paget Disease**

Paget disease accounts for 1% of all breast cancers. The disease presents as an eczematoid lesion of the nipple and areola (Fig. 54.15). Paget disease usually is associated with an infiltrating, intraductal carcinoma. When the lesion is limited to the nipple only, the rate of axillary metastasis is approximately 5%. Complete examination is required and includes a mammogram and biopsy. Treatment depends on the extent of spread.

**IN SUMMARY**

The breasts are subject to benign and malignant diseases. Mastitis is inflammation of the breast, occurring most frequently during lactation. Galactorrhea is an abnormal secretion of milk that may occur as a symptom of increased prolactin secretion. Ductal ectasia and intraductal papilloma cause abnormal drainage from the nipple. Fibroadenoma and fibrocystic changes are characterized by abnormal masses in the breast that are benign. By far, the most important disease of the breast is breast cancer, which is a significant cause of death of women. Clinical breast examination and mammography afford a woman the best protection against breast cancer. They provide the means for early detection of breast cancer and, in many cases, allow early treatment and cure.

**INFERTILITY**

Infertility is the inability to conceive a child after 1 year of unprotected intercourse. Primary infertility refers to situations in which there has been no prior conception. Secondary infertility is infertility that occurs after one or more previous pregnancies. Sterility is the inability to father a child or to become pregnant because of congenital anomalies, disease, or surgical intervention. Approximately, 15% of couples in the United States are affected by infertility and 1% to 2% by sterility.

The complexity of the process that must occur to achieve a pregnancy is taken for granted by most couples. For some couples, pregnancy occurs very easily, whereas for others, no amount of money, hard work, love, patience, or medical resources seems to be able to bring about this amazing, desired event. Although a full discussion of the diagnosis and treatment of infertility is beyond the scope of this book, an overview of the areas in which problems can occur is presented.

The causes of infertility are almost equally divided between male factors (30% to 40%), female factors (30% to 40%), and combined factors (30% to 40%). In approximately 10% to 25% of infertile couples, the cause remains unknown even after a full workup.
Male Factors

For pregnancy to occur, the man must be able to provide sperm in sufficient quantity, delivered to the upper end of the vagina, with adequate motility to traverse the female reproductive tract. The male contribution to this process is assessed by means of a semen analysis, which evaluates volume of semen (normally 2 to 5 mL), sperm density (20 million/mL), motility (50% good progressive), viability (50%), morphology (60% normal), and viscosity (full liquefaction within 20 minutes). The specimen is best collected by masturbation into a sterile container after 3 days of abstinence. Because of variability in specimens, abnormal results should lead to a repeat test before the need for treatment is presumed. Azospermia is the absence of sperm, oligospermia refers to decreased numbers of sperm, and asthenospermia refers to poor motility of sperm.

The causes of male infertility include varicocele, ejaculatory dysfunction, hyperprolactinemia, hypogonadotropic hypogonadism, infection, immunologic problems (i.e., antisperm antibodies), obstruction, and congenital anomalies. There are some male risk factors for sperm problems including a history of mumps orchitis, cryptorchidism (i.e., undescended testes), testicular torsion, hypospadias, previous urologic surgery, and history of STIs. Treatment depends on the cause and may include surgery, medication, or the use of artificial insemination to deliver a more concentrated specimen directly to the cervical canal or uterine fundus.

Female Factors

The female contribution to pregnancy is more complex, requiring production and release of a mature ovum capable of being fertilized, production of cervical mucus that assists in sperm transport and maintains sperm viability in the female reproductive tract, patent fallopian tubes with the motility potential to pick up and transfer the ovum to the uterine cavity, development of an endometrium that is suitable for the implantation and nourishment of a fertilized ovum, and a uterine cavity that allows for growth and development of a fetus. Each of these factors is discussed briefly, along with an overview of diagnostic tests and treatment.

Ovulatory Dysfunction

In a normally menstruating woman, ovulatory cycles begin several months to a year after menarche. Release of FSH from the pituitary causes the development of several primordial follicles in the ovary. At some point, a dominant follicle is selected and the remaining follicles undergo atresia. When the dominant follicle has become large enough to contain a mature ovum (16 to 20 mm in diameter) and is producing sufficient estradiol to ensure adequate proliferation of the endometrium, production of LH increases (i.e., the LH surge), and the increased LH level induces release of the ovum from the follicle (i.e., ovulation).

After ovulation, under the influence of LH, the former follicle luteinizes and begins producing progesterone in addition to estradiol. The progesterone stimulates the development of secretory endometrium, which has the capability to nourish a fertilized ovum if one should implant.

The presence of progesterone after ovulation causes a rise in the woman’s basal body temperature (BBT). This thermogenic property of progesterone provides the basis for the simplest, most inexpensive beginning test of ovulatory function—the measurement of BBT. Women should be able to detect at least a 0.4°F rise in their BBT (at rest) after ovulation that should be maintained throughout the luteal phase. This biphasic temperature pattern demonstrates that ovulation has taken place, where in the cycle it occurred, and the length of the luteal phase. BBT can be influenced by many other factors, including restless sleep, alcohol intake, drug use, fever due to illness, and change in usual rising time.

Another test for ovulation is LH predictor kits one can buy at the pharmacy. These test for LH, which should appear in the urine after the LH surge indicating ovulation. Serum progesterone can also be measured after expected ovulation to confirm if ovulation occurred. Finally, endometrial biopsy can also give information on the current phase of a woman’s cycle. However, given the invasiveness of the procedure, this is not usually done.

Ovulatory dysfunction, including anovulation (no ovulation) and oligo-ovulation (irregular ovulation), can be due to primary problems of the ovary or secondary problems related to endocrine dysfunction. When disturbances in ovulation are confirmed, it is reasonable to rule out other endocrine system problems before initiating treatment. If the results of tests for pituitary hormones (e.g., FSH, LH, prolactin), thyroid studies, and tests of adrenal function (e.g., DHEAS, androstenedione) are normal, ovulatory dysfunction is primary and should respond to treatment. Abnormalities in any of the other endocrine areas should be further evaluated as needed and treated appropriately. Hyperprolactinemia requires workup for pituitary lesions or associated endocrinopathies (such as thyroid dysfunction). Continued hyperprolactinemia can be treated with bromocriptine or cabergoline (Dostinex). Hypothyroidism requires thyroid replacement, and hyperthyroidism requires suppressive therapy and, sometimes, surgical intervention with thyroid replacement later. Adrenal suppression can be instituted with dexamethasone, a glucocorticoid analog. Normal ovulatory function may resume without further intervention. If not, treatment can be concurrent with management of other endocrine problems.

Cervical Mucus Problems

High preovulatory levels of estradiol stimulate the production of large amounts of clear, stretchy cervical mucus that aids the transport of sperm into the uterine cavity and helps to maintain an environment that keeps the sperm viable for up to 72 hours. Insufficient estrogen production (i.e., inherent or secondary to treatment with clomiphene citrate, an antiestrogen), cervical abnormalities from disease or invasive procedures (e.g., DES exposure, stenosis, conization), and cervical infection (e.g., chlamydial infection, mycoplasmal infection, gonorrhea) can adversely affect the production of healthy cervical mucus.

A postcoital test (Sims-Huhner) involves evaluation of the cervical mucus 1 to 8 hours after intercourse within the 48 hours.
before ovulation. A sample of cervical mucus is obtained using a special syringe and evaluated grossly for amount, clarity, and stretch (i.e., spinnbarkeit) and microscopically for cellularity, number and quality of motile sperm, and the presence of ferning after the sample has air dried on the slide. To obtain good-quality mucus, it is essential to obtain the sample within the 48 hours before ovulation. Tests may have to be repeated in the same cycle or in subsequent cycles to ensure appropriate timing. This can be a source of stress and frustration, as well as added cost to the couple. Intrauterine insemination (IUI) with the husband’s sperm can bypass the cervical mucus, and is often offered empirically as an alternative to postcoital testing.

If the quality of the mucus is good but sperm are inadequate in number or motility, further evaluation of the man may be needed. The man and woman can be tested for antisperm antibodies when repeated postcoital tests reveal that the sperm are all dead or agglutinated. However, IUI is the only effective treatment for sperm antibodies and is frequently offered without the need for further testing.

Cervical cultures for gonorrhea, chlamydial infection, and mycoplasmal infection should be obtained and treatment instituted as needed. Prophylactic treatment with antibiotics can be provided before IUI or other procedures that pass through the cervical canal as a more cost-effective alternative to obtaining cervical cultures.

**Uterine Cavity Abnormalities**

Alterations in the uterine cavity can occur because of DES exposure, submucosal fibroids, cervical polyps, bands of scar tissue, or congenital anomalies (e.g., bicornuate uterus, uterine septum, single horn). These defects may be suspected from the person’s history or pelvic examination but require hysterosalpingography (i.e., x-ray study in which dye is placed through the cervix to outline the uterine cavity and demonstrate tubal patency) or hysteroscopy (i.e., study in which a lighted fiberoptic endoscope placed through the cervix under general anesthesia allows direct visualization of the uterine cavity) for confirmation. Treatment is surgical when possible.

**Tubal Factors**

Tubal patency is required for fertilization and can be disrupted secondary to PID, ectopic pregnancy, large myomas, endometriosis, pelvic adhesions, and previous tubal ligation. Hysterosalpingography can reveal the location and type of any blockage, such as fimbrial, cornual, or hydrosalpinx. Microsurgical repair sometimes is possible.

Even when tubal patency is demonstrated, tubal disease may make ovum pickup impossible. Contrary to popular belief, the ovum is not extruded directly into the fallopian tube. The tube must be free to move to engulf the ovum after release. Pelvic adhesions from previous infection, surgery, or endometriosis may interfere with the tube’s mobility. Laparoscopic evaluation of the pelvis is needed for diagnosis. Laser ablation or cautery can be used to lyse adhesions and remove endometriosis through the laparoscope or, if severe, by means of laparotomy.

**Assisted Reproductive Technologies**

The number of assisted reproductive technologies (ARTs) cycles performed annually in the United States has increased exponentially from 64,681 cycles in 1996 to 146,244 cycles performed in reporting fertility clinics in 2009. Future research will focus on improving the implantation process in an effort to decrease the risk of multiple births while providing an optimal chance for pregnancy.

In vitro fertilization (IVF) was developed in 1978 for women with significantly damaged or absent tubes to provide them with an opportunity for pregnancy where none normally exists. The oocytes are hyperstimulated to produce multiple follicles using human menopausal gonadotropins (e.g., Reprotron, Menopur) containing FSH and LH, pure FSH (e.g., Gonal F, Follistim, Bravelle), or a combination of these drugs. Follicular maturation is monitored by means of ultrasonography and assay of serum estradiol levels. When preovulatory criteria are met, an injection of hCG is given to simulate an LH surge; 35 hours later, the follicles are aspirated transvaginally using ultrasound guidance. The follicular fluid is evaluated microscopically for the presence of ova. When found, they are removed and placed into culture media in an incubator.

The eggs are inseminated with sperm from the husband that have been prepared by a washing technique that removes the seminal and begins the capacitation process, and allows the strongest sperm to be used for fertilization. When very low numbers of normal motile sperm are available, intracytoplasmic sperm injection (ICSI) is used, where a single spermatozoon is injected directly into the cytoplasm of the egg.

Between 12 and 24 hours after insemination, the ova are evaluated for signs of fertilization. Those that were successfully fertilized are allowed to continue to divide for 3 or 5-to-6 days, depending on the appearance of the cells of the embryo. Because many embryos will not advance to the 5-to-6 day blastocyst stage in vitro, this therapy may be limited to those women who have produced a significant number of embryos. Embryos with the best grades are chosen for embryo transfer with the extras kept as candidates for cryopreservation. Embryos are placed into the woman’s uterus by means of a transcervical catheter.

Hormonal supplementation of the luteal phase is typically used to increase the possibility of implantation. Indications for IVF have been expanded to include male factors (i.e., severe oligospermia or asthenospermia), ovulatory dysfunction, uterine factors, endometriosis, and idiopathic infertility (i.e., infertility of unknown cause). The substantial risk of multiple births with IVF procedures has been reduced with the availability of cryopreservation, which allows freezing of excess embryos and limits the number of fresh embryos transferred.

An outgrowth of IVF technology is gamete intrafallopian transfer (GIFT), which uses similar ovarian stimulation protocols and egg retrieval procedures but uses laparoscopy to place ovum and sperm directly into the fallopian tube. Alternatively, zygote intrafallopian transfer (ZIFT) proceeds like an IVF cycle through egg retrieval and fertilization in the laboratory, but the resulting embryo (zygote) is placed directly into the
The use of donor gametes (eggs, sperm, embryos) provides an alternative for achieving pregnancy for those couples who are unable to use their own gametes and are comfortable raising a child that is not genetically related to them. Donor eggs provide a much higher likelihood of success for women older than 40 years of age, when both egg numbers and egg quality decline.

**In Summary**

Infertility is the inability to conceive a child after 1 year of unprotected intercourse. Male factors are related to number and motility of sperm and their ability to penetrate the cervical mucus and the ovum. Causes of male infertility include varicocele, ejaculatory dysfunction, hyperprolactinemia, hypogonadotropic hypogonadism, infection, immunologic problems (i.e., antisperm antibodies), obstruction, and congenital anomalies. Risk factors for sperm disorders include a history of mumps orchitis, cryptorchidism, testicular torsion, hypospadias, previous urologic surgery, infection, and exposure to known gonadotoxins.

The female contribution to pregnancy is more complex, requiring production and release of a mature ovum capable of being fertilized, production of cervical mucus that assists in sperm transport and maintains sperm viability in the female reproductive tract, patent fallopian tubes with the mobility potential to pick up and transfer the ovum to the uterine cavity, development of an endometrium that is suitable for the implantation and nourishment of a fertilized ovum, and a uterine cavity that allows for growth and development of a fetus.

Evaluation and treatment of infertility can be lengthy and highly stressful for the couple. Options for therapy continue to expand, but newer ART modalities are expensive, and financial resources can be strained while couples seek to fulfill their, sometimes elusive, dream of having a child.

Sexually transmitted infections (STIs) encompass a broad range of infectious diseases that are spread by sexual contact. The incidence of STIs is increasing as is the technology’s ability to screen STIs. The Centers for Disease Control and Prevention (CDC) (2009) requires reporting of chlamydia, syphilis, and gonorrhea and, therefore, tracks these three STIs most specifically. However, the actual figures of total STIs are probably much higher because many STIs are not reportable or not reported.

There are many factors that contribute to the increased prevalence and the continued spread of STIs. One key factor is that STIs are frequently asymptomatic, which promotes the spread of infection by people who are unaware they are carrying the infection. Furthermore, partners of infected people are often difficult to notify and treat. In addition, there currently are no cures for viral STIs (e.g., human immunodeficiency virus [HIV], herpes simplex virus [HSV]). Although there are drugs available that may help to manage the infections, they do not entirely control the spread. Also, drug-resistant microorganisms are rapidly emerging, making treatment of many STIs more difficult.

The agents of infection for STIs include bacteria, Chlamydia, viruses, fungi, protozoa, parasites, and unidentified microorganisms. portals of entry include the mouth, genitalia, urinary meatus, rectum, and skin. The rates of many STIs are highest among adolescents. All STIs are more common in people who have more than one sexual partner. Furthermore, it is not uncommon for a person to be concurrently infected with more than one type of STI.

This chapter discusses the manifestations of STIs in men and women in terms of infections of the external genitalia, vaginal infections, and infections that have genitourinary as well as systemic manifestations.
STIs can selectively infect the mucocutaneous tissues of the external genitalia, cause vaginitis in women, or produce both genitourinary and systemic effects. Some STIs may be transmitted by an infected mother to a fetus or newborn, causing congenital defects or death of the child. The discussion in this section of the chapter focuses on STIs that affect the mucocutaneous tissues of the oropharynx and external genitalia, and anorectal tissues. These infections include condylomata acuminata, genital herpes, molluscum contagiosum, chancroid, granuloma inguinale, and lymphogranuloma venereum.

Condylomata Acuminata (Genital Warts)

Condylomata acuminata, or genital warts, are caused by the human papillomavirus (HPV) (Fig. 55.1). Although recognized for centuries, HPV-induced genital warts have become the most common STI and there are over 40 different types of the HPV virus. The CDC estimates that 20 million Americans carry the virus and up to 6 million new cases are diagnosed each year. Risk factors for acquiring HPV include young age (<25 years), early age of first intercourse (<16 years), increased numbers of sex partners, and having a male partner with multiple sex partners. HPV infection can occur with any type of vaginal or anal penetration and is common in men having sex with men and women having sex with women.

Most HPV infections are asymptomatic and transient, and resolve spontaneously within 2 years without treatment if the person has an intact immunologic system. However, infection with some HPV types results in genital warts, cervical dysplasia, and cervical cancer. Considered low risk. They are found in most external genital warts but usually are benign, with only a low potential for dysplasia. Types 31, 33, 35, 39, 45, 51, 52, 56, and 58 are considered to be intermediate risk because they are common causes of intraepithelial neoplasia, but less common causes of squamous cell carcinoma. HPV types 16 and 18 are strongly associated with cervical dysplasia and anogenital cancers and are considered high risk. However, only a small percentage of women infected with HPV go on to develop cervical cancer. This suggests that even the most virulent HPV strains may vary in terms of their oncogenic potential. Cofactors that may increase the risk for cervical cancer include smoking, immunosuppression, and exposure to hormonal alteration (e.g., pregnancy, oral contraceptives).

Pathogenesis and Clinical Manifestations

HPV infection begins with viral inoculation into a stratified squamous epithelium, where infection stimulates replication of the squamous epithelium, producing the various HPV-proliferative lesions. The incubation period for HPV-induced genital warts ranges from 6 weeks to 8 months, with a mean of 2 to 3 months. Genital warts typically present as soft, raised, fleshy lesions on the external genitalia, including the penis (Fig. 55.2), vulva, scrotum, perineum, and perianal skin. External warts may appear as small bumps, or they may be flat, rough surfaced, or pedunculated. Less commonly, they can appear as smooth reddish or brown raised papules or as dome-shaped lesions on keratinized skin. Internal warts are cauliflower-shaped lesions that affect the mucous membranes of the vagina, urethra, anus, or mouth.
Subclinical infection occurs more frequently than visible genital warts. Both spontaneous resolution and infection with new HPV types are common. Approximately, 70% of women with HPV become HPV DNA negative within 1 year, and as much as 90% become negative within 2 years.6 Many women with transient HPV infections develop atypical squamous cells of undetermined significance (ASC-US) or low-grade squamous intraepithelial lesions (LSILs) of the cervix as detected on a Pap test, colposcopy, or biopsy. In men, transient HPV infection may be associated with intraepithelial neoplasia of the penis and anus. Development of an effective immune response helps clear the infection, but the virus can remain dormant for years and reactivate at a later time.

Diagnosis
The association with premalignant and malignant changes has increased the concern regarding the diagnosis and treatment of this viral infection. Lack of regular cervical cancer screening (Pap test) is the primary risk factor for development of invasive cervical cancer.6,7 There are no approved serologic tests for HPV or routine methods for culturing the virus. The only test that is currently approved by the U.S. Food and Drug Administration (FDA) is a solution hybridization method to test for high-risk HPV DNA.6 The HPV DNA test detects whether one or more of the high-risk types of HPV are present. It does not identify the individual HPV type. HPV DNA testing is warranted with equivocal (ASC-US) Pap test results, and is now recommended to determine which women older than 30 years of age need annual Pap smear screening.

Genital condylomata should be considered in any woman who presents with the primary complaint of vulvar pruritus or who has had an abnormal Pap smear result. Microscopic examination of a wet-mount slide preparation and cultures are used to exclude associated vaginitis. Careful inspection of the vulva, with magnification as needed, generally reveals the characteristic lesions, and specimens for biopsy can be taken from questionable areas. Colposcopic examination of the cervix and vagina may be advised as a follow-up measure when there is an abnormal Pap smear result or when HPV lesions are identified on the vulva.

Prevention and Treatment
There are two vaccines (Gardisil and Cervarix)8,9 currently available to protect against specific HPV strains. Both protect against types 16 and 18, which cause 70% of cervical cancers8 and Gardisil also protects against types 6 and 11, which are known to lead to genital warts. Currently, however, there is no treatment to eradicate the virus once a person has become infected. Prevention of HPV transmission through condom use has not been adequately demonstrated, but circumcision has been shown to decrease acquisition of some STIs, including HPV.10 Treatment goals are aimed at elimination of symptomatic warts, surveillance for malignancy and premalignant changes, and education and counseling to decrease psychosocial distress.

The choice of treatment is based on the number, size, site, and morphology of the lesions, as well as the person’s preference. Genital warts can resolve spontaneously, so expectant management is acceptable if the person is comfortable with this approach. Evaluation and treatment of sexual partners may be suggested, although this may be difficult considering that warts often do not become clinically apparent for several years after exposure.

The CDC identifies several pharmacologic treatments for symptomatic removal of visible genital warts, including patient-applied (imiquimod) and provider-administered (trichloroacetic acid) therapies.3 Imiquimod cream is a therapeutic agent that stimulates the body’s immune system (i.e., production of interferon-α and other cytokines). It is a category B drug and therefore potentially safe for use in pregnancy. Topical application of a solution of trichloroacetic acid is the most common treatment.

Genital warts also may be removed using cryotherapy (i.e., freezing therapy), surgical excision, laser vaporization, or electrocautery. Because it can penetrate deeper than other forms of therapy, cryotherapy often is the treatment of choice for cervical HPV lesions. Laser surgery can be used to remove large or widespread lesions of the cervix, vagina, or vulva, or lesions that have failed to respond to other first-line methods of treatment.

Genital Herpes
Genital herpes is one of the most common causes of genital ulcers in the United States. Because herpesvirus infection is not reportable in all states, reliable data on its true incidence (estimated number of new cases every year) and prevalence...
Recent estimates in the United States indicate a 16.2% prevalence of genital herpes. Women have a greater mucosal surface area exposed in the genital area and therefore are at greater risk of acquiring the infection. Herpesviruses are large, encapsulated viruses with a double-stranded genome. There are nine types of herpesviruses, belonging to three groups, which cause infections in humans:

1. Neurotropic α-group viruses, including herpes simplex virus type 1 (HSV-1; usually associated with cold sores although an increasing number of anogenital herpetic infections caused by HSV-1 are now becoming documented) and HSV-2 (usually associated with genital herpes).
2. Varicella-zoster virus (causes chickenpox and shingles).
3. Lymphotropic β-group viruses, including cytomegalovirus (causes cytomegalic inclusion disease), Epstein-Barr virus (causes infectious mononucleosis and Burkitt lymphoma), and human herpesvirus type 8 (the apparent cause of Kaposi sarcoma).

**Pathogenesis**

HSV-1 and HSV-2 are genetically similar. Both cause a similar set of primary and recurrent infections, and both can cause genital lesions. These viruses replicate in the skin and mucous membranes at the site of infection (oropharynx or genitalia), where they cause vesicular lesions of the epidermis and infect the neurons that innervate the area. HSV-1 and HSV-2 are neurotropic viruses, meaning that they grow in neurons and share the biologic property of latency. Latency refers to the ability to maintain disease potential in the absence of clinical signs and symptoms. In genital herpes, the virus ascends through the peripheral nerves to the sacral dorsal root ganglia (Fig. 55.3). The virus can remain dormant in the dorsal root ganglia, or it can reactivate, in which case the viral particles are transported back down the nerve root to the skin, where they multiply and cause a lesion to develop. During the dormant or latent period, the virus replicates in a different manner so that the immune system or available treatments have no effect on it. It is not known what reactivates the virus. It may be that the body’s defense mechanisms are altered. Numerous studies have shown that host responses to infection influence initial development of the disease, severity of infection, development and maintenance of latency, and frequency of HSV recurrences.

HSV is transmitted by contact with infectious lesions or secretions. HSV-1 is transmitted by oral secretions, and infections frequently occur in childhood. HSV-1 may be spread to the genital area by autoinoculation after poor handwashing or through oral–genital contact. It has been estimated that among sexually active adults, new genital HSV-1 infections are almost as common as new HSV-2 infections. HSV-2 usually is transmitted by sexual contact but can be passed to an infant during childbirth if the virus is actively being shed from the genital tract. Most cases of HSV-2 infection are subclinical, manifesting as truly asymptomatic or symptomatic but unrecognized infections. These subclinical infections can occur in people who have never had a symptomatic outbreak or they can occur between recognized clinical recurrences. Genital herpes is spread through asymptomatic shedding by people who do not realize they have the infection. This “unknown” transmission of the virus to sex partners explains why this infection has reached epidemic proportions throughout the world. The incubation period for HSV is 2 to 10 days.

**Clinical Manifestations**

Genital HSV infection may manifest as a first episode or recurrent infection. Usually one’s first episode is the most painful with an obvious lesion. However, some people may test positive for HSV and not have had any symptoms. Recurrent infections refer to the second or subsequent outbreak due to the same virus type. First-episode infections have more numerous and scattered vesicles and more systemic manifestations. Viral shedding lasts longer with first-episode infections (10 to 15 days) and new lesions continue to form for about 10 days after the initial infection. Many “severe” presumed primary cases are actually first-recognized recurrences in people with long-standing infection.

The initial symptoms of primary genital herpes infections include tingling, itching, and pain in the genital area, followed by eruption of small pustules and vesicles. These lesions rupture on approximately the 5th day to form wet ulcers that are excruciatingly painful to touch and can be associated with dysuria, dyspareunia, and urine retention. This period is followed by a 10- to 12-day interval during which the lesions crust over and gradually heal. Involvement of the cervix, vagina,
urethra, and inguinal lymph nodes is common in women with primary infections. In men, the infection can cause urethritis and lesions of the penis and scrotum. Rectal and perianal infections are possible with anal contact. Systemic symptoms associated with primary infections include fever, headache, malaise, muscle ache, and lymphadenopathy.

Recurrent HSV episodes are usually milder than the initial episode. There typically are fewer lesions, and viral shedding occurs at a lower concentration and for a shorter duration (about 3 days). However, the prodromal symptoms of itching, burning, and tingling at the lesion site are similar. Except for the greater tendency of HSV-2 to recur, the clinical manifestations of HSV-2 and genital HSV-1 infection are similar. The frequency and severity of recurrence vary from person to person. Numerous factors, including emotional stress, lack of sleep, overexertion, other infections, vigorous or prolonged coitus, and premenstrual or menstrual distress, have been identified as triggering mechanisms.

**Diagnosis**

Diagnosis of genital herpes is based on the symptoms, appearance of the lesions, and identification of the virus from swab tests taken from the lesions for cell culture. The likelihood of obtaining a positive culture decreases with each day that has elapsed after a lesion develops. The chance of obtaining a positive culture from a crusted lesion is slight, and people suspected of having genital herpes should be instructed to have a culture as soon as possible after development of new lesions. Polymerase chain reaction (PCR) testing for HSV DNA is more sensitive than culture. Although PCR is more expensive than culture, even small amounts of the virus will result in a positive test, the results can be obtained more quickly, and the method can distinguish between HSV-1 and HSV-2. In many clinics, PCR testing has become the preferred method of testing when active lesions are present.

Type-specific (HSV-1 and HSV-2) serologic tests are available for determining past infection. Because almost all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibodies usually indicates anogenital infection, whereas the presence of HSV-1 antibodies does not distinguish between anogenital and orolabial infections. HSV-1 is generally an oral infection and HSV-2 tends to be an anal–genital infection; however, one can have HSV-1 in the anal–genital region and HSV-2 in the oral area.

**Treatment**

There is no known cure for genital herpes, and the methods of treatment are largely symptomatic. The antiviral drug valacyclovir has become the cornerstone for management of genital herpes. By interfering with viral DNA replication, this antiviral drug decreases the frequency of recurrences, shortens the duration of active lesions, reduces the number of new lesions formed, and decreases viral shedding with primary infections. Valacyclovir, the active component of acyclovir, has good bioavailability, which enables improved dosing schedules and increased compliance. Episodic intervention reduces the duration of viral shedding and the healing time for recurrent lesions. Continuous antiviral suppressive therapy may be advised when more than six outbreaks occur within 1 year. Valacyclovir is well tolerated, with few adverse effects. This long-term suppressive therapy does not limit latency, and reactivation of the disease frequently occurs after the drug is discontinued.

Good hygiene is essential during HSV outbreaks to prevent secondary infections. Sometimes, symptomatic relief can be obtained with cool compresses, sitz baths, topical anesthetic agents, and oral analgesic drugs. Loose-fitting clothing and cotton undergarments are helpful. To prevent spread of the infection, intimate contact should be avoided until lesions are completely healed.

Pregnant women with a history of genital herpes are started on valacyclovir suppression at 36 weeks’ gestation. If a woman has an outbreak of herpes when she presents in labor, a cesarean section is recommended. Disseminated neonatal infection carries high mortality and morbidity rates.

**Molluscum Contagiosum**

Molluscum contagiosum is a common poxvirus that gives rise to multiple umbilicated papules. The infection is mildly contagious. It is transmitted by skin-to-skin contact, fomites, and autoinoculation. Lesions are domelike and have a dimpled appearance. A curdlike material can be expressed from the center of the lesion. Necrosis and secondary infection are possible. Diagnosis is based on the appearance of the lesion and microscopic identification of intracytoplasmic molluscum bodies. Molluscum is a benign and self-limited disease.

Spontaneous regression of mature lesions followed by continued emergence of new lesions is common with molluscum. In the absence of therapy this cycle may persist for 6 months to a few years. When indicated, treatment consists of removing the top of the papule with a sterile needle or scalpel, expressing the contents of each lesion, and applying alcohol or silver nitrate to the base. Electrodesiccation, cryosurgery, laser ablation, and surgical biopsy are alternative treatments but seldom are needed unless lesions are large or extend over a wide area. Another approach to therapy is the application of imiquimod 1% cream to lesions. This self-applied therapy is the first to show efficacy in people with immunosuppressive diseases, such as acquired immunodeficiency syndrome (AIDS).

**Chancroid**

Chancroid (i.e., soft chancre) is a disease of the external genitalia and lymph nodes. The causative organism is the gram-negative bacterium *Haemophilus ducreyi*, which causes acute ulcerative lesions with profuse discharge. This disease has become uncommon in the United States, with most outbreaks occurring in Africa and the Caribbean. It typically occurs in discrete outbreaks rather than as an endemic disease in this country. As a highly infectious disease, chancroid usually is
transmitted by sexual intercourse or through skin and mucous membrane abrasions. Autoinoculation may lead to multiple chancre.

Lesions begin as macules, progress to pustules, and then rupture. This painful ulcer has a necrotic base and jagged edges. In contrast, the syphilitic chancre is nontender and indurated. Subsequent discharge can lead to further infection of self or others. On physical examination, lesions and regional lymphadenopathy may be found. Secondary infection may cause significant tissue destruction. Diagnosis usually is made clinically, but may be confirmed through culture. Gram stain rarely is used today because it is insensitive and nonspecific.

**Granuloma Inguinale**

Granuloma inguinale (i.e., donovanosis, granuloma venereum) is caused by a gram-negative bacillus, *Klebsiella granulomatis* (previously known as *Calymmatobacterium [Donovania] granulomatis*), which is a tiny, encapsulated intracellular parasite. This disease is almost nonexistent in the United States. It is found most frequently in tropical areas such as India, Brazil, the West Indies, and parts of China, Australia, and Africa.13

Granuloma inguinale causes ulceration of the genitalia, beginning with an innocuous papule. The papule progresses through nodular or vesicular stages until it begins to break down as pink, granulomatous tissue. At this final stage, the tissue becomes thin and friable and bleeds easily. There are complaints of swelling, pain, and itching. Extensive inflammatory scarring may cause late sequelae, such as lymphatic obstruction with the development of enlarged and elephantoid external genitalia. The liver, bladder, bone, joint, lung, and bowel tissue may become involved. Genital complications include tubo-ovarian abscess, fistula, vaginal stenosis, and occlusion of vaginal or anal orifices. Lesions may become neoplastic.

Diagnosis is made through the identification of Donovan bodies (i.e., large mononuclear cells filled with intracytoplasmic gram-negative rods) in tissue smears, biopsy samples, or culture.13 A minimum 3-week period of treatment with doxycycline, azithromycin, ciprofloxacin, or erythromycin is used in treating the disorder.13

**Lymphogranuloma Venereum**

Lymphogranuloma venereum (LGV) is an acute and chronic venereal disease caused by *Chlamydia trachomatis* types L1, L2, and L3.13 The disease, although found worldwide, has a low incidence outside the tropics. Most cases reported in the United States are in men.

The lesions of LGV can incubate for a few days to several weeks and thereafter cause small, painless papules or vesicles that may go undetected. An important characteristic of the infection is the early (1 to 4 weeks later) development of large, tender, and sometimes fluctuant inguinal lymph nodes called buboes.13 There may be flulike symptoms with joint pain, rash, weight loss, pneumonitis, tachycardia, splenomegaly, and proctitis.13 In later stages of the disease, a small percentage of affected people develop elephantiasis of the external genitalia, caused by lymphatic obstruction or fibrous strictures of the rectum or urethra from inflammation and scarring. Urethral involvement may cause pyuria and dysuria. Cervicitis is a common manifestation of primary LGV, and could extend to perimetritis or salpingitis, which are known to occur in other chlamydial infections.14 Anorectal structures may be compromised to the point of incontinence. Complications of LGV may be minor or extensive, involving compromise of whole systems or progression to a cancerous state.

Diagnosis usually is accomplished by a complement fixation test for LGV-specific *Chlamydia* antibodies. High titers for this antibody differentiate this group from other chlamydial subgroups.13 Treatment involves 3 weeks of doxycycline or erythromycin.13 Surgery may be required to correct sequelae such as strictures or fistulas or to drain fluctuant lymph nodes.

**STIs that primarily affect the external genitalia include HPV-induced genital warts, genital herpes, molluscum contagiosum, chancroid, granuloma inguinale, and LGV.** The lesions of these infections occur on the external genitalia of male and female sexual partners. Of concern is the relation between HPV and genital neoplasms. Genital herpes is caused by a neurotropic HSV (HSV-2 and, sometimes, HSV-1) that ascends through the peripheral nerves to reside in the sacral dorsal root ganglia. The herpesvirus can be reactivated, producing recurrent lesions in genital structures that are supplied by the peripheral nerves of the affected ganglia. There is no permanent cure for herpes infections. Molluscum contagiosum is a benign and self-limited infection that is contagious. Chancroid, granuloma inguinale, and LGV produce external genital lesions with various degrees of inguinal lymph node involvement. These last three diseases are uncommon in the United States.

**KEY POINTS**

**SEXUALLY TRANSMITTED INFECTIONS**

- In general, STIs due to bacterial pathogens can be successfully treated and the pathogen eliminated by antimicrobial therapy. However, many of these pathogens are developing antibiotic resistance.
- STIs due to viral pathogens such as genital herpes simplex virus infections (HSV-1 and HSV-2) are not eliminated by current treatment modalities and persist with risk of recurrence (HSV infections).
Candidiasis, trichomoniasis, and bacterial vaginosis are vaginal infections that may be associated with sexual activity. Trichomoniasis is the only form of vaginitis that is known to be sexually transmitted and requires partner treatment. The male partner usually is asymptomatic.

**Candidiasis**

Also called yeast infection, thrush, and moniliasis, candidiasis is the second leading cause of vulvovaginitis in the United States. Approximately, 75% of reproductive-age women in the United States experience one episode in their lifetime: 40% to 45% experience two or more infections.15

*Candida albicans* is the most commonly identified organism in vaginal yeast infections. However, other *Candida* species, such as *Candida glabrata* and *Candida tropicalis*, may also be present and be responsible for complicated candidiasis.15 Although vulvovaginal candidiasis usually is not transmitted sexually, it is included in the CDC STI treatment guidelines because it often is diagnosed in women being evaluated for STIs.3 The possibility of sexual transmission has been recognized for many years. However, candidiasis requires a favorable environment for growth of the organism. The gastrointestinal tract also serves as a reservoir for this organism, and candidiasis can develop through autoinoculation in women who are not sexually active. Although studies have documented the presence of *Candida* on the penis of male partners of women with vulvovaginal candidiasis (Fig. 55.4), few men develop balanoposthitis that requires treatment.15

**Etiology and Clinical Manifestations**

Reported risk factors for the overgrowth of *C. albicans* include recent antibiotic therapy, which suppresses the normal protective bacterial flora; high hormone levels owing to pregnancy or the use of oral contraceptives, which cause an increase in vaginal glycogen stores; and uncontrolled diabetes mellitus or HIV infection, because they compromise the immune system.4 Women with vulvovaginal candidiasis commonly complain of vulvovaginal pruritus accompanied by irritation, erythema, swelling, dysuria, and dyspareunia. The characteristic discharge, when present, is usually thick, white, and odorless. In obese people, *Candida* may grow in skin folds underneath the breast tissue, the abdominal flap, and the inguinal folds.

**Diagnosis and Treatment**

Accurate diagnosis is made by identification of budding yeast filaments (i.e., hyphae) or spores on a wet-mount slide using 20% potassium hydroxide. The pH of the discharge, which is checked with litmus paper, typically is less than 4.5. When the wet-mount technique is negative but the clinical manifestations are suggestive of candidiasis, a culture may be necessary.

Antifungal agents such as clotrimazole, miconazole, butoconazole, and terconazole, in various forms, are effective in treating candidiasis. These drugs, with the exception of terconazole, are available without prescription for use by women who have had a previously confirmed diagnosis of candidiasis. Oral fluconazole has been shown to be as safe and effective as the standard intravaginal regimens.3 Chronic vulvovaginal candidiasis, defined as four or more mycologically confirmed episodes within 1 year, affects approximately 5% of women and is difficult to manage.15 Subsequent prophylaxis (maintenance therapy) often is required for long-term management of this problem.15

**Trichonomiasis**

Trichonomiasis is credited with being a far more prevalent STI than gonorrhea infection, and almost as common as chlamydia.15–17 In the United States, it has been estimated that 7.4 million new cases of trichonomiasis appear annually.16 Epidemiologically, *Trichomonas vaginalis* infections are commonly associated with other STIs and are therefore a marker for high-risk sexual behavior. An anaerobic protozoan that can be transmitted sexually, *T. vaginalis* is shaped like a turnip and has three or four anterior flagella (see Fig. 55.5). Trichomonads can reside in the paraurethral glands of both sexes.

**Clinical Manifestations and Complications**

Men harbor the organism in the urethra and prostate and are asymptomatic. Although 10% to 25% of women are asymptomatic, trichonomiasis is a common cause of vaginitis when some imbalance allows the protozoan to proliferate.17
This extracellular parasite feeds on the vaginal mucosa and ingests bacteria and leukocytes. The infection causes a copious, frothy, malodorous, green or yellow discharge. There commonly is erythema and edema of the affected mucosa, with occasional itching and irritation. Sometimes, small hemorrhagic areas, called strawberry spots, appear on the cervix.

Trichomoniasis can cause a number of complications. It is a risk factor for HIV transmission and infectivity in both men and women. In women, it increases the risk of tubal infertility and atypical pelvic inflammatory disease (PID), and it is associated with adverse outcomes such as premature birth in pregnant women. Trichomonads attach easily to mucus membranes. They may serve as vectors for the spread of other organisms, carrying pathogens attached to their surface into the fallopian tubes. In men, it is a common cause of nongonococcal urethritis and is a risk factor for infertility.

Diagnosis and Treatment
Diagnosis is made microscopically by identification of the motile protozoan on a wet-mount slide preparation. The pH of the discharge usually is greater than 6.0. Because the organism resides in other urogenital structures besides the vagina, systemic treatment is recommended. The treatment of choice is oral metronidazole or tinidazole, medications that are effective against anaerobic protozoans. Both drugs are chemically similar to disulfiram (Antabuse), a drug used in the treatment of alcohol addiction that causes nausea, vomiting, flushing of the skin, headache, palpitations, and lowering of the blood pressure when alcohol is ingested. Gastrointestinal disturbances and a metallic taste in the mouth are potential adverse effects of the drugs. Although metronidazole is considered safe for use during pregnancy, data on tinidazole use are limited. Sexual partners should be treated to avoid reinfection, and abstinence is recommended until the full course of therapy is completed.

Bacterial Vaginosis
Bacterial vaginosis is the most prevalent form of vaginal infection seen by health care professionals. The prevalence for bacterial vaginosis is approximately 21.2 million people per year in the 14 to 49 age-group. The disorder is associated with having multiple sex partners, a new sex partner, douching, and a lack of vaginal lactobacilli. Its relation to sexual activity is not clear. Sexual activity is believed to be a catalyst rather than a primary mode of transmission, and endogenous factors may play a role in the development of symptoms.

Pathogenesis
The pathogenesis of bacterial vaginosis is poorly understood. It is a complex polymicrobial disorder characterized by a shift in the vaginal flora from one dominated by hydrogen peroxide–producing lactobacilli to one with greatly reduced numbers of Lactobacillus species and an overgrowth of other organisms, including Gardnerella vaginalis, Mobiluncus species, Mycoplasma hominis, and numerous anaerobes. The massive overgrowth of vaginal anaerobes is associated with increased conversion of vaginal peptides to a variety of amines that, in high pH, become volatile and malodorous. The amines are associated with increased vaginal transudation and squamous epithelial cell exfoliation, creating the typical discharge. In conditions of elevated pH, G. vaginalis more efficiently adhere to the exfoliating epithelial cells, creating clue cells (squamous epithelial cells covered with masses of cocccobacilli, often with large clumps of organisms floating free from the cell). Amines further provide a suitable substrate for M. hominis growth.

Clinical Manifestations
The predominant symptom of bacterial vaginosis is a thin, grayish-white discharge that has a foul, fishy odor. Burning, itching, and erythema usually are absent because the bacteria have only minimal inflammatory potential. Because of the lack of inflammation, the term vaginosis rather than vaginitis is used to describe the condition. The organisms associated with bacterial vaginosis may be carried asymptomatically by men and women.

In addition to causing bothersome symptoms, bacterial vaginosis is associated with an increased risk of PID, preterm labor, premature rupture of membranes, chorioamnionitis, and postpartum endometritis linked to the organisms associated with bacterial vaginosis. Postoperative infections, including postabortion PID, posthysterectomy cuff cellulitis, and postcesarean endometritis, have been shown to be associated with asymptomatic bacterial vaginosis.

Diagnosis and Treatment
The diagnosis of bacterial vaginosis is made when at least three of the following characteristics are present:

- Homogeneous, thin, white discharge
- Production of a fishy, amine odor when a saline solution is dropped onto the secretions
- Vaginal pH above 4.5 (usually 5.0 to 6.0)
- Appearance of characteristic “clue cells” on wet-mount microscopic studies
When indicated, treatment is aimed at relieving the vaginal symptoms and signs of infection and reducing the risk of infectious complications after abortion or hysterectomy. All women who have symptomatic disease should be treated. Other potential benefits might include a reduction in the risk of other STIs. The CDC recommends treatment by oral metronidazole, metronidazole vaginal gel, or clindamycin vaginal cream. The same treatment regimens used for nonpregnant women can be used in pregnancy. Routine screening for bacterial vaginosis is not advocated, but all pregnant women with bacterial vaginosis should be treated. In addition, women at increased risk for preterm labor should be screened during the first trimester.

**IN SUMMARY**

Candidiasis, trichomoniasis, and bacterial vaginosis are common vaginal infections that become symptomatic because of changes in the vaginal ecosystem. Only trichomoniasis is spread through sexual contact. Candidiasis, also called a yeast infection, is a frequent cause of vulvovaginitis. *Candida* can be present without producing symptoms; usually some host factor, such as altered immune status, contributes to the development of vulvovaginitis. It can be treated with over-the-counter medications. The infection, which is caused by the anaerobic protozoan *T. vaginalis*, incites the production of a copious, frothy, yellow or green, malodorous discharge. It is a risk factor for HIV transmission and infectivity in both men and women. In women, it increases the risk of tubal infertility and atypical PID and it is associated with adverse outcomes such as premature birth in pregnant women. Bacterial vaginosis is the most common cause of vaginal discharge. It is a complex polymicrobial disorder characterized by a shift in the vaginal flora from one dominated by hydrogen peroxide–producing lactobacilli to one with greatly reduced numbers of lactobacilli and an overgrowth of other organisms, including *G. vaginalis*, *Mobiluncus* species, *M. hominis*, and numerous anaerobes. The predominant symptom of bacterial vaginosis is a thin, grayish-white discharge that has a foul, fishy odor. Because it does not produce inflammation, it is referred to as *vaginosis* rather than *vaginitis*.

**VAGINAL–UROGENITAL–SYSTEMIC INFECTIONS**

After completing this section of the chapter, you should be able to meet the following objectives:

- State the genital and nongenital complications that can occur with chlamydial infections, gonorrhea, and syphilis.
- Describe the three stages of syphilis.

Some STIs infect male and female genital and extragenital structures. Among the infections of this type are chlamydial infections, gonorrhea, and syphilis. Many of these infections also pose a risk to infants born to infected mothers. Some infections, such as syphilis, may be spread to the infant while in utero, whereas others, such as chlamydial and gonorrheal infections, can be spread to the infant during the birth process.

**Chlamydial Infections**

Chlamydia infection is the most prevalent STI in the United States, with an incidence estimated to be more than twice that of gonorrhea. As of 2010, chlamydial infections are reportable in all 50 states and the District of Columbia. According to CDC estimates, chlamydial infections reported from each of the 50 states and the District of Columbia equalled approximately 1.3 million new cases in 2010, predominantly among people younger than 25 years of age. There was an increase of 5.1% of cases since 2009. The CDC estimates that about twice the reported rate of people actually are infected with chlamydia. Rates for chlamydial infections have risen significantly over the past 15 years because of an increase in screening programs, improved sensitivity of diagnostic tests, and improved surveillance and reporting systems.

*Chlamydia trachomatis* is an obligate intracelluar bacterial pathogen that tends to be much smaller than most bacteria. It resembles a virus in that it requires tissue culture for isolation, but like bacteria, it has ribonucleic acid (RNA) and DNA and is susceptible to some antibiotics. *C. trachomatis* causes a wide variety of genitourinary infections, including nongonococcal urethritis in men and PID in women. The closely related organisms *Chlamydia pneumoniae* and *Chlamydia psittaci* cause mild and severe pneumonia, respectively. *C. trachomatis* is the most common sexually transmitted disease in North America. It can be serologically subdivided into types A, B, and C, which are associated with trachoma and chronic keratoconjunctivitis; types D through K, which are associated with genital infections and their complications; and types L1, L2, and L3, which are associated with LGV. *C. trachomatis* can cause significant ocular disease in neonates. It is a leading cause of blindness in underdeveloped countries. In these countries, the organism is spread primarily by flies, fomites, and nonsexual personal contact. In industrial countries, the organism is spread almost exclusively by sexual contact and therefore affects primarily the genitourinary structures.

*Chlamydiae* exist in two forms: elementary and reticulate bodies. The 48-hour growth cycle starts with attachment of the elementary body to the susceptible host cell, after which it is ingested by a process that resembles phagocytosis. Once inside the cell, the elementary body is organized into the reticulate body, the metabolically active form of the organism that is capable of reproduction. The reticulate body is not infectious and cannot survive outside the body. The reticulate bodies divide in the cell for up to 36 hours and then condense to form new elementary bodies, which are released when the infected cell bursts.
bral joints.4 Women can also develop reactive arthritis, but the
weight-bearing joints, such as the knees, sacroiliac and verte-
symptoms includes urethritis, conjunctivitis, and arthritis of
infection is the development of Reiter syndrome. This triad of
penile discharge, and urethral itching4 (Fig. 55.7). Prostatitis
urethritis, including meatal erythema and tenderness, a purulent
further chlamydial infections.
Thematous, edematous, and extremely friable. This can lead
to greater fallopian tube damage and increase the reservoir for
further chlamydia infections.
In men, chlamydial infections, if there are symptoms, cause
urethritis, including meatal erythema and tenderness, a purulent
penile discharge, and urethral itching4 (Fig. 55.7). Prostatitis
and epididymitis with subsequent infertility may develop.
The signs and symptoms of chlamydial infection resemble
those produced by gonorrhea. The most significant differ-
ence between chlamydial and gonococcal salpingitis is that
chlamydial infections may be asymptomatic or clinically non-
specific. If there are symptoms in women, the most common
symptom is a mucopurulent cervical discharge (Fig. 55.6).
The cervix itself frequently hypertrophies and becomes ery-
thematos, edematous, and extremely friable. This can lead
to greater fallopian tube damage and increase the reservoir for
further chlamydia infections.

Clinical Manifestations
The signs and symptoms of chlamydial infection resemble
the development of Reiter syndrome. This triad of
symptoms includes urethritis, conjunctivitis, and arthritis of
weight-bearing joints, such as the knees, sacroiliac and verte-
bral joints.4 Women can also develop reactive arthritis, but the
male-to-female ratio for this complication is 5:1. The arthritis
begins 1 to 3 weeks after the onset of chlamydia infection. The
joint involvement is asymmetric, with multiple affected joints
and a predilection for the lower extremities. Mucocutaneous
lesions also occur and are papulosquamous eruptions that tend to
be located on the palms of the hands and soles of the feet of both
genders. The U.S. Preventive Services Task Force (USPSTF)
has suggested annual screening for sexually active adolescents
and young female adults in an effort to minimize infection.21

Diagnosis and Treatment
Diagnosis of chlamydial infections takes several forms. The
identification of polymorphonuclear leukocytes on Gram stain of
penile discharge in the man or cervical discharge in the woman
provides presumptive evidence. The direct fluorescent antibody
test and the enzyme-linked immunosorbent assay that use anti-
bodies against an antigen in the *Chlamydia* cell wall are rapid
tests that are highly sensitive and specific. The positive predictive
value of these tests is excellent among high-risk groups, but false-
positive results occur more often in low-risk groups. The meth-
oodlogic challenges of culturing this organism have led to the
development of non–culture-based tests that amplify and detect
*C. trachomatis*–specific DNA and RNA sequences.22 One of the
newest sets of nonculture techniques, the nucleic acid amplifica-
tion tests (NAATs), do not require viable organisms for detection,
and can produce a positive signal from as little as a single copy
of the target DNA or RNA.23 The amplification procedures that
are now commercially available for chlamydial testing are PCR,
transcription-mediated amplification (TMA) of RNA, and strand
displacement amplification (SDA). These amplification methods
are highly sensitive and, if properly monitored, very specific.
NAATs can be performed on urine or self-collected swab speci-
mens from the distal vagina as well as the traditional endocervi-
cal and urethral specimens. Most NAATs in use today detect both
*C. trachomatis* and *Neisseria gonorrhoeae* in a single test.

The CDC recommends the use of azithromycin or doxy-
cycline in the treatment of chlamydial infection. Penicillin
is ineffective. Azithromycin is the preferred choice in preg-
nancy.3 Simultaneous antibiotic treatment of both sexual
partners is recommended. Abstinence from sexual activity is
encouraged to facilitate cure.

Gonorrhea
Gonorrhea is a reportable STI caused by the bacterium
*N. gonorrhoeae*. In 2010, there were 309,341 reported cases
of gonorrhea in the United States.28 Like chlamydial infection,
gonorrhea is frequently underdiagnosed. The CDC estimates
there are 600,000 new cases every year.29 Improved screen-
ing efforts as well as greater use of more sensitive nonculture
methods of testing may have contributed to this trend.
The gonococcus is a pyogenic (i.e., pus-forming),
gram-negative diplococcus.4 Humans are the only natural
host for *N. gonorrhoeae*. The organism grows best in warm,
mucus-secreting epithelia. The portal of entry can be the geni-
tourinary tract, eyes, oropharynx, anorectum, or skin.
Transmission usually is by sexual intercourse except for perinatal transmission. Autoinoculation of the organism to the conjunctiva is possible. Neonates born to infected mothers can acquire the infection during passage through the birth canal and are in danger of developing gonorrheal conjunctivitis, with resultant blindness unless treated promptly. An amniotic infection syndrome characterized by premature rupture of the membranes, premature delivery, and increased risk of infant morbidity and mortality has been identified as an additional complication of gonococcal infections in pregnancy. Genital gonorrhea in young children should raise the possibility of sexual abuse.

The infection commonly manifests 2 to 7 days after exposure. It typically begins in the anterior urethra, accessory urethral glands, Bartholin or Skene glands, and the cervix. If untreated, gonorrhea spreads from its initial sites upward into the genital tract. In men, it spreads to the prostate and epididymis. In women, it commonly produces endometritis, salpingitis, and PID. Pharyngitis may follow oral–genital contact. The organism also can invade the bloodstream (i.e., disseminated gonococcal infection), causing serious sequelae such as bacteremic involvement of joint spaces, heart valves, meninges, and other body organs and tissues.

**Clinical Manifestations**

People with gonorrhea may be asymptomatic and may unwittingly spread the disease to their sexual partners. In men, the initial symptoms include urethral pain and a creamy yellow, sometimes bloody, discharge (Fig. 55.8). The disorder may become chronic and affect the prostate, epididymis, and periurethral glands. Rectal infections are common in homosexual men. In women, recognizable symptoms include unusual genital or urinary discharge, dysuria, dyspareunia, pelvic pain or tenderness, unusual vaginal bleeding (including bleeding after intercourse), fever, and proctitis (Fig. 55.9). Symptoms may occur or increase during or immediately after menses because the bacterium is an intracellular diplococcus that thrives in menstrual blood but cannot survive long outside the human body. There may be infections of the uterus and development of acute or chronic infection of the fallopian tubes (i.e., salpingitis), with ultimate scarring and sterility (Fig. 55.10).

**FIGURE 55.9** • Gonorrhea—Secretions are yellow and the women report dyspareunia and dysuria. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 799). Philadelphia, PA: Lippincott Williams & Wilkins.)

**Diagnosis**

Diagnosis is based on the history of sexual exposure and symptoms. It is confirmed by identification of the organism on Gram stain or culture. A Gram stain usually is an effective means of diagnosis in symptomatic men (i.e., those with discharge). In women and asymptomatic men, a culture usually is preferred because the Gram stain often is unreliable. Culture has been the gold standard, particularly when the Gram stain is negative. A specimen should be collected from the appropriate site (i.e., endocervix, urethra, anal canal, or oropharynx), inoculated onto a suitable medium, and transported under appropriate conditions. *N. gonorrhoeae* is a fastidious organism with specific nutrient and environmental needs. Detection by NAATs (PCR) is generally done. The sensitivity of these tests is similar to that of culture. Men are often more willing to provide a urine specimen than to have a urethral swab done, and NAAT can be offered to women in locations where pelvic examination is not possible.

Updated recommendations from the USPSTF suggest that clinicians screen all sexually active women for gonorrhea who are at increased risk for infection (i.e., younger than 25 years of age, new or multiple sexual partners, inconsistent condom use, sex work, or drug use). Testing for other STIs, particularly syphilis and chlamydial infection, is suggested at the time of examination. Pregnant women are routinely screened at the time of their first prenatal visit. High-risk populations should have repeat cultures during the third trimester. Neonates are routinely treated with various antibacterial agents applied to the conjunctiva within 1 hour of birth to protect against undiagnosed gonorrhea and other diseases.

**Treatment**

Penicillin-resistant strains of *N. gonorrhoeae* are prevalent worldwide and strains with other kinds of antibiotic resistance continue to evolve and spread. The current treatment recommendation to combat tetracycline- and penicillin-resistant strains of *N. gonorrhoeae* is ceftriaxone in a single injection or cefixime, ciprofloxacin, ofloxacin, or levofloxacin in a single oral dose. All are equally effective and should be followed with azithromycin for chlamydiae. Quinolone-resistant strains are now common in Asia, the Pacific islands (including Hawaii), and California, so the CDC recommends avoiding the use of fluoroquinolones in those areas for infections in men who have sex with men or for people with a history of recent foreign travel. All sex partners within 60 days prior to discovery of the infection should be contacted, tested, and treated. Test of cure is not required with observed single-dose therapy.

**Syphilis**

Syphilis is a reportable systemic STI caused by a spirochete, *Treponema pallidum*. In 2009, there were 13,604 early latent syphilis cases and 18,079 late and late latent cases of syphilis reported in the United States. A total of 45,834 cases of syphilis were reported to the CDC in the United States. Sixty-three percent of the primary- and secondary-staged syphilis cases were among men who have sex with men and/or women.

*T. pallidum* is spread by direct contact with an infectious moist lesion, usually through sexual intercourse. Bacteria-laden secretions may transfer the organism during any type of intimate contact. Skin abrasions provide another possible portal of entry. There is rapid transplacental transmission of the organism from the mother to the fetus after 16 weeks' gestation, so that active infection in the mother during pregnancy can produce congenital syphilis in the fetus. Untreated syphilis can cause prematurity, stillbirth, and congenital defects and active infection in the infant. Because the manifestations of maternal syphilis may be subtle, testing for syphilis is mandatory in all pregnancies. Once treated for syphilis, a pregnant woman usually is followed throughout pregnancy by repeat testing of serum titers.

**Clinical Manifestations**

The clinical disease is divided into three stages: primary, secondary, and tertiary. Primary syphilis is characterized by the appearance of a chancre at the site of exposure, such as on the penis, vulva, anus, or mouth. Chancres typically appear within an average of 3 weeks of exposure but may incubate up to 3 months. The primary chancre begins as a single, indurated, papule up to several centimeters in diameter that erodes to create a clean-based ulcerated lesion on an elevated base. They also are solitary and have discrete raised borders. These lesions usually are painless and located at the site of sexual contact. Primary syphilis is readily apparent in the male, where the lesion is on the scrotum or penis (Fig. 55.11). Although chancres can develop on the external genitalia in females, they are more common on the vagina or cervix, and primary syphilis therefore may go untreated since they are not visible without a speculum examination. Often there is an accompanying inguinal lymphadenopathy. The infection is highly contagious at this stage, but because the symptoms are mild, it frequently goes unnoticed. The chancre usually heals within 3 to 12 weeks, with or without treatment.
Cardiovascular manifestations usually result from scarring of the medial layer of the thoracic aorta with aneurysm formation. These aneurysms produce enlargement of the aortic valve ring with aortic valve insufficiency.

**Diagnosis**

*T. pallidum* is difficult to culture and requires special dark field microscopy to adequately detect the organism. As it evokes a humoral immune response leading to production of antibodies, serologic testing can be done. Although PCR tests have now been developed for syphilis, serology remains the mainstay for diagnosis. Because the disease’s incubation period may delay test sensitivity, serologic tests usually are repeated after 6 weeks if the initial test results were negative.

The nontreponemal tests identify the presence of regain, which is an autoantibody directed against cardiolipin antigens. These antibodies are detected by flocculation tests such as the Venereal Disease Research Laboratory (VDRL) test or the rapid plasma reagin (RPR) test. Because these tests are nonspecific, positive results can occur with diseases other than syphilis. The tests are easy to perform, rapid, and inexpensive and frequently are used as screening tests for syphilis. Results become positive 4 to 6 weeks after infection or 1 to 3 weeks after the appearance of the primary lesion. Because these tests are quantitative, they can be used to measure the degree of disease activity or treatment effectiveness. The VDRL titer usually is high during the secondary stage of the disease and becomes less so during the tertiary stage. A falling titer during treatment suggests a favorable response. The fluorescent treponemal antibody absorption test is used to detect specific antibodies to *T. pallidum*. These qualitative tests are used to determine whether a positive result on a nonspecific test such as the VDRL or RPR is attributable to syphilis.

**Treatment**

The treatment of choice for syphilis is penicillin. Because of the spirochetes’ long generation time, effective tissue levels of penicillin must be maintained for several weeks. Long-acting injectable forms of penicillin are used. Tetracycline or doxycycline is used for treatment in people who are sensitive to penicillin. Pregnant women should be desensitized and treated with penicillin because erythromycin does not treat fetal infection. Sexual partners should be evaluated and treated prophylactically even though they may show no sign of infection.

**IN SUMMARY**

The vaginal–urogenital–systemic STIs—chlamydial infections, gonorrhea, and syphilis—can severely involve the genital structures and manifest as systemic infections. Gonorrheal and chlamydial infections can cause a wide variety of genitourinary complications in men and women, and both can cause ocular disease and blindness in neonates born to infected mothers. Syphilis is caused by a spirochete, *T. pallidum*. It can produce widespread systemic effects and is transferred to the fetus of infected mothers through the placenta.

Mrs. Tukey, 68 years of age, presents at a walk-in clinic with steadily worsening lower back pain of 2 weeks duration. She has had no medical care for 8 years. She does not recall any recent falls or trauma, but she moved several large boxes in her attic over the last couple of weeks. Eight years ago, she had her left hip pinned after a fracture. She has mild kyphosis, has smoked 1.5 packs of cigarettes per day for 40 years, and takes no medications. She states that “her mother had the bone disease that older women get.” Mrs. Tukey’s diet consists primarily of cereal and biscuits. She does not eat meat and rarely performs aerobic exercise. Her neurological examination is normal, but she has decreased range of motion in multiple joints and pain and tenderness upon palpation of her lower back muscles. She ranks her back pain as 6/10. Clinical findings include the following: temperature, 99°F; heart rate, 88/minute and regular; respiration rate, 14/minute; blood pressure, 110/64 mm Hg; and BMI, 23 (normal). Her bone density is significantly reduced (T score = −3.0), and the lumbar x-ray shows a fracture of the fifth lumbar vertebra (L5). Her serum calcium concentration is high (12.8 mg/dL), and her serum magnesium concentration is low (1.0 mg/dL). The diagnosis is a pathologic fracture secondary to osteoporosis. She is referred to a nutritionist and Meals-on-Wheels to address her nutritional issues, the Visiting Nurses Association for follow-up care, and the YMCA for a monitored exercise regimen involving swimming and light resistance exercise. She also is prescribed a bisphosphonate medication to inhibit bone resorption. You will read more about Mrs. Tukey in Chapter 58.
The bones of the skeletal system serve as a framework for the attachment of muscles, tendons, and ligaments. The skeletal system protects and maintains soft tissues in their proper position, provides stability for the body, and maintains the body’s shape. The bones act as a storage reservoir for calcium, and the central cavity of some bones contains the hematopoietic connective tissue in which blood cells are formed. Coordinated movement of the skeleton is made possible by the tendons and ligaments that join bones at joints.

For our purposes, the skeletal system is considered to include the bones and cartilage of the skeletal system, as well as the connective tissue structures (i.e., ligaments and tendons) that connect the bones and join muscles to bone.
tissue. Bones provide protection for internal organs and rigid support for the extremities. Cartilage provides for flexibility and cushioning of bony structures and for skeletal development in both prenatal and postnatal life.

**Bone Structures**

There are two types of mature bones: compact and cancellous bone (Fig. 56.1). Compact (cortical) bone, which forms the outer shell of a bone, has a densely packed, calcified intercellular matrix that makes it more rigid than cancellous bone. Cancellous (spongy) bone is found in the interior of bones and is composed of trabeculae, or spicules, of bone that form a lattice-like pattern. These lattice-like structures are lined with osteogenic cells and filled with red or yellow bone marrow. Cancellous bone is relatively light, but its structure is such that it has considerable tensile strength and weight-bearing properties. Although bones contain both cancellous and compact elements, their proportions vary in different bones throughout the body and in different parts of the same bone, depending on the relative needs for strength and lightness. Compact bone is the major component of tubular bones. It is also found along the lines of stress on long bones and forms an outer protective shell on other bones.

![Diagram of bone structures](image)

**KEY POINTS**

**THE SKELETAL SYSTEM**

- Two types of connective tissue are found in the skeletal system: (1) cartilage, a semirigid and slightly flexible structure that plays an essential role in prenatal and childhood development of the skeleton and as a surface for the articulating ends of skeletal joints, and (2) bone, which provides for the firm structure of the skeleton and serves as a reservoir for calcium and phosphate storage.
- Bone matrix is maintained by four types of cells: osteoblasts, which synthesize and secrete the constituents of bone; osteoclasts, which resorb surplus bone and are required for bone remodeling; osteocytes, which make up the osteoid tissue of bone; and osteoprogenitor cells, which are the source of all bone cells, except osteoclasts.

**Types of Bones**

Bones are classified by shape as long, short, flat, and irregular. Long bones are found in the upper and lower extremities. Short bones are irregularly shaped bones located in the ankle and the wrist. Except for their surface, which is compact bone, these bones are spongy throughout. Flat bones are composed of a layer of cancellous bone between two layers of compact bone. They are found in areas such as the skull and rib cage, where extensive protection of underlying structures is needed, or, as in the scapula, where a broad surface for muscle attachment must be provided. Irregular bones, because of their shapes, cannot be classified in any of the previous groups. This group includes bones such as the vertebrae and the bones of the jaw.

A typical long bone has a shaft, or diaphysis, and two ends, called epiphyses (Fig. 56.2). Long bones usually are narrow in the midportion and broad at the ends so that the weight they bear can be distributed over a wider surface. The shaft of a long bone is formed mainly of compact bone roughly hollowed out to form a marrow-filled medullary canal. The ends of long bones are covered with articular cartilage.

In growing bones, the part of the bone shaft that funnels out as it approaches the epiphysis is called the metaphysis. It is composed of bony trabeculae that have cores of cartilage. In the child, the epiphysis is separated from the metaphysis by the cartilaginous growth plate. After puberty, the metaphysis and epiphysis merge, and the growth plate is obliterated.

**Periosteum and Endosteum**

The periosteum covers the bones, except at their articular ends (see Fig. 56.1). The periosteum has an outer fibrous layer and an inner layer that contains the osteoprogenitor cells needed for bone growth and development. The periosteum contains blood vessels and acts as an anchorage point for vessels as they
**Figure 56.2** Long bone structure. (A) Description of a long bone. (B) The epiphysis. (C) The diaphysis. (From McConnell, T. H., Hull, K. L. (2011). *Human form human function: Essentials of anatomy & physiology* (p. 169, Figure 6-3). Philadelphia, PA: Lippincott Williams & Wilkins.)
enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the Haversian canals of compact bone. It is composed mainly of osteoprogenitor cells that contribute to the growth and remodeling of bone and are necessary for bone repair.1

**Bone Marrow**
Bone marrow occupies the medullary cavities of the long bones throughout the skeleton and the cavities of cancellous bone in the vertebrae, ribs, sternum, and flat bones of the pelvis. The cellular composition of the bone marrow varies with age and skeletal location. Red bone marrow contains developing red blood cells and is the site of blood cell formation. Yellow bone marrow is composed largely of adipose cells.1 At birth, nearly all of the marrow is red and hematopoietically active. As the need for red blood cell production decreases during postnatal life, red marrow is gradually replaced with yellow bone marrow in most of the bones. In the adult, red marrow persists in the vertebrae, ribs, sternum, and ilia.

**Blood Supply**
The compact bone of long tubular bones is provided with blood supply from two sources, nutrient arteries and perforating arteries. The nutrient arteries enter the bone through a nutrient foramen and supply the marrow space and the internal one half of the cortex.1 The perforating arteries are small arteries that extend inward from the periosteal arteries on the external surface of the periosteum and anastomose in the cortex with branches of the nutrient arteries coming from the bone marrow.1 The distribution of blood in the cortex occurs through the Haversian and Volkmann canals (Fig. 56.3). Haversian canals are spaces in the bone of the cortex that move parallel through the long axis of the bone for a short distance and then branch and communicate with other, similar canals. Each canal carries one or two blood vessels, lymphatics, and some nerve fibers.1 Volkmann canals, which also contain blood vessels, are spaces in the cortex that run perpendicular to the long axis of the cortex to connect adjacent Haversian canals.1

Cancellous bone is usually not penetrated by blood vessels. Instead, the bone cells of cancellous bone are nourished by diffusion from the endosteal surface through canaliculi, which interconnect their surrounding fluid-filled lacunae and extend to the bone surface.

**Bone Tissue**
Bone is connective tissue in which the intercellular matrix has been impregnated with inorganic calcium salts so that it has great tensile and compressive strength but is light enough to be moved by coordinated muscle contractions. The intercellular matrix is

---

**FIGURE 56.3** – Haversian systems as seen in a wedge of compact bone tissue. The periosteum has been peeled back to show a blood vessel entering a Volkmann canal. (Top) Osteocytes lying within lacunae; canaliculi permit interstitial fluid to reach each lacuna.
includes bone cells, blood vessels, and nerves and inorganic salts.

The organic matter consists of 88% type I collagen, 10% other proteins, and 1% to 2% lipids and glycosaminoglycans. The inorganic matter consists of hydroxyapatite, an insoluble macrocrystalline structure of calcium phosphate salts \( \text{Ca}_10(\text{PO}_4)_6(\text{OH})_2 \), and small amounts of calcium carbonate and calcium fluoride. Bone may also take up lead and other heavy metals, thereby removing these toxic substances from the circulation. This can be viewed as a protective mechanism. An example of this would be the antibiotic tetracycline being readily bound to calcium deposited in newly formed bones and teeth. When tetracycline is given during pregnancy, it can be deposited in the teeth of the fetus, causing discoloration and deformity. Similar changes can occur if the drug is given for long periods to children younger than 6 years of age.

**Lamellar and Woven Bone**

There are two types of bone tissue: lamellar bone and woven bone. Both forms of bone can be mineralized or unmineralized, the latter being referred to as osteoid. Lamellar bone is a strong, mature form of bone that is formed slowly and is highly organized. It is the mature bone found in the adult skeleton. Anything other than lamellar bone in an adult skeleton is abnormal. Lamellar bone is composed largely of cylindrical units called osteons or Haversian systems. The osteons consist of concentric lamellae of bone matrix, surrounding a central canal, called the Haversian canal, that contains the blood vessels and nerve supply for the osteon (see Fig. 56.3). In compact bone, the central Haversian canal runs essentially parallel to the long axis of the bone. Between the osteons are remnants of previous concentric lamellae, called the interstitial lamella. Circumferential lamellae follow the entire inner and outer shaft of a long bone, appearing much like the growth rings of a tree. Cancellous bone is also composed of lamellae, but, as mentioned previously, its trabeculae usually are not penetrated by blood vessels.

Woven bone, often referred to as bundle bone, is deposited more rapidly than lamellar bone. It is of low tensile strength, serving as temporary scaffolding for support. It is found in the developing fetus, in areas surrounding tumors and infections, and as part of a healing fracture.

**Bone Cells**

Four types of bone cells participate in the formation and maintenance of bone tissue: osteoprogenitor cells, osteoblasts, osteocytes, and osteoclasts (Table 56.1).

**Osteoprogenitor Cells.** The undifferentiated osteoprogenitor cells are found in the periosteum, endosteum, and epiphysyal plate of growing bone. These cells differentiate into osteoblasts and are active during normal growth. They may also be activated in adult life during healing of fractures and other injuries. Osteoprogenitor cells also participate in the continual replacement of worn-out bone tissue.

**Osteoblasts.** The osteoblasts, or bone-building cells, are responsible for the formation of the bone matrix. Bone formation occurs in two stages: ossification and calcification. Ossification involves the formation of osteoid, or prebone. Calcification of bone involves the deposition of calcium salts in the osteoid tissue. The osteoblasts synthesize collagen and other proteins that make up osteoid tissue. They also participate in the calcification process of the osteoid tissue, probably by controlling the availability of calcium and phosphate. In addition, the osteoblasts secrete many growth factors and tumor necrosis factor, which are needed for bone growth regulation.

Osteoblasts secrete the enzyme alkaline phosphatase, which is thought to act locally in bone tissue to raise calcium and phosphate levels to the point at which precipitation occurs. The activity of the osteoblasts undoubtedly contributes to the increase in serum levels of alkaline phosphatase that follows bone injury and fractures.

**Osteocytes.** The osteocytes are mature bone cells that are actively involved in maintaining the bony matrix. Death of the osteocytes results in the resorption of this matrix. The osteocytes lie in a small lake filled with extracellular fluid, called a lacuna, and are surrounded by a calcified intercellular matrix (see Fig. 56.3). Extracellular fluid-filled passageways permeate the calcified matrix and connect with the lacunae of adjacent osteocytes. These passageways are called canaliculi. Because diffusion does not occur through the calcified matrix of bone, the canaliculi serve as communicating channels for
the exchange of nutrients and metabolites between the osteocytes and the blood vessels on the surface of the bone layer.

**Osteoclasts.** Osteoclasts are “bone-chewing” cells that function in the resorption of bone, removing the mineral content and the organic matrix. They are large phagocytic cells of monocyte/macrophage lineage. Although the mechanism of osteoclast formation and activation remains elusive, it is known that parathyroid hormone (PTH) increases the number and resorptive function of the osteoclasts. Calcitonin is thought to reduce the number and resorptive function of the osteoclasts. Estrogen also reduces the number and function of the osteoclasts. Thus, the decrease in estrogen levels that occurs at menopause results in increased resorption of bone. The mechanism whereby osteoclasts exert their resorptive effect on bone is unclear.

*Remember* Mrs. Tukey from the unit opener case study? At 68 years of age and postmenopausal, Mrs. Tukey more than likely has little to no estrogen left; she has been diagnosed with osteoporosis. She is experiencing an increase in bone resorption to the point where she has actually experienced a lumbar vertebral 5 fracture.

These cells may secrete an acid that removes calcium from the bone matrix, releasing the collagenic fibers for digestion by osteoclasts or mononuclear cells. Osteoclasts, by virtue of their phagocytic lineage, also ingest minute particles of bone matrix and crystals, eventually dissolving and releasing them into the blood.

**Cartilage**

Cartilage is an essential part of the skeletal system. It constitutes the articular cartilage of joints. It is found in the tendinous and ligamentous insertions, menisci, the symphysis pubis, and insertions of joint capsules. It is also essential for growth before and after birth. In the embryo, most of the axial and appendicular skeleton is formed first as a cartilage model and then replaced by bone. In postnatal life, cartilage continues to play an essential role in the growth of long bones and persists as articular cartilage in the adult.

As a tissue, cartilage both resembles and differs from bone. Both of these connective tissue types consist of living cells, nonliving intercellular fibers, and an amorphous ground substance. The tissue cells are responsible for secreting and maintaining the intercellular substances in which they are housed. However, cartilage consists of more extracellular substance than bone, and its fibers are embedded in a firm gel rather than a calcified cement-like substance. Hence, cartilage has the flexibility of a firm plastic material rather than the rigid characteristics of bone. In fact, articular cartilage has many advantageous characteristics and is considered resilient. Therefore, it is used by surgeons performing cartilage replacement and in preservation surgeries.

There are three types of cartilage: elastic cartilage, hyaline cartilage, and fibrocartilage. Elastic cartilage contains some elastin in its intercellular substance. It is found in areas, such as the ear, where some flexibility is important. Pure cartilage is called hyaline cartilage (from a Greek word meaning “glass”) and is pearly white. It is the opaque type of cartilage seen on the articulating ends of fresh soup bones found in the supermarket. Fibrocartilage has characteristics that are intermediate between dense connective tissue and hyaline cartilage. It is found in the intervertebral disks, in areas where tendons are connected to bone, and in the symphysis pubis.

Hyaline cartilage is the most abundant type of cartilage. It forms much of the cartilage of the fetal skeleton. In the adult, hyaline cartilage forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, the articular cartilages, and the epiphyseal plates.

Cartilage cells, which are called chondrocytes, are located in lacunae. The lacunae are surrounded by an unciliated, gel-like intercellular matrix of collagen fibers and ground substance. Cartilage is devoid of blood vessels and nerves. The free surfaces of most hyaline cartilage, with the exception of articular cartilage, are covered by a layer of fibrous connective tissue called the perichondrium.

It has been estimated that approximately 80% of the wet weight of cartilage is water held in its gel structure. Because cartilage has no blood vessels, this tissue fluid allows the diffusion of gases, nutrients, and wastes between the chondrocytes and blood vessels outside the cartilage. Diffusion cannot take place if the cartilage matrix becomes impregnated with calcium salts, and cartilage dies if it becomes calcified. The other 20% of cartilage consists of two types of macromolecules: type II collagen and proteoglycans.

**Hormonal Control of Bone Formation and Metabolism**

The process of bone formation and mineral metabolism is complex. It involves the interplay among the actions of PTH, calcitonin, and vitamin D. Other hormones, such as cortisol, growth hormone, thyroid hormone, and the sex hormones, also influence bone formation directly or indirectly (Table 56.2).

**Parathyroid Hormone**

PTH is one of the important regulators of calcium and phosphate levels in the blood. Additionally, PTH has been found to be advantageous in increasing fracture healing if given supplementally to people with fractures. PTH prevents serum calcium levels from falling below and serum phosphate levels from rising above normal physiologic concentrations. The secretion of PTH is regulated by negative feedback; increased serum levels of ionized calcium inhibit PTH release. PTH maintains serum calcium levels by initiation of calcium release from bone, by conservation of calcium by the kidney, by enhanced intestinal absorption of calcium through activation of vitamin D, and by reduction of serum phosphate levels (Fig. 56.4). PTH also increases the movement of calcium and phosphate from bone into the extracellular fluid. Calcium is immediately released from the canaliculi and bone cells. A more prolonged release of
calcium and phosphate is mediated by increased osteoclast activity. In the kidney, PTH stimulates tubular reabsorption of calcium while reducing the reabsorption of phosphate. The latter effect ensures that increased release of phosphate from bone during mobilization of calcium does not produce an elevation in serum phosphate levels. This is important because an increase in calcium and phosphate levels could lead to crystallization in soft tissues. PTH increases intestinal absorption of calcium because of its ability to stimulate activation of vitamin D by the kidney.

**Calcitonin**

Whereas PTH increases blood calcium levels, the hormone calcitonin lowers blood calcium levels. Calcitonin, sometimes called thyrocalcitonin, is secreted by the parafollicular, or C, cells of the thyroid gland. Calcitonin inhibits the release of calcium from bone into the extracellular fluid. It is thought to act by causing calcium to become sequestered in bone cells and by inhibiting osteoclast activity. Calcitonin also reduces the renal tubular reabsorption of calcium and phosphate; the decrease in serum calcium level that follows administration of pharmacologic doses of calcitonin may be related to this action.

The major stimulus for calcitonin synthesis and release is an increase in serum calcium. The role of calcitonin in overall mineral homeostasis is uncertain. There are no clearly definable syndromes of calcitonin deficiency or excess, which suggests that calcitonin does not directly alter calcium metabolism. It has been suggested that the physiologic actions of calcitonin are related to the postprandial handling and processing of dietary calcium. This theory proposes that after meals, calcitonin maintains PTH secretion at a time when it normally would be reduced by calcium entering the blood from the digestive tract. Although excess or deficiency states associated with alterations in physiologic levels of calcitonin have not been observed, it has been shown that pharmacologic doses of the hormone reduce osteoclastic activity. Because of this action, calcitonin has proved effective in the treatment of Paget disease. The hormone is also used to reduce serum calcium levels during hypercalcemic crises.

**Vitamin D**

Vitamin D and its metabolites are not true vitamins but steroid hormones. There are two forms of vitamin D: vitamin D$_3$ (ergocalciferol) and vitamin D$_2$ (cholecalciferol). The two forms differ by the presence of a double bond, but they have identical biologic activity. The term vitamin D is used to

Chapter 56  Structure and Function of the Musculoskeletal System

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin D2 and vitamin D3. The vitamin D source comes from the skin and the intestine. Vitamin D is then hydroxylated into 25-hydroxyvitamin D3 in the liver and then goes to the kidneys where it is converted into 24,25-dihydroxyvitamin D3. Other metabolites of vitamin D have been and still are being discovered.

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin D2 and vitamin D3. The most important dietary sources of vitamin D are fish, liver, and irradiated milk. Because vitamin D is fat soluble, its absorption is mediated by bile salts and occurs by means of the lymphatic vessels. In the skin, ultraviolet radiation from sunlight spontaneously converts 7-dehydrocholesterol D3 to vitamin D3. A circulating vitamin D–binding protein provides a mechanism to remove vitamin D from the skin and make it available to the rest of the body.

With adequate exposure to sunlight, the amount of vitamin D that can be produced by the skin is usually sufficient to meet physiologic requirements. The importance of sunlight exposure is evidenced by population studies that report lower vitamin D levels in countries, such as England, that have less sunlight than the United States. Older adults who are housebound or institutionalized frequently have low vitamin D levels. The deficiency often goes undetected until there are problems such as pseudofractures or electrolyte imbalances. Seasonal variations in vitamin D levels probably reflect changes in sunlight exposure.

The most potent of the vitamin D metabolites is 1,25-(OH)2D3. This metabolite increases intestinal absorption of calcium and promotes the actions of PTH on resorption of calcium and phosphate from bone. Bone resorption by the osteoclasts is increased, and bone formation by the osteoblasts is decreased. There is also an increase in acid phosphatase and a decrease in alkaline phosphatase. Intestinal absorption and bone resorption increase the amount of calcium and phosphorus available to the mineralizing surface of the bone. The role of 24,25-(OH)2D3 is less clear. There is evidence that 24,25-(OH)2D3, in conjunction with 1,25-(OH)2D3, may be involved in normal bone mineralization.

Several hormones influence the regulation of vitamin D activity. PTH and prolactin stimulate 1,25-(OH)2D3 production by the kidney. States of hyperparathyroidism are associated with increased levels of 1,25-(OH)2D3, and hypoparathyroidism leads to lowered levels of this metabolite. Prolactin may have an ancillary role in regulating vitamin D metabolism during pregnancy and lactation. Calcitonin inhibits 1,25-(OH)2D3 production by the kidney. In addition to hormonal influences, changes in the concentration of ions such as calcium, phosphate, hydrogen, and potassium exert an effect on 1,25-(OH)2D3 and 24,25-(OH)2D3 production. Under conditions of phosphate and calcium deprivation, 1,25-(OH)2D3 levels are increased, whereas hyperphosphatemia and hypercalcemia decrease the levels of metabolite.

**IN SUMMARY**

Skeletal tissue consists of the bones and cartilage that form the appendicular and axial skeleton. There are two types of bone: compact bone, which forms the outer shell of a bone, and cancellous or spongy bone that forms the interior. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the Haversian canals of compact bone. The periosteum, the membrane that covers bones, contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. Mature bone is largely made up of cylindrical units called osteons, formed from concentric layers or lamellae of bone matrix and surrounding a central Haversian canal. The Haversian canals contain the blood vessels and nerve supply for the osteon. There are four types of bone
cells: osteocytes, or mature bone cells; osteoblasts, or bone-building cells; osteoclasts, which function in bone resorption; and osteoprogenitor cells, which differentiate into osteoblasts.

Cartilage is a firm, flexible type of skeletal tissue that is essential for growth before and after birth. There are three types of cartilage: elastic, hyaline, and fibrocartilage. Hyaline cartilage, which is the most abundant type, forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, and the articular cartilages.

The process of bone formation and mineral metabolism involves the interplay among the actions of PTH, calcitonin, and vitamin D. PTH acts to maintain serum levels of ionized calcium; it increases the release of calcium and phosphate from bone, the conservation of calcium and elimination of phosphate by the kidney, and the intestinal reabsorption of calcium through vitamin D. Calcitonin inhibits the release of calcium from bone and increases renal elimination of calcium and phosphate, thereby serving to lower serum calcium levels. Vitamin D functions as a hormone in regulating body calcium. It increases absorption of calcium from the intestine and promotes the actions of PTH on bone.

Articulations, or joints, are areas where two or more bones meet. The term arthro is the prefix used to designate a joint; for example, arthrology is the study of joints, and arthroplasty is the repair of a joint.

Tendons and Ligaments

In the skeletal system, tendons and ligaments are dense connective tissue structures that connect muscles and bones. The dense connective tissue found in tendons and ligaments has a limited blood supply and is composed largely of intercellular bundles of collagen fibers arranged in the same direction and plane (Fig. 56.6). Collagen is an inelastic and insoluble fibrous protein. Because of its molecular configuration, collagen has great tensile strength; the breaking point of collagenous fibers found in human tendons is reached with a force of several hundred kilograms per square centimeter. Fresh collagen is colorless, and tissues that contain large numbers of collagenous fibers generally appear white.

Tendons, which attach skeletal muscles to bone, are relatively inextensible because of their richness in collagen fibers. The collagen bundles of tendons aggregate into bundles that are enveloped by loose connective tissue, blood vessels, and nerves. Tendons that may rub against bone or other friction-generating surfaces are enclosed in double-layered sheaths. An outer connective tissue tube is attached to the structures surrounding the tendon, and an inner sheath encloses the tendon and is attached to it. The space between the inner and outer sheath is filled with a fluid similar to synovial fluid. Overuse can result in tendonitis or inflammation of the tendon.

Ligaments are fibrous thickenings of the articular capsule that join one bone to its articulating mate. They vary in size and shape depending on their specific role. Although most ligaments are considered inelastic, they are pliable enough to permit movement at the joints. However, ligaments tear rather than stretch when exposed to excess stress. Torn ligaments are extremely painful and accompanied by local swelling.

Types of Joints

Joints exhibit a variety of movements. Some joints have no movement; others allow only slight movement; and some are freely moveable, such as the shoulder joint. There are two classes of joints based on their movement and the presence or absence of a joint cavity: synarthroses and synovial joints.

Synarthroses

Synarthroses are joints that lack a joint cavity and move little or not at all. There are three types of synarthroses: synostoses, synchondroses, and syndesmoses. Synostoses are non-movable joints in which the surfaces of the bones are joined by dense connective tissue or bone. The bones of the skull are joined by synostoses. They are joined by dense connective tissue in children and young adults and by bone in older adults. Synchondroses are joints in which bones are connected by hyaline cartilage and have limited motion. The ribs are attached to the sternum by this type of joint. Syndesmoses permit a certain amount of movement; they are separated by a fibrous disk and joined by interosseous ligaments. The symphyses pubis of the pelvis and the vertebral bodies joined by intervertebral disks are examples of syndesmoses.
**Fibroblast**

**Form**
- Cells: a few fibroblasts
- Extracellular matrix: collagenous fibers arranged in bundles (shown here) or irregular networks

**Function**
- Withstands strong forces
- Attaches structures together
- Forms scar tissue, ligaments, tendons, joint capsules, organ coverings (fascia)

---

**Synovial (Diarthrodial) Joints**

Synovial or diarthrodial joints are freely movable joints. Most joints in the body are of this type. Although they are classified as freely movable, their movement ranges from almost none (e.g., sacroiliac joint), to simple hinge movement (e.g., interphalangeal joint), to movement in many planes (e.g., shoulder or hip joint). The bony surfaces of these joints are covered with thin layers of articular cartilage, and the cartilaginous surfaces of these joints slide past each other during movement. Diarthrodial joints are the joints most frequently affected by rheumatic disorders.

In a diarthrodial joint, the articulating ends of the bones are not connected directly but are indirectly linked by a strong fibrous capsule (i.e., joint capsule) that surrounds the joint and is continuous with the periosteum (Fig. 56.7). This capsule supports the joint and helps to hold the bones in place. Additional support may be provided by ligaments that extend between the bones of the joint.

The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovium surrounds the tendons that pass through the joints and the free margins of other intra-articular structures such as ligaments and menisci. The synovium forms folds that surround the margins of articulations but do not cover the weight-bearing articular cartilage. These folds permit stretching of the synovium so that movement can occur without tissue damage.

The synovium secretes a slippery fluid with the consistency of uncooked egg white called synovial fluid. This fluid acts as a lubricant and facilitates the movement of the articulating surfaces of the joint. Normal synovial fluid is clear or pale yellow, does not clot, and contains fewer than 100 cells/mm³. The cells are predominantly mononuclear cells derived from the synovium. The composition of the synovial fluid is altered in many inflammatory and pathologic joint disorders. Aspiration and examination of the synovial fluid play an important role in the diagnosis of joint diseases.

The articular cartilage is an example of hyaline cartilage and is unique in that its free surface is not covered with perichondrium. It has only a peripheral rim of perichondrium, and calcification of the portion of cartilage abutting the bone may limit or preclude diffusion from blood vessels supplying the subchondral bone. Articular cartilage is apparently nourished by the diffusion of substances contained in the
synovial fluid bathing the cartilage. Regeneration of most cartilage is slow. It is accomplished primarily by growth that requires the activity of perichondrium cells. In articular cartilage, which has no perichondrium, superficial injuries heal slowly.

**Blood Supply and Innervation**

All the tissues of synovial joints, except the articulating surfaces of the articulating cartilage, receive nourishment either directly or indirectly from blood vessels. The articulating areas are nourished indirectly by the synovial fluid that is distributed over the surface of the articular cartilage.

The blood supply to a joint arises from blood vessels that enter the subchondral bone at or near the attachment of the joint capsule and form an arterial circle around the joint. The synovial membrane has a rich blood supply, and constituents of plasma diffuse rapidly between these vessels and the joint cavity. Because many of the capillaries are near the surface of the synovium, blood may escape into the synovial fluid after relatively minor injuries. Healing and repair of the synovial membrane usually are rapid and complete. This is important because synovial tissue is injured in many surgical procedures that involve the joint.

The nerve supply to joints is provided by the same nerve trunks that supply the muscles that move the joints. These nerve trunks also supply the skin over the joints. As a rule, all the peripheral nerves that cross the articulation innervate each joint of an extremity. This accounts for the referral of pain from one joint to another. For example, pain from injury to the knee is often experienced as pain in the hip. The synovial membrane is innervated only by autonomic fibers that control blood flow. It is relatively free of pain fibers, as evidenced by the fact that surgical procedures on the joint are often done under local anesthesia. The joint capsule and the ligaments have pain receptors. These receptors are more easily stimulated by stretching and twisting than are other joint structures. Pain arising from the capsule tends to be diffuse and poorly localized.

The tendons and ligaments of the joint capsule are sensitive to position and movement, particularly stretching and twisting. These structures are supplied by the large sensory nerve fibers that form proprioceptor endings. The proprioceptors function reflexively to adjust the tension of the muscles that support the joint and are particularly important in maintaining muscular support for the joint. For example, when a weight is lifted, there is a proprioceptor-mediated reflex contraction and relaxation of appropriate muscle groups to support the joint and protect the joint capsule and other joint structures. Loss of proprioception and reflex control of muscular support leads to destructive changes in the joint.

**Bursae**

In some diarthrotic joints, the synovial membrane forms closed sacs that are not part of the joint. These sacs, called bursae, contain synovial fluid. Their purpose is to prevent friction on a tendon. Bursae occur in areas where pressure is exerted because of close approximation of joint structures (Fig. 56.8). Such conditions occur when tendons are deflected over bone or where skin must move freely over bony tissue. Bursae may become injured or inflamed, causing discomfort, swelling, and limitation in movement of the involved area. A bunion is an inflamed bursa of the metatarsophalangeal joint of the great toe.

**Intra-Articular Menisci**

Intra-articular menisci are fibrocartilage structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. Menisci may extend part way through the joint and
have a free inner border, as at the lateral and medial articular surfaces of the knee, or they may extend through the joint, separating it into two separate cavities, as in the sternoclavicular joint. The menisci of the knee joint may be torn as the result of an injury.

IN SUMMARY

Articulations or joints are areas where two or more bones meet. Tendons and ligaments are dense connective tissue structures that connect muscles and bones. Tendons connect muscles to bones and ligaments connect the movable bones of joints.

Synarthroses are joints in which bones are joined together by fibrous tissue, cartilage, or bone; they lack a joint cavity and have little or no movement. Synovial or diarthrodial joints are freely movable. The surfaces of the articulating ends of bones in synovial joints are covered with a thin layer of articular cartilage, and they are enclosed in a fibrous joint capsule. The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovial fluid, which is secreted by the synovium into the joint capsule, acts as a lubricant and facilitates movement of the joint’s articulating surfaces. Bursae, which are closed sacs containing synovial fluid, prevent friction in areas where tendons are deflected over bone or where skin must move freely over bony tissue.

Menisci are fibrocartilaginous structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. The menisci may have a free inner border, or they may extend through the joint, separating it into two cavities.

REVIEW EXERCISES

1. Often pain from injury to the knee is experienced as pain in the hip.  
   A. Explain why this might occur.

2. Persons with end-stage kidney disease have a deficiency of activated vitamin D.  
   A. Explain why this occurs and what effect it would have on their bones.

3. Recent studies have revealed that estrogen deficiency as well as normal aging may produce a decrease in osteoblast activity.  
   A. Explain how this would contribute to the development of osteoporosis.

The musculoskeletal system includes the bones, joints, and muscles of the body together with associated structures such as ligaments and tendons. A human infant is born with over 300 bones. As humans age some bones fuse, so an adult has approximately 206 bones. The musculoskeletal system is subject to a large number of disorders. These disorders affect people in all age-groups and walks of life, causing pain and disability. The discussion in this chapter focuses on the effects of trauma, infections, ischemia, and neoplasms on the musculoskeletal structures of the body.
A broad spectrum of musculoskeletal injuries result from numerous physical forces, including blunt tissue trauma, disruption of tendons and ligaments, and fractures of bony structures. Many of the forces that cause injury to the musculoskeletal system are typical for a particular environmental setting, activity, or age-group. Trauma resulting from high-speed motor vehicle accidents is ranked as the number one killer of adults younger than 44 years of age. Motorcycle accidents are especially common, with fractures of the distal radius, midshaft femur, and radius occurring most often.

Unintentional falls are the number one cause of nonfatal injuries in children and adolescents between 0 and 19 years of age in the United States. Childhood falls cause approximately 2.8 million emergency department visits each year. More than half of the 7 million sports injuries are experienced by people between the ages of 5 and 24 years.

Falls are the most common cause of injury in people 65 years of age and older. Current statistics indicate that one out of three people in this age-group experience at least one fall each year. Impaired vision and hearing, dizziness, and unsteadiness of gait contribute to falls in the older adult. Among older adults, the majority of fractures are caused by falls. These falls often are compounded by osteoporosis, or bone atrophy, which makes fractures more likely. Fractures of the vertebrae, distal radius, hip, and shoulder are particularly common in this age-group.

**Athletic Injuries**

Athletic injuries are either acute injuries or overuse injuries. Acute injuries are caused by sudden trauma and include injuries to soft tissues (contusion, strains, and sprains) and to bone (fractures). Overuse injuries have been described as chronic injuries and result from playing sports and working out without allowing sufficient healing time for the initial injury. Overuse injuries have been identified as representing one-half of all pediatric-related sports injuries. They commonly occur in the elbow and in tissue where tendons attach to the bone, such as the heel, knee, and shoulder. Contact sports pose a greater threat for injury to the neck, spine, and growth plates in children and adolescents, who have not yet reached maturity. Injuries can be prevented by proper training, use of safety equipment, and limiting the level of competition according to skill and size of the child or adolescent, rather than chronicologic age. In order to diagnose musculoskeletal trauma and overuse injuries, current practice recommends magnetic resonance imaging (MRI) once all of the classic treatment has been conducted and the problem still exists.

**Soft Tissue Injuries**

Most skeletal injuries are accompanied by soft tissue (muscle, tendon, or ligament) injuries. These injuries include contusions, hematomas, and lacerations. They are discussed here because of their association with musculoskeletal injuries.

A **contusion** is an injury to soft tissue that results from direct trauma and is usually caused by striking a body part against a hard object. With a contusion, the skin overlying the injury remains intact. Initially, the area becomes ecchymotic (i.e., black and blue) because of local hemorrhage; later, the discoloration gradually changes to brown and then to yellow as the blood is reabsorbed. A large area of local hemorrhage is called a **hematoma**. Hematomas cause pain as blood accumulates and exerts pressure on nerve endings. The pain increases with movement or when pressure is applied to the area. The pain and swelling of a hematoma take longer to subside than those accompanying a contusion. A hematoma may become infected because of bacterial growth. Unlike a contusion, which does not drain, a hematoma may eventually split the skin because of increased pressures and produce drainage. Treatment of a contusion and a hematoma consists of elevating the affected part and applying cold every 4 hours for about 20 minutes at a time to reduce the bleeding into the area. A hematoma may need to be aspirated.

A **laceration** is an injury in which the skin is torn or its continuity is disrupted. The seriousness of a laceration depends on the size and depth of the wound and on whether there is contamination from the object that caused the injury. Puncture wounds from nails or rusted metal provide the setting for growth of anaerobic bacteria such as those that cause tetanus and gas gangrene.

Lacerations are usually treated by wound closure, which is done after the area is sufficiently cleaned. The closed wound is then covered with a sterile dressing. It is important to minimize contamination of the wound and to control bleeding. Contaminated wounds and open fractures are copiously irrigated and debrided, and the skin usually is left open to heal to prevent the development of an anaerobic infection or a sinus tract. Antimicrobial agents are selectively used based on the suspected nature of the contaminants.

**Joint (Musculotendinous) Injuries**

Joints, or articulations, are sites where two or more bones meet. Joints (i.e., diarthrodial joints) are supported by tough bundles of collagenous fibers called ligaments that attach to the joint capsule and bind the articular ends of bones together, and by tendons that join muscles to the periosteum of the articulating bones. Joint injuries involve mechanical overloading or forcible twisting or stretching.

**Strains and Sprains**

**Strains.** A **strain** is a stretching injury to a muscle or a musculotendinous unit caused by mechanical overloading. This type of injury may result from an unusual muscle contraction or an excessive forcible stretch. Although there usually is no external evidence of a specific injury, pain, stiffness, and swelling exist. The most common sites for muscle strains are the lower back and the cervical region of the spine. The elbow and the shoulder are also supported by musculotendinous units, which are subject to strains. Foot strain is associated with the weight-bearing stresses of the feet. It may be caused by inadequate muscular and ligamentous support, being overweight, or excessive exercise such as standing, walking, or running.

In the lumbar and cervical spine regions, muscle strains are more common than sprains. Mechanical low back pain is becoming increasingly common in the adolescent athlete. Overuse, especially hyperextension of the lumbar spine in such sports as track, wrestling, gymnastics, and diving, can tear the
muscles, fascia, and ligaments. Careful diagnosis is necessary because chronic low back pain may indicate a stress fracture. Fractures near the top and bottom surface of the vertebrae can occur when the growing lumbar spine is overstressed, causing the disks to push into the spinal nerve roots. Early detection and treatment are important to prevent complications and disability. Treatment of back strains consists of a short period of rest and mild analgesics followed by a gradual return to activities. Cold packs or ice should be used to reduce pain and swelling of the affected area. Exercises, correct posture, and good body mechanics help to reduce the risk for reinjury.

**Sprains.** A *sprain*, which involves the ligamentous structures (strong bands of connective tissue) surrounding the joint, resembles a strain, but the pain and swelling subside more slowly. It usually is caused by abnormal or excessive movement of the joint. With a sprain, the ligaments may be incompletely torn or, as in a severe sprain, completely torn or ruptured (Fig. 57.1). Occasionally, a chip of bone is evident when the entire ligament, including part of its bony attachment, has been ruptured or torn from the bone. The signs of sprain are pain, rapid swelling, heat, disability, discoloration, and limitation of function.

Any joint may be sprained, but the ankle joint is most commonly involved, especially in fast-moving injuries in which an ankle or knee can be suddenly twisted. Most ankle sprains occur in the lateral ankle when the foot is turned inward under a person, forcing the ankle into inversion beyond the structural limits. Other common sites of sprain are the knee (the collateral ligament and anterior cruciate ligament [ACL]) and elbow (the ulnar side). As with a strain, the soft tissue injury that occurs with a sprain is not evident on the radiograph. Wrist sprains most often occur with a fall on an outstretched hand.

**Healing.** If properly treated, musculotendinous injuries usually heal with the restoration of the original tensile strength. Repair is accomplished by fibroblasts from the inner tendon sheath or, if the tendon has no sheath, from the loose connective tissue that surrounds the tendon. Capillaries infiltrate the injured area during the initial healing process and supply the fibroblasts with the materials they need to produce large amounts of collagen. Formation of the long collagen bundles occurs within the first 2 weeks, and although tensile strength increases steadily thereafter, it is not sufficient to permit strong tendon pulls for approximately 2 months. During the healing process, there is a danger that muscle contraction will pull the injured ends apart, causing the tendon to heal in the lengthened position. There is also a danger that adhesions will develop in areas where tendons pass through fibrous channels, such as in the distal palm of the hands, rendering the tendon useless.

**Treatment.** The treatment of muscle strains and ligamentous sprains is similar in several ways. For an injured extremity, elevation of the part followed by local application of cold may be sufficient. Compression, accomplished through the use of adhesive wraps or a removable splint, helps reduce swelling and provides support. A cast is applied for severe sprains, especially those severe enough to warrant surgical repair. Immobilization for a muscle strain is continued until the pain and swelling have subsided. In a sprain, the affected joint is immobilized for several weeks. Immobilization may be followed by graded active exercises. Early diagnosis, treatment, and rehabilitation are essential in preventing chronic ligamentous instability.

**KEY POINTS**

**JOINT INJURIES**

- Joints are the weakest part of the skeletal system and common sites for injury due to mechanical overloading or forcible twisting or stretching.
- Injury can include damage to the tendons, which connect muscle to bone; ligaments, which hold bones together; or the cartilage that covers the articular surface.
- Healing of the dense connective tissue involved in joint injuries requires time to restore the structures so that they are strong enough to withstand the forces imposed on the joint. Ligamentous injuries may require surgical intervention with approximation of many fibrous strands to facilitate healing.
- Injuries involving the articular cartilage may predispose to later joint disease.
**Dislocations**

A *dislocation* involves the displacement or separation of the bone ends of a joint with loss of articulation. It usually follows a severe trauma that disrupts the holding ligaments. Dislocations are seen most often in the shoulder and acromioclavicular joints. Most traumatic shoulder dislocations are anterior or are recurrent episode of a previous injury: either a dislocation or a subluxation. A *subluxation* is a partial dislocation in which the bone ends in the joint are still in partial contact with each other.

Dislocations can be congenital, traumatic, or pathologic. Congenital dislocations occur in the hip and knee. Traumatic dislocations occur after falls, blows, or rotational injuries. For example, car accidents often cause dislocations of the hip and accompanying acetabular fractures because of the direction of impact. This is true of people wearing seat belts and those who are unrestrained. In the shoulder and patella, dislocations may become recurrent, especially in athletes. They recur with the same motion but require less and less force each time to cause the damage.

Pathologic dislocation in the hip is a late complication of infection, rheumatoid arthritis, paralysis, and neuromuscular diseases. Dislocations of the phalangeal joints are not serious and are usually reduced by manipulation. Less common sites of dislocation, seen mainly in young adults, are the wrist and metatarsal region. They usually are the result of direct force, such as a fall on an outstretched hand. Diagnosis of a dislocation is based on history, physical examination, and radiologic findings. The symptoms are pain, deformity, and limited movement.

The treatment depends on the site, mechanism of injury, and associated injuries such as fractures. Dislocations that do not reduce spontaneously usually require manipulation or surgical repair. Various surgical procedures also can be used to prevent redislocation of the patella, shoulder, or acromioclavicular joints. Immobilization is necessary for several weeks after reduction of a dislocation to allow healing of the joint structures. In dislocations affecting the knee, alternatives to surgery are isometric quadriceps-strengthening exercises and a temporary brace.

**Loose Bodies**

Loose bodies are small pieces of bone or cartilage within a joint space. These can result from trauma to the joint or may occur when cartilage has worn away from the articular surface, causing a necrotic piece of bone to separate and become free floating. The symptoms are painful and often cause catching and locking of the joint. Loose bodies are commonly seen in the knee, elbow, hip, and ankle. The loose body repeatedly gets caught in the crevice of a joint, pinching the underlying healthy cartilage. Unless the loose body is removed, it may cause osteoarthritis and restricted movement. The treatment consists of removal using operative arthroscopy. Studies indicate the most common areas for the location of loose bodies in joints include popliteal cysts, in the lateral and medial gutters, and under the menisci. In the hips, it is common to find loose bodies in the inner position of the acetabulum.

**Shoulder and Rotator Cuff Injuries**

The shoulder is a complex series of joints that produce extraordinary range of motion. The extreme mobility is accomplished at the expense of relative instability. This instability, combined with its relatively exposed position, makes the shoulder extremely vulnerable to injuries such as sprains and dislocations and degenerative processes such as rotator cuff disorders.

The shoulder is composed of three bones: the scapula, the clavicle, and the humerus. The scapula articulates with the humerus by way of the glenoid cavity and with the clavicle at the acromion process as well as closely with the chest wall. Clavicle fractures are among the most common fractures of childhood. The typical mechanism of fracture is a fall on the point of the shoulder.

Three articulations form the shoulder joint—the acromioclavicular joint that joins the clavicle to the acromion of the scapula, the sternoclavicular joint that joins the sternum to the clavicle, and the glenohumeral joint that connects the head of the humerus to the relatively shallow glenoid cavity in the scapula. The stability of these joints is provided by a series of muscles and tendons. Sprains of the acromioclavicular joint usually occur as a result of a blow to the top of the shoulder but are known to occur with a fall to the lateral or posterior aspects of the shoulder. The most common site of shoulder dislocation is the glenohumeral joint. Most acute dislocations involve anterior displacement of the humeral head with respect to the glenoid cavity, the result of the shoulder being abducted and forcefully extended and rotated. Other mechanisms include a fall on an outstretched arm or a blow to the posterior shoulder.

Motion of the arm involves the coordinated movement of muscles of the rotator cuff (supraspinatus, teres minor, infraspinatus, subscapularis) and their musculotendinous attachments. These muscles are separated from the overlying coracocromial arch by two bursae, the subdeltoid and subcoracoid. These two bursae, sometimes referred to as the subacromial bursae, often communicate and are affected by lesions of the rotator cuff.

The rotator cuff is like other muscle groups of the body in that its risk for injury increases when it is required to perform a high-stress function in an unconditioned state. Rotator cuff injuries and impingement disorders can result from a number of causes, including excessive use, a direct blow, or stretch injury, usually involving throwing or swinging, as with baseball pitchers or tennis players. Complete tears or rupture of the rotator cuff usually occur in young persons after severe trauma (Fig. 57.2).

Overuse and degenerative disorders have a slower onset and are seen in older adults with minor or no trauma. The tendons of the rotator cuff fuse together near their insertions into the tuberosities of the humerus to form the musculotendinous cuff. Degeneration of these tendons can result from a number of factors, including repetitive microtrauma, impairment of vascularity as a result of aging, or shoulder instability with secondary overload of the cuff. Degeneration is most
severe near the tendon insertion, with the supraspinous being affected most often. Thickening of the musculotendinous unit decreases the distance between the cuff and the overlying coracoacromial arch. Pain and impingement may be noted when motions of the arm squeeze and pinch these tissues between the humerus and the overlying arch. Severe tendinitis also can cause either a partial or complete rotator cuff tear.12

Several physical examination maneuvers are used to define shoulder pathologic processes.13,14 The history and mechanism of injury are important. In addition to standard radiographs, arthrography, computed tomography (CT), or MRI may be used. Arthroscopic examination under anesthesia may be used for diagnostic purposes and operative arthroscopy may be done to repair severe tears. Conservative treatment with anti-inflammatory agents, corticosteroid injections, and physical therapy often is undertaken. A period of rest is followed by a customized exercise and rehabilitation program to improve strength, flexibility, and endurance. After surgery of rotator cuff tears it can take 6 to 12 months before the surgical site is healed.12,13

**Knee Injuries**

The knee is a common site of injury, particularly sport-related injuries in which the knee is subjected to abnormal twisting and compression forces. These forces can result in injury to the menisci, patellar subluxation and dislocation, and chondromalacia. Knee injuries in young adulthood and both knee and hip injuries in middle age substantially increase the risk for osteoarthritis in the same joint later in life.12
Meniscus Injuries. The menisci are C-shaped plates of fibrocartilage that are superimposed between the condyles of the femur and tibia. There are two menisci in each knee, a lateral and medial meniscus (Fig. 57.3). The menisci are thicker at their exterior margins and taper to thin, unattached edges at their interior margin. They are firmly attached at their ends to the intercondylar area of the tibia and are supported by the coronary and transverse ligaments of the knee. The menisci play a major role in load bearing and shock absorption. They also help to stabilize the knee by deepening the tibial socket and maintaining the femur and tibia in proper position. In addition, the meniscus assists in joint lubrication and serves as source of nutrition for articular cartilage in the knee.

Meniscus injury commonly occurs as the result of a rotational injury from a sudden or sharp pivot or a direct blow to the knee, as in hockey, basketball, or football. It is often associated with other injuries, such as a torn ACL. The type and location of the meniscal tear are determined by the magnitude and direction of the force that acts on the knee and the position of the knee at the time of injury. Meniscus tears can be described by their appearance (e.g., parrot beak, bucket handle) or their location (e.g., posterior horn, anterior horn). The injured knee is edematous and painful, especially with sitting with the knees bent. Occasionally, the person experiences weakness of the knee.

Diagnosis is made by examination and confirmed by MRI. A regular radiograph may be needed to rule out osteoarthritis. Initial treatment of meniscal injuries may be conservative. The knee may be placed in a removable knee immobilizer. Isometric quadriceps exercises may be prescribed. Activity usually is restricted until complete motion is recovered. Arthroscopic meniscectomy may be performed when there is recurrent or persistent locking, recurrent effusion, or disabling pain.

There is evidence that loss of meniscal function is associated with progressive deterioration of knee function. Damaged articular cartilage has a limited capacity to heal because of its avascular nature and inadequate mobilization of regenerative cells. Meniscal reconstruction procedures have been developed to preserve these functions before significant degenerative changes develop, thus preventing a total joint replacement later in life.

Patellar Subluxation and Dislocations. Recurrent subluxation and dislocation of the patella (i.e., knee cap) are common injuries in young adults. They account for approximately 10% of all athletic injuries and are more common in women. Sports such as skiing or tennis may cause stress on the patella. These sports involve external rotation of the foot and lower leg with knee flexion, a position that exerts rotational stresses on the knee. Congenital knee variations are also a predisposing factor.

There is often a sensation of the patella “popping out” when the dislocation occurs. Other complaints include the knee giving out, swelling, crepitus, stiffness, and loss of range of motion. Treatment can be difficult, but nonsurgical methods are used first. They include immobilization with the knee extended, bracing, administration of anti-inflammatory agents, and isometric quadriceps-strengthening exercises. Surgical intervention often is necessary and generally involves reduction and internal fixation or removal.

Chondromalacia. Chondromalacia, or softening of the articular cartilage, is seen most commonly on the undersurface of the patella and occurs most frequently in young adults. It can be the result of recurrent subluxation of the patella or overuse in strenuous athletic activities. Persons with this disorder typically complain of pain, particularly when climbing stairs or sitting with the knees bent. Occasionally, the person experiences weakness of the knee.

It is difficult to diagnose chondromalacia patellae without using an MRI and arthroplasty. Treatment consists of rest, isometric exercises, and application of ice after exercise. Part of the patella may be surgically removed in severe cases. In less severe cases, the soft portion is shaved using a saw inserted through an arthroscope. Articular cartilage maintenance and repair is a complex process. Polypeptide growth factors that direct cells to divide, differentiate, migrate, and produce matrix appear to have a role in the preservation and degradation of the articular cartilage matrix.

Hip Injuries

The hip is a ball-and-socket joint in which the femoral head articulates deeply in the acetabulum. The proximal part of the femur consists of a head, neck, and greater trochanter. The vascular anatomy of the femoral head is of critical importance in any disorder of the hip. The main sources of blood supply are the intramedullary vessels and the retinacular arteries arising from the circumflex femoral arteries, both of which course from the intertrochanteric region proximally to nourish the...
Fractures of the Hip. Hip fracture is a major public health problem in the Western world, particularly among older adults. It results in hospitalization, disability, and loss of independence. The incidence of hip fractures increases with age. The incidence is also higher in white women compared with nonwhite women. Risk factors for hip fracture include low body mass index (BMI), tall body structure, use of benzodiazepines, lack of exercise, previous injury to lower body extremity, vision problems, and confusion. Osteoporosis and osteopenia is an important contributing factor.

Most hip fractures result from falls. Occasionally, the person may actually fracture the hip before falling, the fracture being caused by twisting or excessive force on a femur that has been weakened by osteoporosis or neoplasms. The characteristics of the fall (the direction, site of impact, and protective response) and environmental factors are important factors influencing the risk of hip fracture from a fall.

A hip fracture is classified according to the anatomic part of the hip where the fracture occurs. Generally it is a fracture of the proximal femur. Femoral neck fractures are located in the area distal to the femoral head but proximal to the greater and lesser trochanters and are considered intracapsular because they are located within the capsule of the hip joint. Intertrochanteric fractures occur in the metaphyseal region between the greater and lesser trochanter. Subtrochanteric fractures are those that occur just below the greater trochanter. Femoral neck and intertrochanteric fractures account for the majority of hip fractures, occurring in approximately equal proportions.

The location of a hip fracture is important in terms of blood flow to the femoral head, which receives its blood supply from vessels that course proximally up the femoral neck (see Fig. 57.4). Subtrochanteric and intertrochanteric fractures that occur distal to these vessels do not usually disturb the blood supply to the femoral head, whereas femoral neck fractures, particularly those involving marked displacement, often disrupt the blood supply to the femoral head and are therefore associated with increased incidence of complications (nonunion and avascular necrosis).

Most hip fractures are diagnosed based on clinical findings and standard radiographs. A bone scan or MRI may be done when the radiograph is negative but the clinical findings support the diagnosis of hip fracture. Avascular necrosis often occurs with a hip trauma but can also occur without trauma, so it needs to be diagnosed with an MRI.

Impacted fractures have a better prognosis in terms of healing and are often treated nonoperatively or by simple internal fixation to provide stability. Displaced intracapsular fractures in the elderly are usually best treated by surgical hip replacement and early mobilization. Young, healthy people are treated by reduction of the fracture and internal fixation. This method allows for preservation of the femoral head if at all possible so a prosthesis is not needed. Intertrochanteric fractures are usually treated with open reduction and internal fixation. Nonunion in this type of fracture is much less common than with intracapsular fractures. Weight bearing,
However, is usually restricted for 3 months until union of the fracture has occurred.

**Fractures**

Fracture, or discontinuity of the bone, is the most common type of bone lesion. Normal bone can withstand considerable compression and shearing forces and, to a lesser extent, tension forces. A fracture occurs when more stress is placed on the bone than it is able to absorb. Grouped according to cause, fractures can be divided into three major categories: fractures caused by sudden injury, fatigue or stress fractures, and pathologic fractures. The most common fractures are those resulting from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from falling on an outstretched hand. A fatigue fracture results from repeated wear on a bone. Pain associated with overuse injuries of the lower extremities, especially posterior medial tibial pain, is one of the most common symptoms that physically active persons, such as runners, experience. Stress fractures in the tibia may be confused with "shin splints," a nonspecific term for pain in the lower leg from overuse in walking and running, because they frequently do not appear on x-ray films until 2 weeks after the onset of symptoms.

A pathologic fracture occurs in bones that already are weakened by disease or tumors. Fractures of this type may occur spontaneously with little or no stress. The underlying disease state can be local, as with infections, cysts, or tumors, or generalized, as in osteoporosis, Paget disease, or cancer metastasis.

**Classification**

Fractures usually are classified according to location, type, and direction or pattern of the fracture line (Fig. 57.5). A long bone is divided into three parts: proximal, midshaft, and distal. A fracture of the long bone is described in relation to its position in the bone. Other descriptions are used when the fracture affects the head or neck of a bone, involves a joint, or is near a prominence such as a condyle or malleolus.

The type of fracture is determined by its communication with the external environment, the degree of break in continuity of the bone, and the character of the fracture pieces. A fracture can be classified as open or closed. When the bone fragments have broken through the skin, the fracture is called an open or compound fracture. Open fractures often are complicated by infection, osteomyelitis, delayed union, or nonunion. In a closed fracture, there is no communication with the outside skin.

The degree of a fracture is described in terms of a partial or complete break in the continuity of bone. A greenstick fracture, which is seen in children, is an example of a partial break in bone continuity and resembles that seen when a young sapling is broken. This kind of break occurs because children's bones, especially until approximately 10 years of age, are more resilient than the bones of adults.

The character of a fracture is determined by its pieces. A comminuted fracture has more than two pieces. A compression fracture, as occurs in the vertebral body, involves two bones that are crushed or squeezed together. A fracture is called impacted when the fracture fragments are wedged together. This type usually occurs in the humerus, often is less serious, and usually is treated without surgery.

The direction of the trauma or mechanism of injury produces a certain configuration or pattern of fracture. The pattern of a fracture indicates the nature of the trauma and provides information about the easiest method for reduction. Reduction is the restoration of a fractured bone to its normal anatomic position. Transverse fractures are caused by simple angular forces. A spiral fracture results from a twisting motion, or torque. A transverse fracture is not likely to become displaced or lose its position after it is reduced. On the other hand, spiral, oblique, and comminuted fractures often are unstable and may change position after reduction.

**Clinical Manifestations**

The signs and symptoms of a fracture include pain, tenderness at the site of bone disruption, swelling, loss of function, deformity of the affected part, and abnormal mobility. The deformity varies according to the type of force applied, the area of the bone involved, the type of fracture produced, and the strength and balance of the surrounding muscles.
complications depends on the severity of the fracture and the area of the body that is involved. For example, bone fragments from a skull fracture may cause injury to brain tissue, or multiple rib fractures may lead to a flail chest and respiratory insufficiency. With flail chest, the chest wall on the fractured side becomes so unstable that it may move in the opposite direction as the person breathes (*i.e.*, in during inspiration and out during expiration).

### Diagnosis

Diagnosis is the first step in the care of fractures and is based on history and physical manifestations. X-ray examination is used to confirm the diagnosis and direct the treatment. The ease of diagnosis varies with the location and severity of the fracture. In the trauma patient, the presence of other, more serious injuries may make diagnosis more difficult. A thorough history includes the mechanism, time, and place of the injury; first recognition of symptoms; and any treatment initiated. A complete history is important because a delay in seeking treatment or a period of weight bearing on a fracture may cause further injury or displacement of the fracture.

Determination of the severity of injury to soft tissue is an important component of assessment and management of closed fractures. The response of the soft tissue to blunt injury involves microvascular and inflammatory responses that produce localized tissue hypoxia and acidosis. Incisions placed through such compromised tissue can lead to wound breakdown and infections. Therefore, recognizing the signs of soft tissue injury is the foundation for successful management of closed fractures. The classification of Oestern and Tscherne can be used to characterize the severity of closed fractures20 (Table 57.1). This system remains the only published classification system for the soft tissue injury associated with closed fractures. Fractures are assigned one of four grades, from 0 to 3. The presence of deep skin abrasions, muscle contusion, fracture blisters, and massive soft tissue swelling suggests the need to use external fixation methods to limit further soft tissue injury and facilitate rapid recovery before surgical intervention.

Treatment
There are three objectives for treatment of fractures: reduction of the fracture, immobilization, and preservation and restoration of the function of the injured part. Also, it is important to prevent complications during the management of the fracture treatment. Preventive care is most important to follow in order to prevent fracture complications.

Reduction and Internal Fixation. When bones are realigned to restore their original structure it is referred to as reduction. This can be accomplished by closed manipulation or surgical (open) reduction. Closed manipulation uses methods such as manual pressure and traction. Fractures are held in reduction by external or internal fixation devices. The benefits of internal fixation must be balanced against its associated risks. The advantages are precise restoration of the osseous anatomy and early mobilization with at least partial weight bearing. The principal disadvantages are the increased risk of infection and the fact that healing may be impaired if a technique is not used properly. Surgical reduction involves the use of various types of hardware to accomplish internal fixation of the fracture fragments (Fig. 57.7).

Immobilization and External Fixation. Immobilization prevents movement of the injured parts and is the single most important element in obtaining union of the fracture fragments. Immobilization can be accomplished through the use of external devices, such as splints, casts, traction, or external fixation devices; or by internal fixation devices inserted during surgical reduction of the fracture.

Splints are made from many different materials. Metal splints or air splints may be used during transport to a health care facility as a temporary measure until the fracture has been reduced and another form of immobilization instituted. Plaster of Paris splints, which are molded to fit the extremity, work well. Splinting should be done if there is any suspicion of a fracture because motion of the fracture site can cause pain, bleeding, more soft tissue damage, and nerve or blood vessel compression. If the fracture has sharp fragments, movement can cause perforation of the skin and conversion of a closed fracture into an open one. When a splint is applied to an extremity, it should extend from the joint above the fracture site to the joint below it.

Casts, which are made of plaster or synthetic material such as fiberglass, are commonly used to immobilize fractures of the extremities. They often are applied with a joint in partial flexion to prevent rotation of the fracture fragments. Without this flexion, the extremity, which is essentially a cylinder, tends to rotate within the cylindrical structure of the cast. A brace may be used after a cast is removed or instead of a cast, as with a tibial stress fracture. The application of a cast carries the risk for impaired circulation to the extremity because of blood vessel compression. A cast applied shortly after a fracture may not be large enough to accommodate the swelling that inevitably occurs in the hours that follow. After a cast is applied, the peripheral circulation must be observed carefully until this danger has passed. If the circulation becomes inadequate, the parts that are exposed at the distal end of the cast (i.e., the toes with a leg cast and the fingers with an arm cast) usually become cold and cyanotic or pale. An increase in pain may occur initially, followed by paresthesia (i.e., tingling or abnormal sensation) or anesthesia as the sensory neurons that supply the area are affected. There is a decrease in the amplitude or absence of the pulse in areas where the arteries can be palpated. Capillary refill time, which is assessed by applying pressure to the fingernail and observing the rate of blood return, is prolonged to longer than 3 seconds. Signs of impaired circulation demand immediate measures, such as splitting the cast, to restore the circulation and prevent permanent damage to the extremity. A casted extremity should be elevated above the level of the heart for the first 24 hours to minimize swelling.

Traction is another method for achieving immobility, maintaining alignment of the bone ends, and maintaining the reduction, particularly if the fracture is unstable or comminuted.
Traction is a pulling force applied to an extremity or part of the body while a counterforce, or countertraction, pulls in the opposite direction. The five goals of traction therapy are to correct and maintain the skeletal alignment of entire bones or joints; reduce pressure on a joint surface; correct, lessen, or prevent deformities such as contractures and dislocations; decrease muscle spasm; and immobilize the fracture site to promote healing. Traction may be used as a temporary measure before surgery or as a primary treatment method. There are three types of traction: manual traction, skin traction, and skeletal traction. Manual traction consists of a steady, firm pull that is exerted by the hands. It is a temporary measure used to manipulate a fracture during closed reduction, for support of a neck injury during transport when a cervical spine fracture is suspected, or for reduction of a dislocated joint. Skin traction is a pulling force applied to the skin and soft tissue. It is accomplished by strips of adhesive flannel or foam secured to the injured part. Skeletal traction is a pulling force applied directly to the bone. Pins, wires, or tongs are inserted through the skin and subcutaneous tissue into the bone distal to the fracture site. Skeletal traction provides an excellent pull and can be used for long periods with large amounts of weight. It is commonly used for fractures of the femur, the humerus, and the cervical spine (e.g., Crutchfield tongs applied to the skull).

With external fixation devices, pins or screws are inserted directly into the bone above and below the fracture site. They are secured to a metal frame and adjusted to align the fracture. This method of treatment is used primarily for open fractures, infections such as osteomyelitis and septic joints, unstable closed fractures, and limb lengthening.

**Limb-Lengthening Systems.** Limb-lengthening systems, such as the Ilizarov external fixator (Fig. 57.8), are used to lengthen or widen bones, correct angular or rotational defects, or immobilize fractures. The apparatus is applied with a surgical technique, which consists of a percutaneous osteotomy that preserves the periosteal and endosteal tissues. A circular external apparatus is attached to bone by tensioned Kirschner wires. The continuous pulling activates regeneration of bone, soft tissue, nerves, and blood vessels. Newly formed bone fills the posttraumatic defects and eliminates the need for bone grafting. The apparatus is left on until the desired length is achieved and consolidation is complete.

**Preservation and Restoration of Function.** During the period of immobilization required for fracture healing, muscles tend to atrophy because of lack of use. Joints stiffen as muscles and tendons contract and shorten. The degree of muscle atrophy and joint stiffness depends on several factors. In adults, the degree of atrophy and muscle stiffness is directly related to the length of immobilization, with longer periods of immobility resulting in greater stiffness. Children have a natural tendency to move on their own, and this movement maintains muscle and joint function. They usually have less atrophy and recover sooner after the source of immobilization has been removed. Associated soft tissue injury, infection, and preexisting joint disease increase the risk for stiffness.

Although limbs are immobilized in a functional position, casts are removed as soon as fracture healing has taken place so that joint stiffness does not occur. Exercises designed to preserve function, maintain muscle strength, and reduce joint stiffness in the unaffected and affected extremities should be started early. Active range of motion, in which the person moves the extremity, is done on unaffected extremities, and isometric, or muscle-tensing, exercises are done on the affected extremities. In some instances, an electrical muscle stimulator is applied directly to the skin to stimulate isometric muscle contraction as a means of preventing disuse atrophy.

**Bone Healing**

Bone healing occurs in a manner similar to soft tissue healing. It is, however, a more complex process and takes longer. Although the exact mechanisms of bone healing are
open to controversy, four stages of the healing process have been identified:

1. Hematoma formation
2. Inflammatory phase
3. Reparative phase
4. Remodeling phase

The degree of response during each of these stages is in direct proportion to the extent of trauma.

The first stage, hematoma formation, occurs during the first to 2 days after fracture. It develops from torn blood vessels in the periosteum and adjacent muscles and soft tissue. Disruption of blood vessels also leads to death of bone cells at the fracture site. In 2 to 5 days, the hemorrhage forms a large blood clot. The second phase is called inflammation and is characterized by neovascularization, which begins to occur peripheral to the blood clot. By the end of the first week, most of the clot is organized by invasion of blood vessels and early fibrosis. As the result of hematoma formation, clotting factors remain in the injured area to initiate the formation of a fibrin meshwork, which serves as a framework for the ingrowth of fibroblasts and new capillary buds. The woven bone spicules start to appear around the clot and osteoblasts begin to synthesize the bone. There is granulation tissue forming and this is referred to as the beginning of the callus. The reparative phase follows the inflammatory phase and allows the continued formation of the callus of cartilage and woven bone near the fracture site. The final phase is remodeling which gives the cortex time to be re-established. The osteoclastic and osteoblastic functions continue at a rapid rate until the fracture site is healed and bone is reconstructed.

Healing Time. Healing time depends on the site of the fracture, the condition of the fracture fragments, hematoma formation, and other local and host factors. In general, fractures of long bones, displaced fractures, and fractures with less surface area heal more slowly. Function usually returns within 6 months after union is complete. However, return to complete function may take longer. Stress fractures usually require less time to heal, usually 2 to 4 weeks, during which time a reduction in activity and protection of the area are needed.

Union of a fracture has occurred when the fracture is solid enough to withstand normal stresses and it is clinically and radiologically safe to remove the external fixation. In children, fractures usually heal quicker than in adults. The increased rate of healing among children compared with adults may be related to the increased cellularity and vascularity of the child’s periosteum.

Factors that influence bone healing are specific to the person, the type of injury sustained, and local factors that disrupt healing. Individual factors that may delay bone healing are the patient’s age; current medications; debilitating diseases, such as diabetes and rheumatoid arthritis; level of immunocompetency, local stress around the fracture site; circulatory problems and coagulation disorders; and poor nutrition.

Impaired Healing

A number of factors can contribute to impaired bone healing, including the nature and extent of the injury, the health of the person with the fracture and his or her responses to injury, the adequacy of initial treatment, and pharmacologic factors. For large bone defects caused by trauma or a tumor, bone regeneration may need enhancement.

Malunion is healing with deformity, angulation, or rotation that is visible on x-ray films. Early, aggressive treatment, especially of the hand, can prevent malunion and result in earlier alignment and return of function. Malunion is caused by inadequate reduction or alignment of the fracture. Delayed union is the failure of a fracture to unite within the normal period (e.g., 20 weeks for a fracture of the tibia or femur in an adult). Intra-articular fractures (i.e., those through a joint) may heal more slowly and may eventually produce arthritis. Nonunion is failure to produce union and cessation of the processes of bone repair. It is seen most often in the tibia, especially with open fractures or crushing injuries. It is characterized by mobility of the fracture site and pain on weight bearing. Muscle atrophy and loss of range of motion may occur. Nonunion usually is established 6 to 12 months after the time of the fracture. The complications of fracture healing are summarized in Table 57.2.

Treatment methods for impaired bone healing encompass surgical interventions, including bone grafts, bracing, external fixation, or electrical stimulation of the bone ends. The treatment for delayed union consists of determining and correcting the cause of the delay. Electrical stimulation is thought to stimulate the osteoblasts to lay down a network of bone. Three types of commercial bone growth stimulators are available: a noninvasive model, which is placed outside the cast; a semi-noninvasive model, in which pins are inserted around the fracture site; and a totally implantable type, in which a cathode coil is wound around the bone at the fracture site and operated by a battery pack implanted under the skin. The Ilizarov method of circular external fixation is used to treat nonunions, especially those that are infected.

Complications of Fractures and Other Musculoskeletal Injuries

The complications of fractures and other orthopedic injuries are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage (e.g., fracture blisters, compartment syndrome), involvement of nerve fibers (e.g., complex regional pain syndrome [CRPS]), or development of venous thromboembolism and fat embolism syndrome (FES).

Fracture Blisters

Fracture blisters are skin bullae and blisters representing areas of epidermal necrosis with separation of epidermis from the underlying dermis by edema fluid. They occur when the intracompartmental pressure is too high to be relieved.
Understanding Fracture Healing

A fracture, which is any break in a bone, undergoes a healing process to reestablish bone continuity and strength. The repair of simple fractures is commonly divided into four phases: (1) hematoma formation, (2) inflammation, (3) reparative phase, and (4) remodeling.

Hematoma Formation

When a bone breaks, blood vessels in the bone and surrounding tissues are torn and bleed into and around the fragments of the fractured bone, forming a blood clot, or hematoma. The hematoma facilitates the formation of the fibrin meshwork that seals off the fracture site and serves as a framework for the influx of inflammatory cells, the ingrowth of fibroblasts, and the development of new capillary buds (vessels). It is also the source of signaling molecules that initiate the cellular events that are critical to the healing process.

Fibrocartilaginous Callus Formation

As new capillaries infiltrate the hematoma at the fracture site, it becomes organized into a form of granulation tissue, called pro-callus. Fibroblasts from the periosteum, endosteum, and red bone marrow proliferate and invade the procallus. The fibroblasts produce a fibrocartilaginous soft callus bridge that connects the bone fragments. Although this repair tissue usually reaches its maximum girth at the end of the second or third week, it is not strong enough for weight bearing.
Chapter 57  Disorders of Musculoskeletal Function: Trauma, Infection, Neoplasms

Bony Callus Formation

Ossification represents the conversion of the fibrocartilaginous cartilage to bony callus. In areas close to well-vascularized bone tissue, osteogenic cells develop into osteoblasts, or bone-building cells, which produce spongy bone trabeculae. The newly formed osteoblasts first deposit bone on the outer surface of the bone some distance from the fracture site. The formation of bone progresses toward the fracture site until a new bony sheath covers the fibrocartilaginous callus. In time, the fibrocartilage is converted to spongy bone, and the callus is then referred to as bony callus. Gradually, the bony callus calcifies and is replaced by mature bone. Bony callus formation begins 3 to 4 weeks after injury and continues until a firm bony union is formed months later.

Remodeling

During remodeling of the bony callus, dead portions of the bone are gradually removed by osteoclasts. Compact bone replaces spongy bone around the periphery of the fracture, and there is reorganization of mineralized bone along the lines of mechanical stress. During this period, the excess material on the outside of the bone shaft and within the medullary cavity is removed and compact bone is laid down to reconstruct the shaft. The final structure of the remodeled area resembles that of the original unbroken bone; however, a thickened area on the surface of the bone may remain as evidence of a healed fracture.
by normal means. They are seen with more severe, twisting types of injuries (e.g., motor vehicle accidents and falls from heights), but can also occur after excessive joint manipulation, dependent positioning, and heat application, or from peripheral vascular disease. They can be solitary, multiple, or massive depending on the extent of injury. Most fracture blisters occur in the ankle, elbow, foot, knee, or areas where there is little soft tissue between the bone and the skin. Prevention of fracture blisters is important because they pose an additional risk for infection. They also constitute a warning sign of compartment syndrome.

**Compartment Syndrome**

The compartment syndrome has been described as a condition of increased pressure within a limited space (e.g., abdominal and limb compartments) that compromises the circulation and function of the tissues in the space. The abdominal compartment syndrome alters cardiovascular hemodynamics, respiratory mechanics, and renal function. The discussion in this chapter is limited to a discussion of the limb compartment syndromes.

**Etiology and Pathogenesis.** The muscles and nerves of an extremity are enclosed in tough, inelastic fascia often termed a muscle compartment (Fig. 57.9). If the pressure in the compartment is sufficiently high, tissue circulation is compromised, causing death of nerve and muscle cells. Permanent loss of function may occur. The amount of pressure required to produce a compartment syndrome depends on many factors, including the duration of the pressure elevation, the metabolic rate of the tissues, vascular tone, and local blood pressure. Less tissue pressure is required to stop circulation when hypotension or vasoconstriction is present. Intracompartmental pressures greater than 30 mm Hg (normal is approximately 0 to 8 mm Hg) are considered sufficient to impair capillary blood flow.

Compartment syndrome can result from a decrease in compartment size, an increase in the volume of its contents, or a combination of the two factors. Among the causes of decreased compartment size are constrictive dressings and casts, closure of fascial defects, and burns. In persons...
with circumferential third-degree burns, the inelastic and constricting eschar decreases the size of the underlying compartments.

An increase in compartment volume can be caused by trauma, swelling, vascular injury and bleeding, and venous obstruction. One of the most important causes of compartment syndrome is bleeding and edema caused by fractures and bone surgery. Contusions and soft tissue injury also are common causes of compartment syndrome. Increased compartment volume may also follow ischemic events, such as arterial occlusion, that are of sufficient duration to produce capillary damage, causing increased capillary permeability and edema. Infiltration of intravenous fluids or bleeding from an arterial puncture can also cause compartment ischemia and postschismic swelling. During unattended coma caused by drug overdose or carbon monoxide poisoning, high compartment pressures are produced when an extremity is compressed by the weight of the overlying head or torso.

Compartment syndrome can be acute or chronic. Acute compartment syndrome can occur after a fracture or crushing injury, when excessive swelling around the site of injury results in increased pressure in a closed compartment. This increase in pressure occurs because fascia, which covers and separates muscles, is inelastic and unable to stretch and compensate for the extreme swelling. Chronic compartment syndrome may develop from exertion in long distance runners and others involved in a major change in activity level. Exertional compartment syndrome is an increase in compartment size and intramuscular pressure during exercise that causes ischemia, pain, and, rarely, neurologic symptoms and signs.

Clinical Manifestations and Diagnosis. The hallmark symptom of an acute compartment syndrome is severe pain that is out of proportion to the original injury or physical findings. Nerve compression may cause changes in sensation (e.g., paresthesias such as burning or tingling or loss of sensation), diminished reflexes, and eventually the loss of motor function. These symptoms generally begin quickly after injury but can also occur in a few days.

Because muscle necrosis can occur quickly, any one at risk for compartment syndrome need close surveillance. Assessment should include pain assessment, examination of sensory (i.e., light touch and two-point discrimination) and motor function (i.e., movement and muscle strength), as well as tests of passive stretch and palpation of the muscle compartments. Peripheral pulses frequently are normal in the presence of compartment syndrome because the major arteries are located outside the muscle compartments. Although edema may make it difficult to palpate the pulse, the increased compartment pressure seldom is sufficient to occlude flow in a major artery. Doppler methods usually confirm the existence of a pulse. Direct measurements of tissue pressure can be obtained using a needle or wick catheter inserted into the muscle compartment.21 This method is particularly useful in persons who are unresponsive and in those with nerve deficits.

Treatment. Treatment consists of reducing compartmental pressures. This entails cast splitting or removal of restrictive dressings. These procedures often are sufficient to relieve most of the underlying pressure and symptoms. Elevating the extremity on pillows can help to reduce edema. However, excessive elevation should be avoided because the effects of gravity can lower the arterial pressure in the limb, thereby decreasing compartment perfusion. Sometimes, a fasciotomy may be needed to relieve the pressure in an acute situation. During this procedure, the fascia is incised longitudinally and separated so that the compartment volume can expand and blood flow can be reestablished. Because of potential problems with wound infection and closure, this procedure is usually performed as a last resort.

Complex Regional Pain Syndrome

The CRPS, previously referred to as reflex sympathetic dystrophy and causalgia represents soft tissue complications of musculoskeletal injuries.23 The classic complaint is pain that seems out of proportion to the injury, increased sweating, and vasomotor instability.

Pain, which is the prominent symptom of the disorder, is described as severe, aching, or burning. It usually increases in intensity with movement and with noxious and non-noxious stimuli. The pathophysiologic cause of the pain is unclear, but it is thought to have a sympathetic nervous system component. Muscle wasting, thin and shiny skin, and abnormalities of the nails and bone can occur. Decreased muscle strength and disuse can lead to contractures and osteoporosis. Treatment focuses on pain management and prevention of disability with possible continuous epidural infusion analgesia.21

Thromboemboli

Because of inactivity and restrictions in weight bearing, the person with a lower extremity fracture is at risk for the development of venous thromboembolic disorders, which include pulmonary embolism and deep vein thrombosis.24 Fatal pulmonary embolism has an occurrence rate of 1% to 7% within 3 months of hip fracture surgery and is a leading cause of death.25 Anticoagulant prophylaxis with unfractionated heparin or low molecular weight heparin is effective and safe for people with fracture or trauma.24

The majority of symptomatic venous thromboemboli associated with hospital admissions occur at least 2 months after hospital discharge. Venous Doppler ultrasonography is the accepted test for the diagnosis of lower extremity deep vein thrombosis. A lung scan may be used in the diagnosis of a pulmonary embolus, but it may not differentiate between a thrombus and a fat embolus, especially in an individual with a long bone fracture.

Fat Embolism Syndrome

The FES refers to multiple life-threatening manifestations resulting from the presence of fat droplets in the small blood vessels of the lung, kidneys, brain and other organs after a
long bone or pelvic fracture. The fat emboli are thought to be released from the bone marrow or adipose tissue at the fracture site into the venous system through torn veins.

**Pathogenesis.** The pathophysiologic process of FES is unclear. Fat embolization involves the presence of fat emboli in the circulation, and FES, an identifiable clinical pattern of organ dysfunction associated with fat emboli in the circulation. One suggestion is that, when a bone is fractured, disruption of the venous sinusoids and fat cells allows fat globules to gain access to the venous circulation. The larger particles then become lodged in and block small pulmonary capillaries, whereas the smaller particles may pass through the lung capillaries and enter the systemic circulation.

**Clinical Manifestations.** The main clinical features of FES are respiratory failure, cerebral dysfunction, and skin and mucosal petechiae. Cerebral manifestations include encephalopathy, seizures, and focal neurologic deficits unrelated to head injury. Initial symptoms of FES begin to develop within a few hours to 3 to 4 days after injury and do not appear beyond 1 week after the injury. The first symptoms include a subtle change in behavior and signs of disorientation resulting from emboli in the cerebral circulation combined with respiratory depression. There may be complaints of substernal chest pain and dyspnea accompanied by tachycardia and a low-grade fever. Diaphoresis, pallor, and cyanosis become evident as respiratory function deteriorates. A petechial rash that does not blanch with pressure often occurs 2 to 3 days after the injury. This rash usually is found on the anterior chest, axillae, neck, and shoulders. It also may appear on the soft palate and conjunctiva. The rash is thought to be related to embolization of the skin capillaries or thrombocytopenia.

**Diagnosis and Treatment.** An important part of the treatment of FES is early diagnosis. Arterial blood gases should be assayed immediately after recognition of clinical manifestations. Treatment is directed toward correcting hypoxemia and maintaining adequate fluid balance. Mechanical ventilation may be required. Corticosteroid drugs are administered to decrease the inflammatory response of lung tissues, decrease the edema, stabilize the lipid membranes to reduce lipolysis, and combat bronchospasm. Corticosteroids are also given prophylactically to high-risk people. The only preventive approach to FES is early stabilization of the fracture.

---

**BONE INFECTIONS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the implications of bone infection.
- Differentiate among osteomyelitis due to spread from a contaminated wound, hematogenous osteomyelitis, and osteomyelitis due to vascular insufficiency in terms of etiologies, manifestations, and treatment.
- Describe the most common sites of tuberculosis of the bone.

Bone infections, including acute and chronic osteomyelitis, are known for their ability to cause pain, disability, and deformity. Despite the common use of antibiotics, they remain difficult to treat and eradicate. A resurgence of tubercular bone infections are occurring in industrialized parts of the world, attributed in part to immigration from developing countries and greater numbers of immunocompromised people.
Osteomyelitis

Osteomyelitis represents an acute or chronic infection of the bone. Osteo refers to bone, and myelo refers to the marrow cavity, both of which are involved in this disease. The infection can be caused by

- Direct penetration or contamination of an open fracture or wound (exogenous origin)
- Seeding through the bloodstream (hematogenous spread)
- Extension from a contiguous site
- Skin infections in people with vascular insufficiency

Osteomyelitis can occur as an acute, subacute, or chronic condition. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but infections caused by certain pyogenic bacteria and mycobacteria are the most common.

The specific agents isolated in pyogenic bacterial osteomyelitis are often associated with the age of the person or the inciting condition (e.g., trauma or surgery). Staphylococcus aureus is the most common cause, but organisms such as Escherichia coli, Neisseria gonorrhoeae, Haemophilus influenzae, and Salmonella species are also seen.18,26

Hematogenous Osteomyelitis

Hematogenous osteomyelitis originates with infectious organisms that reach the bone through the bloodstream. Acute hematogenous osteomyelitis occurs predominantly in children.18 In adults, it is seen most commonly in debilitated people and in those with a history of chronic skin infections, chronic urinary tract infections, and intravenous drug use and in those who are immunologically suppressed. Intravenous drug users are at risk for infections with Streptococcus and Pseudomonas.18

Pathogenesis. The pathogenesis of hematogenous osteomyelitis differs in children and adults. In children, the infection usually affects the long bones of the appendicular skeleton. It starts in the metaphyseal region close to the growth plate, where termination of nutrient blood vessels and sluggish blood flow favor the attachment of blood-borne bacteria (Fig. 57.10). With advancement of the infection, purulent exudate collects in the rigidly enclosed bony tissue. Because of the bone’s rigid structure, there is little room for swelling and the purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone. Eventually, the purulent drainage may penetrate the periosteum and skin to form a draining sinus. In children 1 year of age and younger, the adjacent joint is often involved because the periosteum is not firmly attached to the cortex.18 From 1 year of age to puberty, subperiosteal abscesses are more common.18 As the process continues, periosteal new bone formation and reactive bone formation in the marrow tend to wall in the infection. Involucrum refers to a lesion in which bone formation forms a sheath around the necrotic sequestrum. It is seen most commonly in cases of chronic osteomyelitis.

In adults, the long bone microvasculature no longer favors seeding, and hematogenous infection rarely affects the appendicular skeleton. Instead, vertebrae, sternoclavicular and sacroiliac joints, and the symphysis pubis are involved. Infection typically first involves subchondral bone, then spreads to the joint space.19 With vertebral osteomyelitis, this causes sequential destruction of the endplate, adjoining disk, and contiguous vertebral body. Infection less commonly begins in the joint and spreads to the adjacent bone.

Clinical Manifestations. The signs and symptoms of acute hematogenous osteomyelitis are those of bacteremia accompanied by symptoms referable to the site of the bone lesion. Bacteremia is characterized by chills, fever, and malaise. There often is pain on movement of the affected extremity, loss of movement, and local tenderness followed by redness and swelling. X-ray studies may appear normal initially, but they show evidence of periosteal elevation and increased osteoclast activity after an abscess has formed.

Treatment. The treatment of hematogenous osteomyelitis begins with identification of the causative organism through blood and bone aspiration cultures.18,26 Antimicrobial agents are given first parenterally and then orally. The length of time the affected limb needs to be rested and pain control measures used are based on the person’s symptoms. Debridement and surgical drainage also may be necessary.

Direct Penetration and Contiguous Spread Osteomyelitis

Direct penetration or extension of bacteria from an outside (exogenous) source is now the most common cause of osteomyelitis in the United States.18 Bacteria may be introduced directly into the bone by a penetrating wound, an open fracture, or surgery. Inadequate irrigation or debridement, introduction of foreign material into the wound, and extensive tissue injury increase the bone’s susceptibility to infection.

KEY POINTS

BONE INFECTIONS

- Bone infections may be caused by a wide variety of microorganisms introduced during injury, during operative procedures, or from the bloodstream.
- Once localized in bone, the microorganisms proliferate, produce cell death, and spread within the bone shaft, inciting a chronic inflammatory response with further destruction of bone.
- Bone infections are difficult to treat and eradicate. Measures to prevent infection include careful cleaning and debridement of skeletal injuries and strict operating room protocols.
Iatrogenic bone infections are those inadvertently brought about by surgery or other treatments. These complications include pin tract infection in skeletal traction, septic (infected) joints in joint replacement surgery, and wound infections after surgery. Staphylococci and streptococci are still commonly implicated, but in 25% of postoperative infections, Gram-negative organisms are detected.\(^\text{18}\) Measures to prevent these infections include preparation of the skin to reduce bacterial growth before surgery or insertion of traction devices or wires, strict operating room protocols, prophylactic use of antibiotics immediately before and for 24 hours after surgery and as a topical wound irrigation, and maintenance of sterile technique after surgery when working with drainage tubes and dressing changes.

**Pathogenesis.** The pathogenesis of osteomyelitis resulting from direct penetration or contiguous spread differs from hematogenous infection in that virtually any traumatized bone may be involved. Although healthy bone is highly resistant to infection, injury from local inflammation and trauma may devitalize bone and surrounding tissue, providing an inert matrix on which microorganisms introduced during trauma thrive.

**Clinical Manifestations.** Osteomyelitis after trauma or bone surgery usually is associated with persistent or recurrent fever, increased pain at the operative or trauma site, and poor incisional healing, which often is accompanied by continued wound drainage and wound separation. Prosthetic joint infections often present with joint pain, fever, and cutaneous drainage.
Diagnosis and Treatment. Diagnosis requires both confirming the infection and identifying the offending microorganism with culture and sensitivity studies. The diagnosis of skeletal infection entails use of various imaging strategies, including conventional radiology, nuclear imaging studies, CT scans, and MRI. Bone biopsy may be used to identify the causative microorganisms.

Treatment includes the use of antibiotics and selective use of surgical interventions. Antimicrobial agents are usually used prophylactically in persons undergoing bone surgery. For persons with osteomyelitis, early antimicrobial treatment, before there is extensive destruction of bone, produces the best results. The choice of agents and method of administration depend on the microorganisms causing the infection. In acute osteomyelitis that does not respond to antibiotic therapy, surgical decompression is used to release intramedullary pressure and remove drainage from the periosteal area. Prosthesis removal may be necessary in cases of an infected prosthetic joint.

Chronic Osteomyelitis

Chronic osteomyelitis usually occurs in adults. Generally, these infections occur secondary to an open wound, most often to the bone or surrounding tissue. Chronic osteomyelitis has long been recognized as a disease. However, the incidence has decreased in the past century because of improvements in surgical techniques and the advent of broad-spectrum antibiotic therapy. Chronic osteomyelitis includes all inflammatory processes of bone, excluding those in rheumatic diseases that are caused by microorganisms. It may be the result of delayed or inadequate treatment of acute hematogenous osteomyelitis or osteomyelitis caused by direct contamination of bone by exogenous organisms. Chronic osteomyelitis can persist for years; it may appear spontaneously, after a minor trauma, or when resistance is lowered.

The hallmark feature of chronic osteomyelitis is the presence of infected dead bone, a sequestrum, that has separated from the living bone. A sheath of new bone, called the involucrum, forms around the dead bone. Radiologic techniques such as x-ray films, bone scans, and sinograms are used to identify the infected site. Chronic osteomyelitis or infection around a total joint prosthesis can be difficult to diagnose because the classic signs of infection are not apparent and the blood leukocyte count may not be elevated. A subclinical infection may exist for years. Bone scans are used with bone biopsy for a definitive diagnosis.

The treatment of chronic bone infections begins with wound cultures to identify the microorganism and its sensitivity to antibiotic therapy. The goal in selecting antimicrobial treatment for osteomyelitis is to use the drug with the highest bactericidal activity and least toxicity, and at the lowest cost. Intravenous therapy is usually needed for up to 6 weeks. Initial antibiotic therapy is followed by surgery to remove foreign bodies (e.g., metal plates, screws) or sequestra and by long-term antibiotic therapy. Immobilization of the affected part usually is necessary, with restriction of weight bearing on a lower extremity. External fixation devices are sometimes used.

Osteomyelitis with Vascular Insufficiency

In persons with vascular insufficiency, osteomyelitis may develop from a skin lesion. It is most commonly associated with chronic or ischemic foot ulcers in people with long-standing diabetes. Neuropathy causes a loss of protective reflexes, and impaired arterial circulation and repetitive trauma are the major contributors to skin fissure and ulcer formation.

People with vascular insufficiency osteomyelitis often present with seemingly unrelated problems such as ingrown toenails, cellulitis, or a perforating foot ulcer, making diagnosis difficult. Furthermore, pain is often muted by peripheral neuropathy. Osteomyelitis is confirmed when bone is exposed in the ulcer bed or after debridement. Radiologic evidence is a late sign.

Treatment depends on the oxygen tension of the involved tissues. Debridement and antibiotic therapy may benefit people who have good oxygen tension in the infected site. Hyperbaric oxygen therapy may be used as an adjunctive treatment.

Tuberculosis of the Bone or Joint

A resurgence of tubercular osteomyelitis is occurring in industrialized countries, attributed to the influx of immigrants from developing countries and the greater numbers of immunocompromised people. In developing countries, affected people are usually adolescents or young adults. However, in the non-immigrant population of developed countries, the victims tend to be older, except for those who are immunocompromised.

Tuberculosis can spread from one part of the body, such as the lungs or the lymph nodes, to the musculoskeletal system. Any bone, joint, or bursa may be affected, but the spine is the most common site, followed by the knees and hips. Tubercular osteomyelitis tends to be more destructive and difficult to control than pyogenic osteomyelitis. The infection spreads through large areas of the medullary cavity and causes extensive necrosis. In tuberculosis of the spine, also known as Pott disease or Tuberculosis spondylitis, the infection spreads through the intervertebral disks to involve multiple vertebrae and extends into the soft tissue, forming abscesses.

Local symptoms include pain, immobility, and muscle atrophy; joint swelling, mild fever, and leukocytosis also may occur. The most feared complication of spinal tuberculosis is neurologic compromise due to spinal deformity and epidural abscess formation. Because there are no specific radiographic findings in tubercular osteomyelitis, the diagnosis is usually made by tissue biopsy or culture findings. In spinal tuberculosis, a CT-guided biopsy is often used. The mainstay of treatment for tubercular osteomyelitis is similar to the guidelines for respiratory tuberculosis.

IN SUMMARY

Bone infections occur because of the direct or indirect invasion of the musculoskeletal system by microorganisms, most commonly S. aureus. Osteomyelitis, or infection of...
Osteonecrosis, or death of a segment of bone, is a condition caused by the interruption of blood supply to the marrow, medullary bone, or cortex in the absence of infection (Fig. 57.11). It is a relatively common disorder and can occur in the medullary cavity of the metaphysis and the subchondral region of the epiphysis, especially in the proximal femur, distal femur, and proximal humerus. It is a common complicating disorder of Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, sickle cell disease, steroid therapy, alcohol abuse, and hip trauma, fracture, or surgery. People treated with corticosteroids and/or bisphosphonates are more vulnerable to developing osteonecrosis.

**Etiology and Pathogenesis**

Although bone necrosis results from ischemia, the mechanisms producing the ischemia are varied and include mechanical vascular interruption such as occurs with trauma or a fracture; thrombosis and embolism (e.g., sickle cell disease, nitrogen bubbles caused by inadequate decompression during deep sea diving); and vessel injury (e.g., vasculitis, radiation therapy). In many cases, the cause of the necrosis is uncertain. Other than fracture, the most common causes of bone necrosis are idiopathic (i.e., those of unknown cause) and prior steroid therapy. Chart 57.1 lists disorders associated with osteonecrosis.

Bone has a rich blood supply that varies from site to site. The flow in the medullary portion of bone originates in nutrient vessels from an interconnecting plexus that supplies the marrow, trabecular bone, and endosteal half of the cortex. The outer cortex receives its blood supply from periosteal, muscular, metaphyseal, and epiphyseal vessels that surround the bone. Some bony sites, such as the head of the femur, have only limited collateral circulation, so that interruption of the flow, such as with a hip fracture, can cause necrosis of a substantial portion of medullary and cortical bone and irreversible damage.

One of the most frequent causes of osteonecrosis is that associated with administration of corticosteroids. Despite numerous studies, the mechanism of steroid-induced osteonecrosis remains unclear. The condition may develop after the administration of very high, short-term doses; during...
Chapter 57  Disorders of Musculoskeletal Function: Trauma, Infection, Neoplasms

long-term treatment; or even from intra-articular injection. Although the risk increases with the dose and duration of treatment, it is difficult to predict who will be affected. The interval between corticosteroid administration and onset of symptoms rarely is less than 6 months and may be more than 3 years. There is no satisfactory method for preventing progression of the disease. Osteonecrosis of the jaw has been reported after long-term use of bisphosphonates.

The pathologic features of bone necrosis are the same, regardless of cause. The site of the lesion is related to the vessels involved. There is necrosis of cancellous bone and marrow. The cortex usually is not involved because of collateral blood flow. In subchondral infarcts (i.e., ischemia below the cartilage), a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base and the center of the epiphysis as its apex, undergoes necrosis. When medul- lary infarcts occur in fatty bone marrow, the death of bone cells causes calcium release and necrosis of fat cells, with the formation of free fatty acids. Released calcium forms an insoluble “soap” with free fatty acids. Because bone lacks mechanisms for resolving the infarct, the lesions remain for life.

Clinical Manifestations, Diagnosis, and Treatment

The symptoms associated with osteonecrosis are varied and depend on the extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated with activity but that gradually becomes more progressive until it is experienced at rest. Subchondral infarcts often collapse and predispose the person to severe secondary osteoarthritis.

Diagnosis of osteonecrosis is based on history, physical findings, radiographic findings, and results of special imaging studies, including CT scans and technetium-99m bone scans. Treatment of osteonecrosis depends on the underlying pathologic process. In some cases, only short-term immobilization, nonsteroidal anti-inflammatory drugs, exercises, and limitation in weight bearing are used. Osteonecrosis of the hip is particularly difficult to treat. In people with early disease, limitation of weight bearing through the use of crutches may allow the condition to stabilize. Although several surgical approaches have been used, the most definitive treatment of advanced osteonecrosis of the knee or hip is total joint replacement.

IN SUMMARY

Osteonecrosis is a common condition that has long been recognized but is not fully understood. Death of bone is caused by disruption of the blood supply from intravascular or extravascular processes. Sites with poor collateral circulation, such as the femoral head, are most seriously affected. Causative factors include corticosteroid therapy. Symptoms include pain that varies in severity, depending on the extent of infarction. Total joint replacement is the most frequently used treatment for advanced osteonecrosis.

Neoplasms in the skeletal system are referred to as bone tumors. Primary malignant tumors of the bone are uncommon, constituting less than 0.2% of all cancers. The American Cancer Society projects 3010 new cases of bone cancer (primary and secondary) in 2013 and approximately 1440 deaths in 2013. Metastatic disease of the bone, however, is relatively common. Primary bone tumors may arise from any of the skeletal components, including osseous bone tissue, cartilage, and bone marrow. The discussion in this section focuses on primary benign and malignant bone tumors of osseous or cartilaginous origin and metastatic bone disease.

Like other types of neoplasms, bone tumors may be benign or malignant. Benign tumors far outnumber malignant tumors. The benign types, such as osteochondromas, tend to grow rather slowly and usually do not destroy the supporting or surrounding tissue or spread to other parts of the body. Malignant tumors, such as osteosarcoma, grow rapidly and can spread to other parts of the body through the bloodstream or lymphatics. The two major forms of bone cancer in children and young adults are osteosarcoma and Ewing sarcoma. Chondrosarcomas tend to occur during middle to late adulthood. The classification of benign and malignant bone tumors is described in Table 57.3.

Characteristics of Bone Tumors

There are three major manifestations of bone tumors: pain, presence of a mass, and impairment of function. Pain is a feature common to almost all malignant tumors, but may or may not occur with benign tumors. For example, a benign bone cyst usually is asymptomatic until a fracture occurs. Pain that persists at night and is not relieved by rest suggests malignancy. A mass or hard lump may be the first sign of a bone tumor. A malignant tumor is suspected when a painful mass exists that is enlarging or eroding the cortex of the bone. The ease of discovery of a mass depends on the location of the tumor; a small lump arising on the surface of the tibia is easy to detect, whereas a tumor that is deep in the medial portion of the thigh may grow to a considerable size before it is noticed. Benign and malignant tumors may cause the bone to erode to the point at which it cannot withstand the strain of ordinary use. In such
Benign Neoplasms

Benign bone tumors usually are limited to the confines of the bone, have well-demarcated edges, and are surrounded by a thin rim of sclerotic bone. An osteoma is a small bony tumor found on the surface of a long bone, flat bone, or the skull. It usually is composed of hard, compact (ivory osteoma), or spongy (cancellous) bone. It may be excised or left alone.

A chondroma is a tumor composed of hyaline cartilage. It may arise on the surface of the bone (i.e., echondroma) or in the medullary cavity (i.e., endochondroma). These tumors may become large and are especially common in the hands and feet. A chondroma may persist for many years and then take on the attributes of a malignant chondrosarcoma. A chondroma usually is not treated unless it becomes unsightly or uncomfortable.

An osteochondroma is the most common form of benign tumor in the skeletal system, representing 50% of all benign bone tumors and approximately 15% of all primary skeletal lesions. It grows only during periods of skeletal growth, originating in the epiphyseal cartilage plate and growing out of the bone like a mushroom. An osteochondroma is composed of cartilage and bone and usually occurs singly, but may affect several bones in a condition called multiple exostoses. Malignant changes are rare, and excision of the tumor is done only when necessary.

A giant cell tumor, or osteoclastoma, is an aggressive tumor of multinucleated cells that often behaves like a malignant tumor, metastasizing through the bloodstream and recurring locally after excision. It arises most often in people in their 20s to 40s and is found most commonly in the knee, wrist, or shoulder. The tumor begins in the metaphyseal region, grows into the epiphysis, and may extend into the joint surface. Pathologic fractures are common because the tumor destroys the bone substance. Clinically, pain may occur at the tumor site, with gradually increasing swelling. X-ray films show destruction of the bone with expansion of the cortex.

The treatment of giant cell tumors depends on their location. If the affected bone can be eliminated without loss of function, such as the clavicle or fibula, the entire bone or part of it may be removed. When the tumor is near a major joint, such as the knee or shoulder, a local excision is done. Irradiation may be used to prevent recurrence of the tumor.

Malignant Bone Tumors

In contrast to benign tumors, primary malignant tumors tend to be ill defined, lack sharp borders, and extend beyond the confines of the bone. Primary bone tumors occur in all age-groups and may arise in any part of the body. However, certain types of tumors tend to target certain age-groups and anatomic sites (Fig. 57.12). For example, most osteogenic sarcomas occur in adolescents and are particularly common around the knee joint. Also, people with certain conditions such as Paget disease are at increased risk for development of bone cancer.

The diagnosis of bone tumors includes radiologic staging and biopsy.29 Radiographs give the most general diagnostic information, such as malignant versus benign and primary versus metastatic status. The radiograph demonstrates the region of bone involvement, extent of destruction, and amount of reactive bone formed. Radioisotope scans are used to estimate the local intramedullary extent of the tumor and screen for other skeletal areas of involvement. CT scans further aid diagnosis and anatomic localization and can identify small pulmonary metastases not seen by conventional

**KEY POINTS**

**BONE NEOPLASMS**

- Neoplasms of the skeletal system can affect bone tissue, cartilage, or bone marrow.
- Benign tumors tend to grow slowly, do not spread to other parts of the body, and exert their effects through the space-occupying nature of the tumor and their ability to weaken bone structures.
- Malignant bone tumors are rare before 10 years of age, have their peak incidence in the teenage years, tend to grow rapidly, and have a high mortality rate.

---

May arise on the surface of the bone (i.e., echondroma) or in the medullary cavity (i.e., endochondroma). These tumors may become large and are especially common in the hands and feet. A chondroma may persist for many years and then take on the attributes of a malignant chondrosarcoma. A chondroma usually is not treated unless it becomes unsightly or uncomfortable.
Etiology. The cause of osteosarcoma is unknown. The tumor is most likely to occur in persons younger than 20 years of age and in older adults. The correlation of age and location of most of the tumors with the period of maximum growth suggests some relation to increased osteoblastic activity. In younger persons, the primary tumor most often is located at the anatomic sites associated with maximum growth velocity—the distal femur, proximal tibia, and proximal humerus.\textsuperscript{18} Bone tumors in older adults are more common in the humerus, pelvis, and proximal femur.\textsuperscript{18} Paget disease, which is linked to osteosarcoma in adults, also is associated with increased osteoblastic activity. Irradiation from an internal source, such as the radioactive pharmaceutical technetium used in bone scans, or an external source, such as x-ray films, also has been associated with osteosarcoma. There are known genetic factors associated with osteosarcoma. Mutations in two genes are reported to increase the susceptibility to the development of osteosarcoma: the retinoblastoma gene (\textit{RB}) and the \textit{TP53} tumor suppressor gene.\textsuperscript{18}

Pathogenesis. Osteosarcomas are aggressive tumors that grow rapidly in a circular, ball-like mass in the bone tissue. They often are eccentrically placed in the bone and move from the metaphysis of the bone out into the periosteal surface, with subsequent spread to adjacent soft tissues (Fig. 57.13). The tumor infrequently metastasizes to the lymph nodes because the cells are unable to grow in the node. Nodal metastases usually occur only in the late course of disseminated disease. Most often, the tumor cells exit the primary tumor through the venous end of the capillary, and early metastasis to the lung is common. Lung metastases, even if massive, usually are relatively asymptomatic. The prognosis for a person with osteosarcoma depends on the aggressiveness of the disease.
presence or absence of pathologic fractures, size of the tumor, and rapidity of tumor growth.

**Clinical Manifestations and Diagnosis.** The primary clinical feature of osteosarcoma is deep, localized pain with nighttime awakening and swelling in the affected bone, which tends to be of a sudden nature. The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

History, physical examination, and radiographic studies are all part of the evaluation of a person with osteosarcoma. Plain films of the primary site and of the chest are first obtained. MRI, CT scan, and full-body scan are required to evaluate the extent of the local disease and to determine the extent of metastasis if present. Radionuclide bone scans are done to evaluate for lung and bone metastasis. An open biopsy is required to confirm the diagnosis and to determine the histologic features and cell type of the tumor.

**Treatment.** Osteosarcoma is treated by surgery and chemotherapy. In the past, treatment usually entailed amputation above the level of the tumor. Amputation is also an option. It involves either the removal of expendable bones such as the fibula, ribs, toes, or ulna, or the complete removal of the tumor and the affected limb. The primary objective of overall treatment of patients with osteosarcoma is long-term survival of persons with osteosarcoma. The success of limb salvage appears to depend on the use of a wide surgical margin, improved radiographic imaging studies, multiagent chemotherapy, the use of interferon alpha and beta receptors, and more refined surgical reconstructive techniques. Advanced imaging techniques, including serum thallium scans, and the use of angiography assist the surgeon in determining the best type of treatment. Amputation is in progress regarding the cancer stem cell and its relationship to osteosarcoma and treatment protocols.

A primary clinical manifestation of Ewing sarcoma is deep, localized pain with nighttime awakening and swelling in the affected bone, which tends to be of a sudden nature. The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

**Clinical Manifestations and Diagnosis.** The primary clinical feature of osteosarcoma is deep, localized pain with nighttime awakening and swelling in the affected bone, which tends to be of a sudden nature. The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

History, physical examination, and radiographic studies are all part of the evaluation of a person with osteosarcoma. Plain films of the primary site and of the chest are first obtained. MRI, CT scan, and full-body scan are required to evaluate the extent of the local disease and to determine the extent of metastasis if present. Radionuclide bone scans are done to evaluate for lung and bone metastasis. An open biopsy is required to confirm the diagnosis and to determine the histologic features and cell type of the tumor.

**Pathogenesis.** The most frequent site of Ewing sarcoma is the femur, usually in the diaphysis. The pelvis represents the second most common site; other sites include the pubis, sacrum, humerus, vertebrae, ribs, skull, and other flat bones. The characteristic pathologic findings of Ewing sarcoma include densely packed, regularly shaped, small cells with round or oval nuclei. A specific reciprocal translocation of chromosomes 11 and 22, or a variant thereof, is found in most of the Ewing sarcoma family of tumors. Detection of the translocation by routine cytogenetic or polymerase chain reaction analysis can be helpful in confirming the diagnosis in highly undifferentiated tumors.

**Clinical Manifestations.** Manifestations of Ewing tumor include bone pain, limitation of movement, and tenderness over the involved bone or soft tissue. It often is accompanied by systemic manifestations such as fever or weight loss, which may serve to confuse the diagnosis. There may be a delay in diagnosis when the pain and swelling associated with the tumor are attributed to a sports injury or when the tumor is located in the pelvis and the pain is not localized and the mass is not apparent. Pathologic fractures are common because of bone destruction. The most common sites of metastasis are the lungs, bone marrow, and other bones.

**Diagnosis and Treatment.** Because Ewing sarcoma is a difficult diagnosis to establish, the diagnostic biopsy is very important. Clinical evaluations include MRI and CT scans of the primary tumor, chest radiographs, CT of the chest, bone scan, bilateral bone marrow aspiration, and biopsy of the primary tumor site. The extent of disease at diagnosis is the most important prognostic factor. The presence of metastatic disease at diagnosis is a poor prognostic factor regardless of the site of the primary lesion.

Treatment methods incorporate a combination of multiagent chemotherapy, surgery, and radiation therapy. Chemotherapy is generally given before local control measures are initiated. Ewing sarcoma is considered to be a radiosensitive tumor, and local control may be achieved through radiation or surgery. Patients with small, nonmetastatic, distally located tumors generally have the best prognosis.

**Chondrosarcoma**

Chondrosarcoma, a malignant tumor of cartilage that can develop in the medullary cavity or peripherally, is the second most common form of malignant bone tumor. It occurs primarily in middle or later life and slightly more often in men. The tumor arises from points of muscle attachment to bone, particularly the knee, shoulder, hip, and pelvis. Chondrosarcomas can arise from underlying benign lesions. There are three types of chondrosarcoma including peripheral, central, and juxtacortical; all three affect cartilage.

Chondrosarcomas are slow growing and metastasize late, and often are painless. They can remain hidden in an area such as the pelvis for a long time. This type of tumor, like many primary malignancies, tends to destroy bone and extend
into the soft tissues beyond the confines of the bone of origin. Chondrosarcomas mainly affect the bones of the trunk, pelvis, or proximal femur and rarely develop in the distal portion of a bone. Irregular flecks and ringlets of calcification often are prominent radiographic findings.

Early diagnosis is important because chondrosarcoma responds well to early radical surgical excision. It usually is resistant to radiation therapy and available chemotherapeutic agents. Not infrequently, these tumors transform into a highly malignant tumor, mesenchymal chondrosarcoma, which requires a more aggressive treatment, including combination chemotherapy.

**Metastatic Bone Disease**

Skeletal metastases are the most common malignancy of osseous tissue. Approximately, half of all people with cancer have bone metastasis at some point in their disease. Metastatic lesions are seen most often in the spine, femur, pelvis, ribs, sternum, proximal humerus, and skull, and are less common in anatomic sites more distant from the trunk of the body. Tumors that frequently spread to the skeletal system are those of the breast, lung, prostate, kidney, and thyroid, although any cancer can ultimately involve the skeleton. Most of bone metastases result from primary lesions in the breast, lung, or prostate. The incidence of metastatic bone disease is highest in people older than 40 years of age.

**Clinical Manifestations and Diagnosis**

The major symptom of bone metastasis is pain in a specific bone area and this is validated with evidence of an impending pathologic fracture. It usually develops gradually, over weeks, and is more severe at night. Pain is caused by stretching of the periosteum of the involved bone or by nerve entrapment, as when the nerve roots of the spinal cord are compressed by the vertebral body. The affected bone of the pathologic fracture appears to be eaten away on x-ray images; in severe cases, it crumbles on impact, much like dried toast. Many pathologic fractures occur in the femur, humerus, and vertebrae.

Radiographic examinations are used along with CT, PET-CT, and bone scans to detect, diagnose, and localize metastatic bone lesions. Approximately, one third of persons with skeletal metastases have positive bone scans without radiologic findings.

Arteriography using radiopaque contrast media may be helpful in outlining the tumor margins. A bone biopsy usually is done when there is a question regarding the diagnosis or treatment. A closed-needle biopsy with CT localization is particularly useful with spine lesions. Serum levels of alkaline phosphatase and calcium often are elevated in persons with metastatic bone disease.

**Treatment**

The primary goals in treatment of metastatic bone disease are to prevent pathologic fractures and promote survival with maximum functioning, allowing the person to maintain as much mobility and pain control as possible. Standard treatment methods include chemotherapy, irradiation, and surgical stabilization. Radiation therapy is primarily used as a palliative treatment to alleviate pain and prevent pathologic fractures. After a pathologic fracture has occurred, bracing, intramedullary nailing of the femur, or spine stabilization may be done. Because adequate fixation often is difficult in diseased bone, cement (i.e., methylmethacrylate) often is used with internal fixation devices to stabilize the bone.

Recent research has focused on the role of osteoclastic and osteoblastic activity in the pathogenesis of metastatic bone disease and on the use of the COX-2 inhibitors, carbon ion therapy, and bisphosphonates (e.g., pamidronate disodium, zoledronic acid) for its treatment. Bone tissue contains a rich environment of growth factors and cells of various embryonic origins, including hematopoietic, stromal, endothelial, and other cell types. The osteoclasts and osteoblasts, in particular, appear to play a dominant role in the pathogenesis of bone metastasis.

The bisphosphonates, which are now well-established agents for the prevention and treatment of osteoporosis, have recently been shown to decrease symptoms associated with bone metastasis secondary to breast and prostate cancer. These agents bind preferentially to bone at sites of active bone metabolism, are released from the bone matrix during bone resorption, and potentially inhibit osteoclast activity and survival, thereby reducing osteoclast-mediated bone resorption.

**IN SUMMARY**

Bone tumors, like any other type of neoplasm, may be benign or malignant. Benign bone tumors grow slowly and usually do not destroy the surrounding tissues. Malignant tumors can be primary or metastatic. Primary bone tumors are rare, grow rapidly, metastasize to the lungs and other parts of the body through the bloodstream, and have a high mortality rate. Metastatic bone tumors usually are multiple, originating primarily from cancers of the breast, lung, and prostate. The incidence of metastatic bone disease probably is increasing because improved treatment methods enable persons with cancer to live longer. Advances in chemotherapy, radiation therapy, and surgical procedures have substantially increased the survival and cure rates for many types of bone cancers. A primary goal in metastatic bone disease is the prevention of pathologic fractures.

**REVIEW EXERCISES**

1. A 39-year-old man is in intensive care after a motorcycle crash in which he skidded across the pavement on his right side. He has fractures of his right femur, pelvis, and several ribs on the right side. His leg was crushed beneath the motorcycle. He is beginning to lose movement in his leg.

Continued
A. What are the priorities in treating his orthopedic injuries? What are the options for stabilizing his leg?
B. What risk factors for complications of fractures are present?
C. What are the symptoms of compartment syndrome, and how is it treated?

2. A 73-year-old woman sustained a comminuted fracture in the middiaphysis of her left humerus when her husband lifted her up in bed. She has multiple lucent lesions scattered throughout her proximal humerus, radius, and ulna. She was recently hospitalized for confusion and was found to have diffuse bone metastases. Her bone marrow biopsy showed adenocarcinoma. She has a history of breast cancer 30 years ago, but her most recent mammogram was negative.
A. What would you consider to be the most likely cause of her fracture?
B. What are the most common sites for bone metastasis?
C. Explain the treatment goals for persons with pathologic fractures.

3. A 14-year-old boy has complained of recent pain and swelling of his knee, with some restriction in movement. Although he thinks he may have injured his knee playing football, his mother insists that he be seen by an orthopedic specialist, and swelling of his knee, with some restriction
A. Use the theory that osteosarcoma has its origin in sites of maximal growth velocity to explain the site of this boy’s possible tumor.
B. What diagnostic tests could be used to establish a diagnosis of osteosarcoma?
C. The boy and his family are concerned that he will require radical surgery with amputation of the leg. How would you explain possible treatment options to him?

The development of skeletal structures begins in utero and continues to change throughout life. During childhood, skeletal structures grow in length and diameter and sustain a large increase in bone mass. The term *modeling* refers to the formation of the macroscopic skeleton, which ceases at maturity, usually between 18 and 20 years of age. Once skeletal growth has attained its adult size, the process of bone remodeling is responsible for skeletal maintenance. It involves bone resorption and formation and is responsible for skeletal maintenance at sites that require replacement or repair. With aging, bone resorption and formation are no longer perfectly coupled, and there is loss of bone.

Skeletal disorders may develop as a result of abnormal growth and developmental processes due to hereditary or congenital influences. Other skeletal disorders can occur later in life as a result of nutritional deficiencies, metabolic disorders, hormonal influences, or the aging process. This chapter is divided into two parts including altered skeletal growth and development and metabolic bone disorders.
Bone Growth and Remodeling

Embryonic and Fetal Development

The skeletal system is generated from the mesodermal and neural crest cells of the developing embryo.\(^1\) Development of the vertebrae of the axial skeleton begins at approximately the 4th week in the embryo. During the 9th week, ossification begins with the appearance of ossification centers in the lower thoracic and upper lumbar vertebrae. The paddle-shaped limb buds of the lower extremities make their appearance late in the 4th week of development; the hand pads are developed by days 33 to 36; and the finger rays are evident on days 41 to 43.\(^1\)

Abnormalities originating from the embryonic stage of development are relatively uncommon. When they do occur, they are usually limited to defined embryonic structures (e.g., congenital absence of a phalanx; formation of extra bones [supernumerary digits], or fusion of adjacent digits [syndactylyism]). In utero positioning during fetal development causes the more common problems. In the newborn, the imprint of intrauterine positions may be evident and confused with an abnormality. The effects of in utero positioning are usually physiologic in origin, rather than anatomic.

Bone Growth in Childhood

During the first two decades of life, the skeleton undergoes general overall growth. The long bones of the skeleton, which grow at a relatively rapid rate, are provided with a specialized structure called the epiphyseal growth plate\(^2\) (Fig. 58.1). The chondrocytes are involved in synthesizing cartilage of the epiphyseal plate.\(^2\) As long bones grow in length, the deeper layers of cartilage cells in the growth plate multiply and enlarge and ultimately calcify. The embedded cartilage cells then die attracting the osteoblasts to migrate into the area. Osteoid is secreted from the osteoblasts, which assists the mature bone in forming. Therefore, in the epiphyseal plates, there is continuous cartilage synthesis, calcification, erosion, and osteoblast invasion so that there is always active bone formation\(^3\) (Fig. 58.2). This process allows bone growth to proceed without changing the shape of the bone or causing disruption of the articular cartilage. The cells in the growth plate stop dividing at puberty, at which time the epiphysis and metaphysis fuse.

Several factors can influence the growth of cells in the epiphyseal growth plate. Epiphyseal separation can occur in children as a result of trauma. The separation usually occurs in the zone of the mature enlarged cartilage cells, which is the weakest part of the growth plate. The blood vessels that nourish the epiphysis pass through the growth plate. These vessels are ruptured when the growth plate separates. This can cause cessation of growth and a shortened extremity. The growth plate also is sensitive to nutritional and metabolic changes. Scurvy (i.e., vitamin C deficiency) impairs the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate and decreased diaphyseal growth. In rickets (i.e., vitamin D deficiency), calcification of the newly developed bone on the metaphyseal side of the growth plate is impaired. Thyroid hormone, insulin-like growth factor, and insulin are required for normal growth. Alterations in these and other hormones can also affect growth. A few years after reaching puberty, the epiphyseal plates in the long bones become less responsive to the hormones and then become totally unresponsive.\(^2\) Generally, people reach the end of bone growth by the age of 20 as the epiphyseal plate closes. However, some bones remain responsive to hormones and continue to grow. Examples include the skull, fingers, feet, and jaw.\(^2\)

Growth in the diameter of bones occurs as new bone is added to the outer surface of existing bone along with an accompanying resorption of bone on the endosteal or inner surface. Such oppositional growth allows for widening of the marrow cavity while preventing the cortex from becoming too thick and heavy. In this way, the shape of the bone is maintained. As a bone grows in diameter, concentric rings are added to the bone surface, much as rings are added to a tree trunk. These rings form the lamellar structure of mature bone. Osteocytes, which develop from osteoblasts, become buried in the rings. Haversian channels form as periosteal vessels running along the long axis become surrounded by bone.\(^3\)

Alterations during Normal Growth Periods

Infants and children undergo changes in muscle tone and joint motion during growth and development. Toeing-in, toeing-out, bowlegs, and knock-knees occur frequently in infancy and childhood.\(^4\) They usually cause few problems and are corrected during normal growth processes. There may be physiologic flexion contractures of the hips, which tend to be externally rotated and the patellae point outward, whereas the feet appear to point forward because of the internal pulling force of the tibiae. During the first year of life, the lower extremities begin to straighten out in preparation for walking. Internal and external rotations become equal, and the hips extend.

Musculoskeletal assessment of the newborn is important to identify abnormalities that require early intervention, facilitate treatment, establish baselines for future reference, and educate and counsel parents.\(^5\)\(^6\) There are many clinical deviations that are easily correctable in a newborn and others that correct spontaneously as the child grows.

KEY POINTS

DEVELOPMENTAL SKELETAL DISORDERS

- Many disorders of early infancy are caused by intrauterine positions and resolve as the child grows.
- Nutritional and metabolic disorders can impair the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate.
Torsional Deformities

All infants and toddlers have lax ligaments that become tighter with age and assumption of the weight-bearing posture. The hypermobility that accompanies joint laxity, coupled with the torsional (i.e., rotational) forces exerted on the limbs during growth, is responsible for a number of variants seen in young children. Torsional forces caused by intrauterine positions or sleeping and sitting patterns twist the growing bones and can produce the deformities as a child grows and develops.

In infants, the femur normally is rotated to an antverted position, with the femoral head and neck rotated anteriorly with respect to the femoral condyles. Femoral anteverision (i.e., medial rotation) decreases from approximately 40 degrees at birth to approximately 15 degrees at maturity (Fig. 58.3). The normal tibia is externally rotated approximately 5 degrees at birth and approximately 15 degrees at maturity. Torsional abnormalities frequently demonstrate a familial tendency.5,6
The foot progression angle describes the angle between the axis of the foot and the line of progression.\(^4\)\(^7\) It is determined by watching the child walking and running, although it is usually less noticeable when the child is running or barefoot. Figure 58.4 illustrates the position of the foot in toeing-in and toeing-out, and the line of progression, when a child is walking.

**Toeing-In.** Toeing-in (i.e., metatarsus adductus) is the most common congenital foot deformity, with an incidence of approximately 1 per every 1000 to 2000 live births.\(^7\) It is sometimes called pigeon toe. The forefoot commonly is adducted and gives the foot a kidney-shaped appearance, whereas the hindfoot is normal\(^8\) (Fig. 58.5). It can be caused by torsion in the foot, lower leg, or entire leg. Toeing-in due to adduction of
Bone remodeling constitutes a process of skeletal maintenance once skeletal growth is complete. It takes place in the (1) osteons of mature bone and consists of a cycle of (2) bone resorption by osteoclasts, (3) followed by bone formation by osteoblasts. Bone remodeling is (4) controlled by cytokines and growth factors that interact with a paracrine system consisting of the RANK ligand (RANKL), the RANK receptor, and OPG.

**Bone Remodeling Cycle**

Mature bone is made up of osteons or units of concentric lamellae (bone layers) and the haversian canal they surround. Bone remodeling consists of a sequence of bone resorption within an osteon by osteoclasts, followed by new bone formation by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the resorbed bone. If it does not, there is net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

**Bone Resorption**

The osteoclasts, which are bone-resorbing cells derived from monocyte/macrophage precursors, are the cells involved in the initiation of bone remodeling. The sequence of bone resorption and bone formation is activated by many stimuli, including the action of parathyroid hormone and calcitonin. It begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and inorganic (mineral) components are removed, creating a tunnel-like space in the osteon. Soluble factors released during resorption aid in the recruitment of osteoblasts to the site, thereby linking bone resorption to bone formation.
Chapter 58 Disorders of Musculoskeletal Function: Developmental and Metabolic Disorders

Bone Formation

After osteoclastic activity has ceased, osteoblasts begin to deposit the organic matrix (osteoid) on the wall of the osteon canal. As successive lamellae of bone are deposited, the canal ultimately attains the relative proportions of the original osteon. In the formation and maintenance of bone, osteoblasts provide much of the local control because not only do they produce new bone matrix, they play an essential role in mediating osteoclast activity. Many of the primary stimulators of bone resorption, such as parathyroid hormone, have minimal or no direct effects on osteoclasts. Once the osteoblast, which has receptors for these substances, receives the appropriate signal, it releases a soluble mediator called RANKL that induces osteoclast activity.

Control of Bone Metabolism and Remodeling

The pivotal pathway linking osteoclast-mediated bone resorption with osteoblast-mediated bone formation consists of a paracrine system that includes RANKL, its receptor RANK, and a soluble protein called osteoprotegerin. RANKL, which is produced by osteoblasts and their precursors, binds to RANK, promoting osteoclast differentiation and proliferation. The soluble OPG molecule, which is produced by a number of tissues, acts as a decoy receptor to block the action of RANKL. This system ensures the tight coupling of bone formation and resorption, and provides a means whereby a wide variety of biologic mediators (e.g., hormones, cytokines, growth factors) influence the homeostasis of bone.
UNIT XIV Disorders of Musculoskeletal Function

Femoral head
Femoral anteversion
Internal tibial torsion
Femoral condyles

FIGURE 58.3 • Femoral anteversion and internal tibial rotation. Femoral anteversion normally decreases from about 40 degrees at birth to 15 degrees at maturity, and internal tibial rotation from 5 degrees at birth to 15 degrees at maturity.

the forefoot (i.e., congenital metatarsus adductus) usually is the result of the fetal position maintained in utero. It may occur in one foot or both feet. Diagnostic methods include examination of the plantar aspect of the foot, noting the overall shape of the foot and the presence or absence of an arch.6 The presence of a skin crease indicates a congenital deformity (see Fig. 58.5). Metatarsus adductus is graded based on the foot’s flexibility while applying pressure to the medial forefoot. The defect is defined as grade I, grade II, or grade III. Grade I is a supple deformity that can be passively manipulated into a straight position and requires no treatment. A grade II deformity corrects only to a straight lateral border, and a grade III deformity is more rigid and may require further treatment.7 Treatment consisting of serial long leg casting or a brace that pushes the metatarsals (not the hindfoot) into abduction usually is required in a fixed (rigid) deformity (i.e., one in which the forefoot cannot be passively manipulated into a straight position).6,8

Toeing-Out. Toeing-out (slew foot) is a common problem in children and is caused by external femoral torsion. It is less common than toeing-in and occurs sometimes with calcaneovalgus and pes planovalgus.9 This occurs when the femur can be externally rotated to approximately 90 degrees but internally rotated only to a neutral position or slightly beyond. Because the femoral torsion persists when a child habitually sleeps in the prone position, an external tibial torsion also may develop. If external tibial torsion is present, the feet point lateral to the midline of the medial plane. External tibial torsion rarely causes toeing-out; it only intensifies the condition. Toeing-out usually corrects itself as the child becomes proficient in walking. Occasionally, a night splint is used.

Tibial Torsion. Tibial torsion is determined by measuring the thigh–foot angle, which is done with the ankle and knee positioned at 90 degrees. In this position, the foot normally rotates outward. Internal tibial torsion (i.e., bowing of the tibia) is a rotation of the tibia that makes the feet appear to turn inward (see Fig. 58.3). It is the most common cause of toeing-in in children younger than 2 years of age. It is present at birth and may fail to correct itself if children sleep on their knees with the feet turned in, or sit on in-turned feet.7 It is thought to be caused by genetic factors and intrauterine compression, such as an unstretched uterus during a first pregnancy or intrauterine crowding with twins or multiple fetuses. Tibial torsion generally improves naturally with growth, but this may take years.
External tibial torsion, a much less common disorder, is associated with calcaneovalgus foot and is caused by a normal variation of intrauterine positioning or a neuromuscular disorder. It is characterized by an abnormally positive thigh-foot angle of 30 to 50 degrees. The condition corrects itself naturally, and treatment is observational. Significant improvement begins during the first year with the onset of ambulation, and usually is complete by 2 to 3 years of age. The normal adult exhibits about 20 degrees of tibial torsion.

Femoral Torsion. Femoral torsion refers to abnormal variations in hip rotation. Hip rotation is measured at the pelvic level with the child in the prone position and the knees flexed at a 90-degree angle. In this position, the hip is in a neutral position. Rotating the lower leg outward produces internal or medial femoral rotation; rotating it inward produces external or lateral rotation. During measurement of hip rotation, the legs are allowed to fall to full internal rotation by gravity alone; lateral rotation is measured by allowing the legs to fall inward and cross. Hip rotation in flexion and extension also can be measured with computed tomography (CT). By 1 year of age, there is normally approximately 45 degrees of internal rotation and 45 degrees of external rotation.

Internal femoral torsion, also called femoral antever sion (see Fig. 58.3), is a normal variant commonly seen during the first 6 years of life, especially in 3- and 4-year-old girls. Characteristically, there is 80 to 90 degrees of internal rotation of the hip in the prone position. The condition is thought to be related to increased laxity of the anterior capsule of the hip such that it does not provide the stable pressure needed to correct the antever sion that is present at birth. Children are most comfortable sitting in the “W” position, with their hips between their knees. It is believed that this position allows the lower leg to act as a lever, producing torsional changes in the femur. When the child stands, the knees turn in and the feet appear to point straight ahead. When the child walks, the knees and toes point in. Children with this problem are encouraged to sit cross-legged or in the so-called tailor position. If left untreated, the patella may subluxate and produce intra-articular stress. There is a new surgical treatment for patellofemoral malalignment with patellar subluxation or dislocation and pain. A derotational osteotomy may be done in severe cases or if there is functional disability.

External femoral torsion is an uncommon disorder characterized by excessive external rotation of the hip. Bilateral external torsion is usually a benign condition, and treatment is observational. When the disorder is unilateral, slipped capital femoral epiphysis should be ruled out.

Genu Varum and Genu Valgum

Genu varum, or bowlegs, is an outward bowing of the knees greater than 1 inch when the medial malleoli of the ankles are touching (Fig. 58.6). As children grow, lower limb alignment usually follows a predictable pattern (Fig. 58.7). Most infants and toddlers have some bowing of their legs up to 18 months of age. If there is a large separation between the knees (>15 degrees) after 2 years of age, the child may require bracing. The child also should be evaluated for diseases such as rickets or tibia vara (i.e., Blount disease) (Fig. 58.8).

Genu valgum, or knock-knees, is a deformity in which there is decreased space between the knees (Fig. 58.6). The medial malleoli in the ankles cannot be brought in contact with each other when the knees are touching. Valgus gradually develops after age 24 months and is most apparent between 3 and 4 years of age. The condition usually is the result of lax medial collateral ligaments of the knee. Obesity is also associated with the development of genu valgum and is becoming almost epidemic in the United States. By 7 years of age, the lower limb is in slight valgus and changes very little thereafter. Genu valgum can be ignored up to 7 years of age, unless it is a larger angle, one sided, or associated with short stature. It usually resolves spontaneously and rarely requires treatment. If genu varum or genu valgum persists and is not corrected, osteoarthritis may develop in adulthood as a result of abnormal intra-articular stress. There is a new surgical treatment of both knock-knees and bowlegs, which includes the use of extraphyseal tension band plates that manipulate the angle of the growth plate. Genu varum can cause gait awkwardness and increased risk for sprains and fractures. Uncorrected genu valgum may cause subluxation and recurrent dislocation of the patella, with a predisposition to chondromalacia and joint pain and fatigue. Therefore, new challenges such as obesity need to become a priority management outcome in pediatric orthopedics.

Blount Disease

Blount disease, or idiopathic tibia vara, is a developmental deformity of the medial half of the proximal tibial epiphysis.
that results in a progressive varus angulation below the knee\textsuperscript{10,13} (Fig. 58.8). Onset can occur early in infancy up until 4 years of age and this type is referred to as early-onset disease.\textsuperscript{13,14} Late onset disease is when the deformity occurs after the age of 4.\textsuperscript{13} Obesity is also associated with Blount disease and other musculoskeletal diseases.\textsuperscript{15} There is also increased evidence that being overweight can be the etiology of musculoskeletal pain and increased fractures.\textsuperscript{15}

Untreated infantile tibia vara is almost always progressive, with evidence of outward angulation, flexion, internal rotation, and abnormal lateral knee laxity. There is radiographic evidence of progressive depression of the medial metaphysis, the growth plate, and the epiphysis. Fusion of the metaphysis to the epiphysis may occur in severe cases. Night-brace treatment is used for mild early-onset disease for realignment. Valgus rotational osteotomy of the tibia is often indicated if angulation persists beyond 3 to 4 years of age. Persistent tibia vara leads to early degenerative changes of the knee.

**Flatfoot**

Flatfoot (i.e., pes planus) is a deformity characterized by the absence of the longitudinal arch of the foot. Infants normally have a wider and fatter foot than adults. The fat pads that normally are accentuated by pliable muscles with young children create the appearance of fullness often mistaken for flatfoot.\textsuperscript{16} Until the longitudinal arch develops around 2 years of age, most children appear to have flat feet. The true criterion for flatfoot is that the talus points medially and downward, so that the heel is everted and the forefoot is inverted.

Obesity, ligament laxity (which is genetically linked), and the wearing of nonsupportive shoes over time are other possible etiologies of pes planus.\textsuperscript{17} Overweight children have lower plantar arch height due to the excessive body weight putting increased pressure on the child’s feet.\textsuperscript{17}

There are two types of flatfoot—flexible and rigid. Most children with flexible flatfoot have loose ligaments, allowing the feet to sag when they gain weight. With this type of flatfoot, the arch disappears only with weight bearing. No special treatment is needed for flexible flatfoot. People with flexible flatfoot are less prone to pain and injury than those with normal or high arches. The rigid flatfoot is fixed with no apparent arch in any position. It is seen in conjunction with neuromuscular diseases such as cerebral palsy.

In the adult, treatment of flatfoot is conservative and aimed at relieving fatigue and discomfort. Supportive, well-fitting shoes with arch supports may be helpful and prevent ligaments from becoming overstretched. Surgery may be done in cases of severe and persistent symptoms.
Hereditary and Congenital Deformities

Congenital deformities are abnormalities that are present at birth. They range in severity from mild limb deformities, which are relatively common, to major limb malformations, which are relatively rare. The most common anomaly of the toes or fingers is polydactyly or the presence of an extra digit on the hand or foot. Macrodactyly occurs when one or more toes or fingers are hypertrophied and are significantly larger than the surrounding toes or fingers.

There may also be a simple webbing of the fingers or toes (syndactyly), or the absence of a bone such as the phalanx, rib, or clavicle. Joint contractures and dislocations produce more severe deformity, as does the absence of entire bones, joints, or limbs. Surgery is done to relieve functional symptoms, such as pain or difficulty in fitting shoes. The cosmetic goal is to alter the grotesque appearance of the hand or foot and to achieve a similar size to the opposite extremity.

Congenital deformities are caused by many factors, some unknown. These factors include hereditary influences, external agents that injure the fetus (e.g., radiation, alcohol, drugs, such as thalidomide taken by pregnant women with morning sickness in the 60s, and viruses), and intrauterine environmental factors. Many of the organic bone matrix components have been identified only recently, and their interactions were found to be more complex than originally thought. Hand and foot disorders associated with abnormalities in bone matrix include those with deficient collagen synthesis and decreased bone mass.18

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a hereditary disease characterized by defective synthesis of type I collagen19,20 (Fig. 58.9). OI is one of the most common hereditary bone diseases, with an estimated 20,000 to 50,000 people with OI in the United States. OI is usually transmitted as an autosomal dominant trait. However, the type III form of OI, which is the most progressively deforming type with multiple life-threatening defects, is sometimes, although rarely, inherited as an autosomal recessive trait.20 Mutations in the genes connected with type I collagen, which impacts the development of bones, joints, ears, ligaments, teeth, sclerae, and skin cause the problems.20 The genes are COL1A1 and COL1A2, which encode the alpha, and alpha, chains of type I procollagen.20 These genes are found in chromosome 17 and 7 and cause different structural and clinical changes in the types of OI.

Clinical Manifestations. The clinical manifestations of OI include a spectrum of disorders marked by extreme skeletal fragility. Four major subtypes of the disorder have been identified each with their specific manifestations20 (Table 58.1). The disorder is characterized by thin and poorly developed bones that are prone to multiple fractures. These children have short limbs and a soft, thin cranium with bifrontal prominences that give a triangular appearance to the face. Other problems associated with defective connective tissue synthesis include wormian bone in the skull, thin skin, blue or gray sclera, abnormal tooth development, hypotonic muscles, loose-jointedness, and scoliosis.21 Hearing loss due to otosclerosis of the tiny bones in the middle ear is common in affected adults. The most serious defects occur with type II. Severely affected fetuses have multiple intrauterine fractures and bowing and shortening of the extremities. Many of these infants are stillborn or die during infancy.

*FIGURE 58.9* • Osteogenesis imperfecta. (A) A radiograph illustrates the thin humerus and bones of the forearm. There is a fracture callus in the proximal ulna. (B) A photomicrograph of the fracture callus with prominent cartilage in the upper left. The cortex is thin and composed of hypercellular woven bone. (From Rubin R., Strayer D. S. (Eds.) (2011). *Rubin’s pathology: Clinicopathologic foundations of medicine* (6th ed., p. 1213). Philadelphia, PA: Lippincott Williams & Wilkins.)
Treatment. There is no definitive treatment for correction of the defective collagen synthesis that is characteristic of OI. However, the bisphosphonates have been shown to produce an increase in cortical bone width and cancellous bone volume, as well as increased bone strength and mineral content.\(^2\) Prevention and treatment of fractures is important. Precise alignment is necessary to prevent deformities. Nonunion is common, especially with repeated fractures. Surgical intervention is often needed to stabilize fractures and correct deformities.

**Developmental Dysplasia of the Hip**

Developmental dysplasia of the hip (DDH), formerly known as *congenital dislocation of the hip*, is an abnormality in hip development that leads to a wide spectrum of hip problems in infants and children, including hips that are unstable, malformed, subluxated, or completely dislocated.\(^2\) In less severe cases, the hip joint may be unstable, with excessive laxity of the joint capsule, or subluxated, so that the joint surfaces are separated and there is a partial dislocation (Fig. 58.10).

With dislocated hips, the head of the femur is located outside of the acetabulum.

The results of newborn screening programs have shown that 1 of 100 infants have some evidence of hip instability, whereas dislocation of the hip is seen in 1 of every 1000 live births.\(^4\) The left hip is involved more frequently than the right hip because of the left occipital intrauterine positioning of most infants.\(^5\) The disorder occurs most frequently in first-born children and is six times more common in female than in male infants.\(^2\)

**Etiology.** The cause of DDH is multifactorial, with heredity, environmental, and mechanical factors playing a role. A positive family history and generalized laxity of the ligaments are related. The increased frequency in girls is thought to result from their susceptibility to maternal estrogens and other hormones associated with pelvic relaxation. Dislocation also may result from environmental factors such as fetal position, a tight uterus that prevents fetal movement, and breech delivery. The presence of other congenital abnormalities is associated with an increased incidence of DDH. Thus, the hips of children presenting with congenital abnormalities should be examined carefully.

**Diagnosis.** Early diagnosis of DDH is important because treatment is easiest and most effective if begun during the first 6 months of life.\(^2\) Also, repeated dislocations cause damage to the femoral head and the acetabulum. There is no uniformly accepted method for diagnosis of DDH during the newborn period. However, there is evidence that ultrasound is most effective during the first month of life for screening hip joint problems.\(^2\) However, the U.S. Preventive Services Task Force (USPSTF) states that 90% of the hip abnormalities identified by ultrasound resolve on their own.\(^2\) Clinical examination of

the hips is recommended at birth and every several months during the first year of life. Research states that 60% to 80% of hip deformities identified in children from clinical examination resolve on their own. Follow-up clinical examinations should be done in the presence of an abnormality. In infants, signs of DDH include asymmetry of the hip or gluteal folds, shortening of the thigh so that one knee (on the affected side) is higher than the other hip, and limited abduction of the affected hip (Fig. 58.11). The asymmetry of gluteal folds is not definitive but indicates the need for further evaluation. The USPSTF states that evidence is insufficient to recommend routine screening of asymptomatic infants as a means of preventing adverse outcomes.

Several examination techniques can be used to screen for a dislocatable hip. Two specific maneuvers for assessing hip stability in the newborn are the Ortolani maneuver (for reducible dislocation) (Fig. 58.12) and the Barlow maneuver (for the dislocatable hip) (Fig. 58.13). The Barlow maneuver involves a manual attempt to dislocate and reduce the abnormal hip while the infant is in the supine position with both knees flexed. With gentle downward pressure being applied to the knees, the knee and thigh are manually abducted as an upward and medial pressure is applied to the proximal thigh. In infants with the disorder, the initial downward pressure on the knee produces a dislocation of the hip, a positive Barlow sign. This is followed by a palpable or audible click (i.e., Ortolani sign) as the hip is reduced and moves back into the acetabulum. The sensitivity of these tests is improved significantly with the use of trained and experienced examiners. The Galeazzi test is a measurement of the length of the femurs that is done by comparing the height at the knees while they are flexed at 90 degrees. An inequality in the height of the knees is a positive Galeazzi sign and is usually caused by hip dislocation or congenital femoral shortening. This test is not useful in detecting bilateral DDH because both leg lengths will be equal. In an older child, instability of the hip may produce a delay in standing or walking and eventually cause a characteristic waddling gait. When the thumbs are placed over the anterior iliac crest and the hands are placed over the lateral pelvis in examination, the levels of the thumbs are not even; the child is unable to elevate the opposite side of the pelvis (positive Trendelenburg test).

Diagnosis of DDH is confirmed by ultrasonography or radiography. Ultrasonography is used in infants with high-risk factors (e.g., female infants born in the breech position) or an abnormal result on examination. Radiographs of newborns with suspected DDH are of limited value because the femoral heads do not ossify until 4 to 6 months of age. After 6 months of age, the increasing ossification of the femur renders ultrasonography less reliable, and radiographs are preferred.

**Treatment.** Treatment of a DDH should be individualized and depends on whether the hip is subluxated or dislocated. Subluxation of the hip at birth often resolves without treatment and should be observed for 2 weeks. When subluxation persists beyond this time, treatment may be indicated and referral is recommended. The best results are obtained if the
Congenital Clubfoot

Clubfoot, or talipes, is one of the most common pediatric orthopedic conditions. It has an incidence of approximately 1 to 2 cases per 1000 live births, is bilateral in about 50% of cases, and affects boys more often than girls. Like congenital dislocation of the hip, its occurrence follows a multifactorial inheritance pattern. Clubfoot may be associated with chromosomal abnormalities or congenital syndromes that are transmitted by Mendelian inheritance patterns. However, it is most commonly idiopathic and found in normal infants in whom no genetic or chromosomal abnormality or other extrinsic cause can be found.

In forefoot adduction, which accounts for approximately 95% of idiopathic cases, the foot is plantar flexed and inverted. This is the so-called equinovarus type in which the foot resembles a horse's hoof. The other 5% of cases are of the calcaneovalgus type, or reverse clubfoot, in which the foot is dorsiflexed and everted. The reverse clubfoot can occur as an isolated condition or in association with multiple congenital defects. At birth, the feet of many infants assume one of these two positions, but they can be passively overcorrected or brought back into the opposite position. If the foot cannot be overcorrected, some type of correction may be necessary.

Treatment of clubfoot is begun as soon as the diagnosis is made. One screening tool for equinovarus type clubfoot is the俱乐部foot assessment protocol, which is also helpful in developing a management plan. When treatment is initiated during the first few weeks of life, a nonoperative procedure may be effective. Serial manipulations and casting are used gently to correct each component of the deformity. One method, called the Ponseti method, involves weekly gentle stretching and manipulation of the misaligned bones followed by application of a well-molded long leg plaster cast with the knee held at a right angle. The cast maintains the correction and allows for further relaxation of tight structures in anticipation of the next week's casting. Correction of the deformity is usually obtained within 6 to 8 weeks. Frequently, a percutaneous Achilles tendon lengthening is performed using a topical anesthetic cream before application of the final cast to allow for complete correction of the equinus deformity. The correction is maintained by full-time wear of a Denis Browne splint for 3 months and part-time night and nap wear for approximately 2 to 3 years. Surgery may be required for severe deformities or when nonoperative treatment methods are unsuccessful.

Juvenile Osteochondroses

The term juvenile osteochondroses is used to describe a group of children’s diseases in which one or more growth ossification centers undergo a period of degeneration, necrosis, or inactivity that is followed by regeneration and usually deformity. The osteochondroses are separated into two groups according to their causes. The first group consists of the true osteonecrotic osteochondroses, so called because the diseases are caused by localized osteonecrosis of an apophyseal or epiphyseal center (e.g., Legg-Calvé-Perthes disease, Freiberg infraction, Panner disease, Kienböck disease). The second group of juvenile osteochondroses is caused by abnormalities in ossification of cartilaginous tissue resulting from a genetically determined normal variation or from trauma (e.g., Osgood-Schlatter disease, Blount disease, Sever disease, Scheuermann disease). The discussion in this section focuses on Legg-Calvé-Perthes disease from the first group and Osgood-Schlatter disease from the second group. Slipped capital femoral epiphysis is a disorder of the growth plate.
**Legg-Calvé-Perthes Disease**

Legg-Calvé-Perthes disease is an idiopathic osteonecrotic disease of the proximal (capital) femoral epiphysis.\(^{20}\) It occurs in 1 of 1200 children, affecting primarily those, mostly boys, between ages 3 and 12 years, with a median age of 7 years.\(^{29}\) It occurs primarily in boys and is much more common in whites than in African Americans. Although no definite genetic pattern has been established, it occasionally affects more than one family member.

**Etiology and Pathogenesis.** The cause of Legg-Calvé-Perthes disease is unknown. The disorder is usually insidious at onset and occurs in otherwise healthy children. It may, however, be associated with acute trauma. Evidence suggests a correlation between acquiring Legg-Calvé-Perthes disease and some procoagulation parameters with boys.\(^{30}\) Affected children usually have a shorter stature. Undernutrition has been suggested as a causative factor. When girls are affected, they usually have a poorer prognosis than boys because they are skeletally more mature and have a shorter period for growth and remodeling than boys of the same age.\(^{29}\)

The primary pathologic feature of Legg-Calvé-Perthes disease is an avascular necrosis of the bone and marrow involving the epiphyseal growth center in the femoral head.\(^{20}\) The disorder may be confined to part of the epiphysis, or it may involve the entire epiphysis. In severe cases, there is a disturbance in the growth pattern that leads to a broad, short femoral neck. The necrosis is followed by slow absorption of the dead bone over 2 to 3 years. Although the necrotic trabeculae eventually are replaced by healthy new bone, the epiphysis rarely regains its normal shape. The process occurs in four predictable stages.\(^{31}\) The *first stage*, which lasts for 6 to 12 months, is the avascular stage when the ossification center is becoming necrotic. Damage to the femoral head is determined by the amount of necrosis occurring during this stage. The *second stage*, lasting about 1 to 3 years, is the revascularization stage, during which resorption of the necrotic bone takes place. The *third stage* is the reossification stage, during which radiolucent areas become dense, while the shape of the femoral head improves. The *fourth stage*, which is the healed stage, involves the forming of immature bone cells by normal bone cells and the resulting femoral head.\(^{31}\)

**Clinical Manifestations.** The main symptoms of Legg-Calvé-Perthes disease are pain in the thigh or knee and difficulty in walking. The child may have a painless limp with limited abduction and internal rotation and a flexion contracture of the affected hip. The age of onset is important because young children have a greater capability for remodeling of the femoral head and acetabulum, and thus less flattening of the femoral head occurs.

**Diagnosis and Treatment.** Early diagnosis is important and is based on correlating physical symptoms with radiographic findings (e.g., magnetic resonance imaging [MRI], CT scan, ultrasound, arthrography, bone scintigraphy, and radiography), which are related to the stage of the disease.\(^{32}\)

The goal of treatment is to reduce deformity and preserve the integrity of the femoral head while the necrotic bone is resorbed.\(^{31}\) Conservative and surgical interventions are used in the treatment of Legg-Calvé-Perthes disease. Children younger than 4 years of age with little or no involvement of the femoral head may require only periodic observation. In all other children, some intervention is needed to relieve the force of weight bearing, muscular tension, and subluxation of the femoral head. It is important to maintain the femur in a well-seated position in the concave acetabulum to prevent deformity. This is done by keeping the hip in abduction and mild internal rotation. Treatment involves periods of rest, use of assistive devices for walking, non–weight bearing, and abduction braces to keep the legs separated in abduction with mild internal rotation.

Surgery may be done to contain the femoral head in the acetabulum. This treatment usually is reserved for children older than 6 years of age who at the time of diagnosis have more serious involvement of the femoral head. The best surgical results are obtained when surgery is done early, before the epiphysis becomes necrotic. One method, creeping substitution, is the process by which the necrotic marrow is removed and replaced by neurovascular tissue with pluripotent cells.\(^{20,33}\) Some children with Legg-Calvé-Perthes disease may require total hip replacement surgery at some point in time depending on the degree of avascular necrosis.\(^{34}\)

**Osgood-Schlatter Disease**

Osgood-Schlatter disease involves microfractures in the area where the patellar tendon inserts into the tibial tubercle, which is an extension of the proximal tibial epiphysis.\(^{35}\) This area is particularly vulnerable to injury caused by sudden or continued strain from the patellar tendon during periods of growth, particularly in athletic adolescents.

The patellar tendon is inflamed and thickened from the continuous inflammation and causes pain in front of the knee. There is swelling, tenderness, and increased prominence of the tibial tubercle. The symptoms usually are self-limiting. They may recur during growth periods, but usually resolve after closure of the tibial growth plate. In some cases, limitations on activity, tibial bands, or braces to immobilize the knee; anti-inflammatory agents; and application of cold are necessary to relieve the pain.\(^{35}\) The objective of treatment is to release tension on the quadriceps to permit revascularization and reossification of the tibial tubercle. Complete resolution of symptoms through healing (physical closure) of the tibial tubercle can extend to a year or even 2 years.\(^{35}\)

**Slipped Capital Femoral Epiphysis**

Slipped capital femoral epiphysis, or coxa vara, is a disorder of the growth plate that occurs near the age of skeletal maturity. It involves a three-dimensional displacement of the epiphysis (posteriorly, medially, inferiorly), meaning that the
femur is rotated externally from under the epiphysis. The condition is rare, with an estimated frequency of 10 in 10,000.36

The cause of slipped capital femoral epiphysis is obscure, but it may be related to the child’s susceptibility to stress on the femoral neck as a result of genetics or structural abnormalities.36 Boys are affected twice as often as girls, and in approximately half the cases the condition is bilateral. Affected children often are overweight with poorly developed secondary sex characteristics, or, in some instances, are extremely tall and thin. In many cases, there is a history of rapid skeletal growth preceding displacement of the epiphysis. The condition also may be affected by nutritional deficiencies or endocrine disorders such as hypothyroidism, hypopituitarism, and hypogonadism.37

Children with the condition often complain of referred knee pain accompanied by difficulty in walking, fatigue, and stiffness.38 The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity (mild, <33%; moderate, 33% to 50%; and severe, >50%).39 Early treatment is imperative to prevent lifelong crippling. In situ fixation is recommended.39 Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate closes.

Children with the disorder must be followed closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with the internal fixation.37 Degenerative arthritis may develop, requiring joint replacement later in life.

**Scoliosis**

Scoliosis is a lateral deviation of the spinal column commonly in the coronal or frontal plane that may or may not include rotation or deformity of the vertebrae.39 Scoliosis, a threedimensional deformity of the spine, often affects the entire skeletal torso.39 It can be classified with regard to age of onset—infantile, juvenile, and adolescent.20 It is seen with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops from neuropathic or myopathic diseases. It is seen with cerebral palsy, muscular dystrophy, myelodysplasia, and poliomyelitis. There is often a long, C-shaped curve from the cervical to the sacral region. In children with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops with Duchenne muscular dystrophy and usually is not severe.

**Idiopathic Scoliosis**

Idiopathic scoliosis is a structural spinal curvature for which no cause has been established. It occurs in healthy, neurologically normal children. The cause is most likely complex and multifactorial. It seems likely that heredity is involved because mother–daughter pairings are common, but identical twins are not uniformly affected. The magnitude of the curvature in an affected child is not related to magnitude of curvature in relatives. A recent study of the melatonin receptor 1B (MTNR1B) gene in people with adolescent idiopathic scoliosis suggests that MTNR1B may serve as a susceptibility gene for adolescent idiopathic scoliosis.41 Also, evidence suggests that many people with neurofibromatosis type 1 (NF-1) have some type of scoliosis.42 One new screening tool available for diagnosis and determination of treatment especially with adolescent idiopathic scoliosis is the ScoliScore assessment (a collection of genetic markers correlated with scoliosis), which is a genetic testing that studies the person’s DNA sample and predicts the curve progression risk for individual people with scoliosis.39

Although a scoliotic curve may be present in any area of the spine, the most common curve is a right thoracic curve, which produces a rib prominence on the convex side and hypokyphosis from rotation of the vertebral column around its long axis as the spine begins to curve.

**Congenital Scoliosis**

Congenital scoliosis is caused by disturbances in vertebral development during the 6th to 8th weeks of embryologic development.42 Congenital scoliosis may be divided into failures of formation and failures of segmentation. Failures of formation indicate the absence of a portion of the vertebra, such as hemivertebra (absence of a whole side of the vertebra) and wedge vertebra (missing only a portion of the vertebra). Failure of segmentation is the absence of the normal separation between the vertebrae.43 The child may have other anomalies and neurologic complications if the spine is involved. Early diagnosis and treatment of progressive curves are essential for children with congenital scoliosis. Surgical intervention is the treatment of choice for progressive congenital scoliosis.39

**Neuromuscular Scoliosis**

Neuromuscular scoliosis develops from neuropathic or myopathic diseases. It is seen with cerebral palsy, muscular dystrophy, myelodysplasia, and poliomyelitis. There is often a long, C-shaped curve from the cervical to the sacral region. In children with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops with Duchenne muscular dystrophy and usually is not severe.

**Clinical Manifestations**

Scoliosis usually is first noticed because of the deformity it causes. A high shoulder, prominent hip, or projecting scapula may be noticed by a parent or in a school-based screening program. In girls, difficulty in hemming or fitting a dress may call attention to the deformity. Idiopathic scoliosis usually is a painless process, although pain may be present in severe cases,
usually in the lumbar region. The pain may be caused by pressure on the ribs or on the crest of the ilium. There may be shortness of breath as a result of diminished chest expansion and gastrointestinal disturbances from crowding of the abdominal organs. Adults with less severe deformity may experience mild backache. If scoliosis is left untreated, the curve may progress to an extent that compromises cardiopulmonary function and creates a risk for neurologic complications.

**Diagnosis**

Early diagnosis of scoliosis can be important in the prevention of severe spinal deformity. The cardinal signs of scoliosis are uneven shoulders or iliac crest, prominent scapula on the convex side of the curve, malalignment of spinous processes, asymmetry of the flanks, asymmetry of the thoracic cage, and rib hump or paraspinal muscle prominence when bending forward. A complete physical examination is necessary for children with scoliosis because the defect may be indicative of other underlying pathologic processes.

Diagnosis of scoliosis is made by physical examination and confirmed by radiography. A scoliometer should be used at the apex of the curvature to quantify a prominence; a scoliometer reading of greater than 5 degrees requires referral to a physician. The curve is measured by determining the amount of lateral deviation present on radiographs and is labeled “right” or “left” for the convex portion of the curve. Other radiographic procedures may be done, including CT scanning, MRI, and myelography.

Although school screening continues to be mandated in a number of states, the USPSTF recommends against the routine screening of asymptomatic adolescents for idiopathic scoliosis, indicating that the potential harms from screening include unnecessary follow-up visits and evaluations due to false-positive results, and adverse psychological effects, especially related to brace wear. Although routine screening is not recommended, health care professionals should be prepared to evaluate idiopathic scoliosis when it is discovered incidentally or when the adolescent or parent expresses concern about scoliosis.

**Treatment**

The treatment of scoliosis depends on the severity of the deformity and the likelihood of progression. Larger curves are more likely to progress. Age of presentation also is important. Curves that are detected before menarche are more likely to progress than those detected after menarche. For people with lesser degrees of curvature (10 to 20 degrees), the trend has been away from aggressive treatment and toward a “wait and see” approach, taking advantage of the more sophisticated diagnostic methods that now are available. Treatment is considered for physically immature children with curves between 20 and 30 degrees. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

A brace may be used to control the progression of the curve during growth and can provide some correction. A commonly used brace is the Milwaukee brace, which was developed by Blount and Schmitt in the 1940s. This was the first brace to provide some degree of active correction. It involves a pelvic mold, various pads, and two metal upright supports around the throat. It is cumbersome, and compliance with wearing the brace has been shown to be poor. In an effort to improve compliance, a number of new bracing techniques have been developed. They include underarm or thoracolumbosacral orthoses. These orthoses consist of easily concealed, prefabricated forms that are modified to suit the patient.

Surgical intervention with instrumentation and spinal fusion is done in severe cases—when the curvature has progressed to 40 degrees or more at the time of diagnosis or when curves of a lesser degree are compounded with imbalance or rotation of the vertebrae. Unlike bracing, which is intended to halt progression of the curvature, surgical intervention is used to decrease the curve. Instrumentation helps correct the curve and balance, and spinal fusion maintains the spine in the corrected position. Several methods of instrumentation (i.e., rods that attach to the vertebral column and posterior fusion) are used. Combined anterior and posterior surgery is used for more severe curvatures. The newer systems provide better sagittal control and more stable fixation, which allow earlier mobility. Despite great advances in spinal surgery, no one method seems to be the best for all cases. There is recent interest in growth modulation approaches using minimally invasive techniques that will result in curve correction while maintaining spinal motion and disk and motion segment integrity.

**Skeletal disorders**

Skeletal disorders can result from congenital or hereditary influences or from factors that occur during normal periods of skeletal growth and development. Newborn infants undergo normal changes in muscle tone and joint motion, causing torsional conditions of the femur or tibia. Many of these conditions are corrected as skeletal growth and development take place. OI is a rare autosomal hereditary disorder characterized by defective synthesis of connective tissue, including bone matrix. It results in poorly developed bones that fracture easily. DDH includes a range of structural abnormalities. Dislocated hips are always treated to prevent changes in the anatomic structure. Other childhood skeletal disorders, such as the osteochondroses, slipped capital femoral epiphysis, and scoliosis, are not corrected by the growth process. These disorders are progressive, can cause permanent disability, and require treatment. Disorders such as DDH and congenital clubfoot are present at birth. Both of these disorders are best treated during infancy. Regular examinations during the first year of life are recommended as a means of achieving early diagnosis of such disorders.

Scoliosis is a lateral deviation of the spinal column that may or may not include rotation or deformity of the vertebrae. Scoliosis is generally classified using age of onset...
and etiology. There are three general classifications of scoliosis: idiopathic (which is the most common and accounts for 80% of all scoliosis), neuromuscular, and congenital. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

**METABOLIC BONE DISEASE**

*After completing this section of the chapter, you should be able to meet the following objectives:*

- Cite the origin of osteoclasts and osteoblasts and describe their functions in bone remodeling.
- Describe the function of the RANK ligand/RANK receptor, and the osteoprotegerin-blocking molecule in the regulation of bone remodeling.
- Describe risk factors that contribute to the development of osteoporosis and relate them to the prevention of the disorder.

Bone is an admixture of inorganic elements and organic matrix that is in a constant state of bone resorption and bone formation (Fig. 58.15). The inorganic elements include the calcium and phosphorus that mineralize bone, and the organic matrix includes bone cells and matrix proteins. The bone cells include the osteoprogenitor cells, the osteoblasts, and the osteoclasts.46–48

![Image of bone cells](image)

**FIGURE 58.15** (A) Photomicrograph of developing bone cells. Osteoblasts are responsible for producing the new bone matrix. (B) Osteocytes maintain the bone matrix. (C) Osteoclasts break down the bone matrix. (From Wingerd B. (2014). The human body: Concepts of anatomy and physiology (3rd ed., p. 116 Figure 6.3). Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins.)

The osteoprogenitor cells are pluripotent mesenchymal cells that are located in the vicinity of all bony surfaces. When appropriately stimulated by growth factors such as bone morphogenic proteins (BMPs), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), insulin-like growth factor, and transforming growth factor-β (TGF-β), they undergo cell division and differentiate into osteoblasts, adipocytes, fibroblasts, chondrocytes, and muscle cells.49 The osteoblast needs a transcription factor, core binding factor alpha-1 (CBFA1), to assist it in expression of genes characteristic of the osteoblasts.49

The osteoblasts are the bone-forming cells and are found in marrow, periosteum, and other areas within the marrow.20 They also initiate the process of mineralization. Osteoblasts express cell surface receptors that bind a number of hormones (parathyroid hormone, vitamin D, estrogen), cytokines, and growth factors. Osteoblasts are able to divide and secrete type I collagen and bone matrix proteins, which are calcium-binding proteins.49 These include osteocalcin and osteonectin.49 Alkaline phosphatase (AL) and osteocalcin are generally the parameters used to denote osteoblastic function.49

The osteoclast is the cell responsible for bone resorption and is found at sites where bone is being removed.46–49 It is derived from the same hematopoietic precursor that gives rise to blood monocytes and tissue macrophages. The cytokines and growth factors crucial to osteoclast differentiation and maturation include the interleukins, tumor necrosis factor (TNF), and colony-stimulating factors. These factors function either by stimulating osteoclast progenitor cells or by participating in a paracrine system in which osteoblasts and marrow stromal cells play a central role.

Osteoblasts and osteoclasts act in coordination and are considered the functional unit of bone, known as the **basic multicellular unit**. The processes of bone formation and resorption are tightly coupled, and their balance determines skeletal mass. As the skeleton grows and enlarges during childhood, a process called **bone modeling** predominates. It results in a bone having adult form and shape. Peak bone mass is achieved during early adulthood after cessation of modeling. It is determined by a number of factors, including the type of vitamin D receptor inherited, nutrition, level of physical activity, age, and hormonal status. Once skeletal growth has attained its adult size, the breakdown and renewal of bone that is responsible for skeletal maintenance is initiated at sites that require replacement or repair. This process is called **bone remodeling**.

The sequence of bone resorption and bone formation begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and the inorganic (mineral) components are removed. The sequence proceeds to the formation of new bone by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the absorbed bone. If it does not, there is a net loss of bone. In older adults, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

Significant progress has been made in understanding the phenomenon of bone remodeling as it relates to the coupling...
of bone resorption with bone formation. The pivotal paracrine pathway linking these two processes consists of three factors: the receptor activator of nuclear factor κB ligand (RANKL); its receptor RANK; and a soluble inhibitor receptor for RANKL, osteoprotegerin (OPG).\(^{44-46}\) So RANK/RANKL are the factors that express bone resorption and OPG is a bone resorption inhibitor. RANKL is a member of the TNF superfamily and both RANK and OPG are members of the TNF receptor family. RANKL is expressed by osteoblasts and their immature precursors and is necessary for osteoclast differentiation and function. RANKL activates its receptor, RANK, which is expressed on osteoclasts and their precursors, thus promoting osteoclast differentiation and activation and prolonging osteoclast survival by suppressing apoptosis. The term osteoprotegerin was coined because of its protective effects against bone loss. The effects of RANKL are blocked by OPG, a soluble receptor protein, which acts as a decoy receptor that binds RANKL and prevents it from binding with RANK on osteoclasts.

It is now believed that dysregulation of the RANKL/RANK/OPG pathway plays a prominent role in the pathogenesis of bone diseases such as neoplasia and bone lesions as well as osteoporosis.\(^{47,50}\) For example, it has been shown that postmenopausal women express higher levels of RANKL on their marrow stromal cells and lymphocytes than premenopausal women or postmenopausal women taking estrogen. It has also been shown that estrogens and the selective estrogen receptor modulator (SERM), raloxifene, stimulate OPG production in osteoblasts. Glucocorticoid exposure, which can contribute to steroid osteoporosis, enhances RANKL expression and suppresses OPG levels, thus elevating the RANKL-to-OPG ratio. There is also evidence linking the pathogenesis of inflammatory conditions such as rheumatoid arthritis to dysregulation of the RANKL/OPG system. Currently there is new evidence that the wingless pathway and interleukin-17, a proinflammatory cytokine, also play a role in various arthritides and bone diseases. There is also evidence that RANKL is expressed on T cells, and in vitro studies have shown that activated T cells can regulate the development and activation of osteoclasts through RANKL.\(^{47}\)

### Osteopenia

Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mass greater than expected for age, race, or sex that occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification.

### Osteoporosis

Osteoporosis is a metabolic bone disease characterized by a loss of mineralized bone mass causing increased porosity of the skeleton and susceptibility to fractures.\(^{38}\) The World Health Organization Osteoporosis Guidelines recommends that postmenopausal women and men over 50 years of age be treated according to the following guidelines:

- Those who have a hip or vertebral fracture.
- Those who have a T score less than \(-2.5\) at the neck of the femur or spine after appropriate evaluation to exclude secondary causes.
- Those who have a 10-year probability of a hip fracture greater than 3% and a T score between \(-1.0\) and \(-2.5\) at the spine or neck of the femur.
- Those who have a 10-year probability of a major osteoporosis-related fracture greater than 20%.\(^{52}\)

Although osteoporosis can occur as the result of a number of disorders, it most often is associated with the aging process. Because bone loss is positively associated with age, the prevalence of osteoporosis and low bone mass is expected to increase.

### Pathogenesis

The pathogenesis of osteoporosis is unclear, but most data suggest an imbalance between bone resorption and formation such that bone resorption exceeds bone formation. Although both of these factors play a role in most cases of osteoporosis, their relative contribution to bone loss may vary depending on age, gender, genetic predisposition, activity level, and nutritional status. Exercise may prevent or delay the onset of...
osteoporosis by increasing peak bone mass density (BMD) during periods of growth. Poor nutrition or an age-related decrease in intestinal absorption of calcium because of deficient activation of vitamin D may contribute to the development of osteoporosis, particularly in older adults.

Under normal conditions, bone mass increases steadily during childhood, reaching a peak in the young adult years. The peak bone mass, or BMD, is an important determinant of the subsequent risk for osteoporosis. It is determined in part by genetic factors, estrogen levels, exercise, calcium intake and absorption, and environmental factors. Genetic factors are linked, in large part, to the maximal amount of bone in a given person, referred to as peak bone mass. Race is a key determinant of BMD and the risk of fractures. Incidence rates obtained from studies among racial and ethnic groups demonstrate that although women have higher fracture rates compared with men overall, these differences vary by race and age. White and Asian women had higher rates for all age groups older than 50 years. The highest BMD values and lowest fracture rates have been reported for black women. Body size is another factor affecting the risk of osteoporosis and risk of fractures. Women with smaller body builds are at increased risk of hip fracture because of lower hip BMD.

Mrs. Tukey is Caucasian and weighs 128 lb and is 5 foot 3 inches tall. Given her family history she is a good example of the part that genetics plays in a person’s peak bone mass. Being 68 years of age and postmenopausal also puts her at higher risk for osteoporosis.

Hormonal factors play a significant role in the development of osteoporosis, which leads to an imbalance in osteoclast and osteoblast activity, particularly in postmenopausal women. Postmenopausal osteoporosis, which is caused by an estrogen deficiency, is manifested by a loss of cancellous bone and a predisposition to fractures of the vertebrae and distal radius. The loss of bone mass is greatest during early menopause, when estrogen levels are withdrawing. Several factors appear to influence the increased loss of bone mass associated with an estrogen deficiency. Decreased estrogen levels are associated with an increase in cytokines (e.g., interleukin-1, interleukin-6, and TNF) that stimulate the production of osteoclast precursors. Estrogen deficiency also influences osteoclast differentiation through the RANK receptor pathways. Estrogen stimulates the production of OPG and thus inhibits the formation of osteoclasts; it also blunts the responsiveness of osteoclast precursors to RANKL. With menopause and its accompanying estrogen deficiency, this inhibition of osteoclast production is lost. Compensatory osteoblastic activity and new bone formation occurs, but it does not keep pace with the bone that is lost.

Sex hormone deficiency may contribute to bone loss in men with senile osteoporosis, although the effect is not of the same magnitude as that caused by estrogen deficiency. Unlike women, men do not have a midlife loss of sex hormone production. Another factor that provides relative protection for men is the fact that they achieve 8% to 10% more peak bone mass than women. Although androgens have long been assumed to be critical for growth and maintenance of the male skeleton, estrogens obtained from peripheral conversion of testicular and adrenal hormone precursors may be even more important than androgens in the maintenance of bone mass in men.

Age-related changes in bone density occur in all people and contribute to the development of osteoporosis in both genders. Age-related changes in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from older adults have reduced replicative and biosynthetic potential compared with those of younger people. Growth factors that stimulate osteoblastic activity also lose their potential over time. The end result is a skeleton that has decreased ability to make bone. Reduced physical activity increases the rate of bone loss because mechanical forces are important stimuli for normal bone remodeling. Thus, the decreased physical activity that often accompanies aging may also contribute to the loss of bone mass in older adults.

Secondary osteoporosis is associated with many conditions, including endocrine disorders, malabsorption disorders, malignancies, alcoholism, and certain medications. People with endocrine disorders such as hyperthyroidism, hyperparathyroidism, Cushing syndrome, or diabetes mellitus are at high risk for development of osteoporosis. Hyperthyroidism causes an acceleration of bone turnover. Some malignancies (e.g., multiple myeloma) secrete the osteoclast-activating factor, causing significant bone loss. Alcohol is a direct inhibitor of osteoblasts and may also inhibit calcium absorption. Corticosteroid use is the most common cause of drug-related osteoporosis, and long-term corticosteroid use in the treatment of disorders such as rheumatoid arthritis and chronic obstructive lung disease is associated with a high rate of fractures. With the increased use of prednisone and other drugs that act like cortisol for the treatment of many inflammatory and autoimmune diseases, this form of bone loss has become a major clinical concern. The prolonged use of medications that increase calcium excretion, such as aluminum-containing antacids, corticosteroids, and anticonvulsants, also is associated with bone loss.

Several groups of children and adolescents are at increased risk for decreased bone mass, including premature infants and those with low birth weight who have lower-than-expected bone mass in the early weeks of life, children who require treatment with corticosteroid drugs (e.g., those with asthma, inflammatory diseases, and transplant recipients), children with cystic fibrosis, and those with hypogonadal states (e.g., anorexia nervosa and the female athlete triad). Children with cystic fibrosis often have impaired gastrointestinal function that reduces the absorption of calcium and other nutrients, and many also require the frequent use of corticosteroid drugs.

Premature osteoporosis is increasingly being seen in female athletes owing to an increased prevalence of eating disorders and amenorrhea. It most frequently affects women engaged in endurance sports, such as running and swimming;
in activities where appearance is important, such as figure skating, diving, and gymnastics; or in sports with weight categories, such as horse racing, martial arts, and rowing. The female athlete triad refers to a pattern of disordered eating that leads to amenorrhea and eventually osteoporosis. Poor nutrition, combined with intense training, can decrease the critical body fat-to-muscle ratio needed for normal menses and estrogen production by the ovary. The decreased levels of estrogen combined with the lack of calcium and vitamin D from dietary deficiencies result in a loss of bone density and increased risk for fractures. There is a concern that athletes with low BMD will be at increased risk for fractures during their competitive years. It is unclear whether osteoporosis induced by amenorrhea is reversible. Data are emerging that confirm that having only one or two elements of the triad greatly increases the risk of long-term morbidity in these women.58

Clinical Manifestations
Osteoporotic changes occur in the diaphysis and metaphysis of bone. In severe osteoporosis, the bones begin to resemble the fragile structure of a fine porcelain vase. There is loss of trabeculae from cancellous bone and thinning of the cortex to such an extent that minimal stress causes fractures. The changes that occur with osteoporosis have been explained by two distinct disease processes: postmenopausal and senile osteoporosis. In postmenopausal women, the increase in osteoclastic activity affects mainly bones or portions of bone that have increased surface area, such as the cancellous compartment of the vertebral bodies. The osteoporotic trabeculae become thinned and lose their interconnections, leading to microfractures and eventual vertebral collapse. In senile osteoporosis, the osteoporotic cortex is thinned by subperiosteal and endosteal resorption and the haversian systems are widened. In severe cases, the haversian systems are so enlarged that the cortex resembles cancellous bone (Fig. 58.16). Hip fractures, which are seen later in life, are more commonly associated with senile osteoporosis.

Osteoporosis is usually a silent disorder. Often, the first manifestations of the disorder are those that accompany a skeletal fracture—a vertebral compression fracture or fractures of the hip, pelvis, humerus, or any other bone (Fig. 58.17). Typically, the fractures occur with less force than usual, such as when a postmenopausal woman is in a crowded area such as a subway and is pushed slightly by the crowd. If the pushing occurs several times such as by someone brushing up alongside the woman as the crowd moves from the door and to the door of the subway enough pressure could cause the woman to sustain a fracture. Women who present with fractures are much more likely to sustain another fracture than are women of the same age without osteoporosis. Wedging and collapse of vertebrae cause a loss of height in the vertebral column and kyphosis, a condition commonly referred to as dowager hump. Usually, there is no generalized bone tenderness. When pain occurs, it is related to fractures. Systemic symptoms such as weakness and weight loss suggest that the osteoporosis may be caused by underlying disease.

FIGURE 58.17 • Clinical manifestations of osteoporosis.
Diagnosis

In 2008, the National Osteoporosis Foundation (NOF) and the World Health Organization (WHO) adapted the WHO Working Group on Osteoporosis Screening Tool, Fracture Risk Assessment Algorithm (FRAX), to identify future hip fracture possibility depending on a person’s risk possibility.\(^{51,52}\) BMD assessment is most commonly undertaken with dual-energy x-ray absorptiometry (DXA) of the spine and hip. Current practice is to perform DXA on the total hip, the femoral neck, and the anterior lumbar spine (L1 to L4). The site with the lowest score should be used to make a diagnosis. Measurement of BMD has become increasingly common for early detection and fracture prevention. Measurement of serial heights in older adults is another simple way to screen for osteoporosis. A further advance in the diagnosis of osteoporosis is the refinement of risk factors, permitting better analysis of risk pertaining to particular persons. Testing for BMD should be performed based on the individual person’s risk. The NOF have recommended that all women should have a measurement of BMD at 65 years of age unless they have risk factors, which means earlier screening should be performed.\(^52\) Risk factors that may indicate a need for testing women at a younger age include:

- A delayed menarche (\(i.e.,\) age 15 years or later).
- Low body weight (\(i.e.,\) <21 kg/m\(^2\), or 127 lb at menopause).
- Current smoker.
- History of fractures after menopause (other than skull, facial bone, ankle, finger, or toe).
- History of a hip fracture in a parent.\(^52\)

Mrs. Tukey’s BMD screening shows a T score of 3.0, which definitely puts her in the osteoporosis range. It is unfortunate that Mrs. Tukey’s physician did not perform a BMD screening at the time of her hip fracture 8 years ago. According to the guidelines from the NOF, she should have been considered high risk (hip fracture after menopause, family history and 1.5 pack/day cigarette smoking history). If she had been screened, it is possible that her osteopenia or osteoporosis could have been slowed down with the use of bisphosphonate therapy.

Treatment

Prevention and early detection of osteoporosis are essential to the prevention of associated deformities and fractures. It is important to identify people in high-risk groups so that treatment can begin early (Chart 58.1). Regular exercise and adequate calcium intake are important factors in preventing osteoporosis. Weight-bearing exercises such as walking, jogging, rowing, and weight lifting are important in the maintenance of bone mass.

Mrs. Tukey has not been doing any exercises and has now been referred to the YMCA for aerobic exercises, which should assist her in managing the osteoporosis along with her prescribed bisphosphonate therapy and calcium and vitamin supplements. She also needs to quit her cigarette smoking habit. In addition, she has been referred to a nutritionist who will be able to assist her with planning a more balanced diet.

Studies have indicated that premenopausal women need more than 1000 mg/day of calcium, and postmenopausal women should take 1500 mg of calcium daily. Because most older American women do not consume a sufficient quantity of dairy products to meet their calcium needs, calcium supplementation is recommended. Calcium tablets vary in content of elemental calcium. Vitamin D deficiency may be an important factor in the impaired intestinal absorption of calcium in the older adult. On the basis of this evidence, 1,25-dihydroxyvitamin D\(_3\) is being studied as a treatment for osteoporosis.\(^59\) A daily intake of 400 to 800 IU of vitamin D is recommended because vitamin D optimizes calcium absorption and inhibits parathyroid secretion.\(^59\)
Pharmacological treatment of osteoporosis includes antiresorptive drugs and anabolic agents. There are three main types of antiresorptive agent: estrogens and SERMs, bisphosphonates, and calcitonin. Although estrogen is one of the most effective interventions for reducing the incidence and progression of osteoporosis in postmenopausal women, the use of hormone therapy (estrogen plus progesterin) has come under scrutiny since the Women’s Health Initiative. Raloxifene, a SERM that acts only on specific estrogen receptors, is effective in the prevention and treatment of osteoporosis in postmenopausal women.

Bisphosphonates are effective inhibitors of bone resorption and the most effective agents for prevention and treatment of osteoporosis. The bisphosphonates (e.g., alendronate, risedronate, ibandronate) are analogs of endogenous inorganic pyrophosphate that the body cannot break down. In bone, they bind to hydroxyapatite and prevent bone resorption by inhibiting osteoclast activity. Bisphosphonates have been shown to be effective in reducing the risk of hip, vertebral, and non-vertebral fractures; however, they also have adverse effects such as causing hip fractures although very rarely. The most dramatic impact has been in the reduction of multiple spine fractures, showing that treatment can decrease progression of the disease.

Calcitonin is an endogenous peptide that partially inhibits osteoclastic activity. Nasal calcitonin and subcutaneous calcitonin have been approved for the treatment of postmenopausal osteoporosis. Teriparatide is a recombinant form of parathyroid hormone for the treatment of osteoporosis. Unlike the antiresorptive drugs, parathyroid hormone stimulates bone remodeling by increasing osteoblast-mediated bone formation.

In men, testosterone appears to play an important role in bone homeostasis by stimulating osteoblasts and inhibiting osteoclasts. The use of testosterone is contraindicated in men with prostate cancer. Men with osteoporosis may also benefit from bisphosphonate, calcitonin, or parathyroid hormone therapy. Like women, they have the same need for calcium and vitamin D supplementation.

People with osteoporosis have many special needs. Walking and swimming are encouraged. Unsafe conditions that predispose people to falls and fractures should be corrected or avoided. In treating fractures, it is important to minimize immobility. Surgical intervention is done for stable fracture fixation that allows early restoration of mobility and function; for fractures of the lower extremities, this means early weight bearing. Vertebral fractures are treated symptomatically. Vertebroplasty and kyphoplasty are minimally invasive spinal procedures that use bone cement to restore vertebral height and relieve pain. Bone cement is instilled directly into the fractured vertebral body to restore height and shape. The procedure for kyphoplasty involves the use of a balloon as a tamp to create a void for the cement. Kyphoplasty seems to be associated with less cement extravasation and better restoration of vertebral height than vertebroplasty.

Osteomalacia and Rickets

In contrast to osteoporosis, which causes a loss of total bone mass and results in brittle bones, osteomalacia and rickets produce a softening of the bones but do not involve a loss of bone matrix. Approximately 60% of bone is mineral content, approximately 30% is organic matrix, and the remainder is living bone cells. The organic matrix and the inorganic mineral salts are needed for normal bone consistency. The term rickets refers to the disorder in children in which changes in bone growth produce characteristic skeletal abnormalities, and osteomalacia is used in adults because the bone that forms during the remodeling process is undermineralized.

Osteomalacia

Osteomalacia is a generalized bone condition in which there is inadequate mineralization of bone. There are two main causes of osteomalacia:

1. Insufficient calcium absorption from the intestine because of a lack of dietary calcium or a deficiency of or resistance to the action of vitamin D.
2. Phosphate deficiency caused by increased renal losses or decreased intestinal absorption.

Vitamin D deficiency is caused most commonly by reduced vitamin D absorption as a result of biliary tract or intestinal diseases that impair fat and fat-soluble vitamin absorption. Lack of vitamin D in the diet is rare in the United States because many foods are fortified with the vitamin. Anticonvulsant medications, such as phenobarbital and phenytoin, induce hepatic hydroxylases that accelerate breakdown of the active forms of vitamin D.

The incidence of osteomalacia is high among older adults because of diets deficient in calcium and vitamin D, a problem often compounded by the intestinal malabsorption that accompanies aging. Osteomalacia often is seen in cultures in which the diet is deficient in vitamin D, such as in northern China, Japan, and northern India. Women in these areas have a higher incidence of the disorder than do men because of the combined effects of pregnancy, lactation, and more indoor confinement. Osteomalacia occasionally is seen in strict vegetarians, persons who have had a gastrectomy, and those on long-term anticonvulsants, tranquillizers, sedatives, muscle relaxants, or diuretic drugs. There also is a greater incidence of osteomalacia in the colder regions of the world, particularly during the winter months, probably because of lesser exposure to sunlight.

A form of osteomalacia called renal rickets occurs in people with chronic renal failure. It is caused by the inability of the kidney to activate vitamin D and excrete phosphate and is accompanied by hyperparathyroidism, increased bone turnover, and increased bone resorption. Long-standing primary hyperparathyroidism causes increased calcium resorption from bone and hypophosphatemia, which can lead to rickets in children and osteomalacia in adults.
Clinical Manifestations. The clinical manifestations of osteomalacia are bone pain, tenderness, and fractures as the disease progresses. In severe cases, muscle weakness often is an early sign. The cause of muscle weakness is unclear. Osteomalacia predisposes a person to pathologic fractures in the weakened areas, especially in the distal radius and proximal femur. In contrast to osteoporosis, it is not a significant cause of hip fractures. There may be delayed healing and poor retention of internal fixation devices. Osteomalacia usually is accompanied by a compensatory or secondary hyperparathyroidism stimulated by low serum calcium levels. Parathyroid hormone reduces renal absorption of phosphate and removes calcium from the bone. Serum calcium levels are only slightly reduced in osteomalacia.

Diagnosis and Treatment. Diagnostic measures are directed toward identifying osteomalacia and establishing its cause. Diagnostic methods include x-ray studies, laboratory tests, bone scan, and bone biopsy. X-ray findings typical of osteomalacia are the development of transverse lines or pseudofractures. These apparently are caused by stress fractures that are inadequately healed. A bone biopsy may be done to confirm the diagnosis of osteomalacia in a person with nonspecific osteopenia who shows no improvement after treatment with exercise, vitamin D, and calcium.

The treatment of osteomalacia is directed at the underlying cause. If the problem is nutritional, restoring adequate amounts of calcium and vitamin D to the diet may be sufficient. The elderly with intestinal malabsorption also may benefit from vitamin D. The least expensive and most effective long-term treatment is a diet rich in vitamin D (i.e., fish, dairy products, and margarine) along with careful exposure to the midday sun. Vitamin D is specific for adult osteomalacia and vitamin D-resistant rickets, but large doses usually are needed to overcome the resistance to calcium absorption and to prevent renal loss of phosphate. The biologically active forms of vitamin D, 25-OH vitamin D (calciferol) or 1,25-(OH)2 vitamin D (calcitriol), are available for use in the treatment of osteomalacia resistant to vitamin D (i.e., osteomalacia resulting from chronic liver disease and kidney failure). If osteomalacia is caused by malabsorption, the treatment is directed toward correcting the primary disease. For example, adequate replacement of pancreatic enzymes is of paramount importance in pancreatic insufficiency. In renal tubular disorders, the treatment is directed at the altered renal physiology.

Rickets

Rickets is a metabolic bone disorder characterized by a failure or delay in calcification of the cartilaginous growth plate in children whose epiphyses have not yet fused. It is also manifested by widening and deformation of the metaphyseal regions of long bones, and a delay in the mineralization of trabecular, endosteal, and periosteal bone surfaces. There are several forms of rickets, including nutritional rickets, vitamin D–dependent rickets, and vitamin D–resistant rickets.

Etiology. As with osteomalacia in the adult, rickets can result from kidney failure; malabsorptive syndromes such as celiac disease and cystic fibrosis; and medications such as anticonvulsants, which cause target organ resistance to vitamin D, and aluminum-containing antacids, which bind phosphorus and prevent its absorption.

Nutritional rickets results from inadequate sunlight exposure or inadequate intake of vitamin D, calcium, or phosphate. Nutritional rickets occurs primarily in underdeveloped areas of the world and among immigrants to developed countries. The causes are inadequate exposure to sunlight (e.g., children are often kept clothed and indoors) and prolonged breast-feeding without vitamin D supplementation. Although the vitamin D content of human milk is low, the combination of breast milk and sunlight exposure usually provides sufficient vitamin D. Another cause of rickets is the use of commercial alternative milks (e.g., soy or rice beverages) that are not fortified with vitamin D. Vitamin D–dependent rickets can result from abnormalities in the gene coding for the enzyme that converts inactive vitamin D to the active vitamin D–resistant rickets and involves hypophosphatemia or a decrease in serum phosphate levels, the most common form being caused by mutations of the phosphate-regulating gene on the X chromosome. Gene mutation causes renal wasting of phosphate at the proximal tubular level of the kidney.

Clinical Manifestations. Rickets is characterized by changes in the growing bones of children with overgrowth of the epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to disintegrate. Bones become deformed; ossification at the epiphyseal plates is delayed and disordered, resulting in widening of the epiphyseal cartilage plate. Any new bone that does grow is unmineralized. During the nonmobile stage of infancy, the head and chest undergo the greatest stresses. The skull is enlarged and soft, and closure of the fontanels is delayed. Teeth are slow to develop, and the child may have difficulty standing. When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and long bones (i.e., tibia), causing, most notably, lumbar lordosis and bowing of the legs. The ends of long bones and ribs are enlarged. The thorax may be abnormally shaped, with prominent rib cartilage (i.e., rachitic rosary). The child usually has stunted growth, with a height sometimes far below the normal range. Weight often is not affected so that the children, many of whom present with a protruding abdomen (i.e., rachitic potbelly), have been described as presenting a Buddha-like appearance when sitting.

Treatment. Nutritional rickets is treated with a balanced diet sufficient in calcium, phosphorus, and vitamin D. Exposure to sunlight also is important, especially for premature infants and those on artificial milk feedings. Supplemental vitamin D in excess of normal requirements is given for several months. Maintenance of good posture, positioning, and bracing in
older children are used to prevent deformities. After the disease is controlled, deformities may have to be surgically corrected as the child grows.

Children with vitamin D–dependent and vitamin D–independent rickets require special treatment measures. Children with vitamin D–dependent rickets caused by lack of the enzyme needed to convert vitamin D to its active form are treated with calcitriol, the active form of vitamin D.64 Vitamin D–resistant forms of rickets are treated with oral phosphorus or oral phosphorus and calcitriol.

**Paget Disease**

Paget disease (*i.e.*, osteitis deformans) is the second most common bone disease after osteoporosis.20,64 The disease tends to occur in people in their fourth decade and is characterized by local areas of excessive bone turnover and disorganized osteoid formation. The disease is more common in people of Northern European heritage.

Paget disease is a focal process with considerable variation in its stage of development in separate sites. At the onset, the disease is marked by regions of rapidly occurring osteoclastic bone resorption, followed by a period of hectic bone formation with increased numbers of osteoblasts rapidly depositing bone in a chaotic fashion such that the newly formed bone is of poor quality and is disorganized rather than lamellar. The poor quality of bone accounts for the bowing and fractures that occur in bones affected by the disease. The bone marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels, which transport blood to and from these metabolically active sites. The lesions of Paget disease may be solitary or may occur in multiple sites. They tend to localize to the bones of the axial skeleton, including the spine, skull, hips, and pelvis. The proximal femur and tibia may be involved in more widespread forms of the disease. Histologically, Paget lesions show increased vascularity and bone marrow fibrosis with intense cellular activity. The bone has a somewhat mosaic-like pattern caused by areas of density outlined by heavy blue lines, called cement lines (Fig. 58.18).

**Etiology**

Although the cause of Paget disease remains unclear, there is evidence of both genetic and environmental influences. It has been reported that 15% to 40% of people with the disease have a first-degree relative with Paget disease, and numerous studies have described extended family members with the disease.65 Additionally, evidence supports that people with Paget disease have been found to have a mutation of the SQSM1/p62 gene in their diseased bone and tumor samples.66 It is possible that factors other than genetics are also involved in the pathogenesis of the disease such as a paramyxovirus.65 This has been supported by the observation of viral particles resembling the paramyxovirus nucleocapsid in the cytoplasm of osteoclasts in persons with Paget disease.

In children, hyperostosis corticalis deformans juvenilis (a rare autosomal recessive disorder), hyperphosphatemia, and diseases that cause diaphyseal stenosis may mimic Paget disease and sometimes are referred to as juvenile Paget disease.67 The disorder presents in infancy or early childhood with pain from debilitating fractures and deformities due to a markedly accelerated rate of bone remodeling throughout the skeleton.

**Clinical Manifestations**

The disease varies in severity from a simple lesion to involvement of many bones. It may be present long before it is detected clinically. In fact, many people have no symptoms and their disease is found when managing another health problem. The clinical manifestations of Paget disease depend on the specific area involved (see Fig. 58.18). Involvement of the skull can cause headaches, intermittent tinnitus, vertigo, and eventual hearing loss. In the spine, collapse of the anterior vertebrae causes kyphosis of the thoracic spine. The femur and tibia become bowed. Softening of the femoral neck can cause coxa vara (*i.e.*, reduced angle of the femoral neck). Coxa vara, in combination with softening of the sacral and iliac bones, causes a waddling gait. When the lesion affects only one bone, it may cause only mild pain and stiffness. Progressive deossification weakens and distorts the bone.
Due to the ability to decrease bone resorption, parenteral therapy is the most effective way to manage Paget disease and neurologic defects. Early diagnosis and bisphosphonate agents such as the bisphosphonates and calcitonin are used nonsteroidal or other anti-inflammatory agents. Suppressive pain and the extent of the disease. Pain can be reduced with

**Diagnosis and Treatment**

Diagnosis of Paget disease is based on characteristic bone deformities and x-ray changes. Elevated levels of serum alkaline phosphatase and urinary hydroxyproline support the diagnosis, and continued surveillance of these levels may be used to monitor the effectiveness of treatment. Bone scans are used to detect the rapid bone turnover indicative of active disease and to monitor the response to treatment. The scan cannot identify bone activity resulting from malignant lesions. Bone biopsy may be done to differentiate the lesion from osteomyelitis or a primary or metastatic bone tumor.

The treatment of Paget disease is based on the degree of pain and the extent of the disease. Pain can be reduced with nonsteroidal or other anti-inflammatory agents. Suppressive agents such as the bisphosphonates and calcitonin are used to manage pain and prevent further spread of the disease and neurologic defects. Early diagnosis and bisphosphonate therapy is the most effective way to manage Paget disease due to the ability to decrease bone resorption. Parenteral bisphosphonates are particularly useful in people who cannot tolerate oral preparations, which have a specific administration protocol. Calcitonin also inhibits bone resorption. It is available in injectable and nasal spray forms, but only the injectable form is approved by the FDA for treatment of Paget disease. Nasal-spray calcitonin, which is approved for other uses, is being studied for use in Paget disease. People with Paget disease should receive adequate doses of calcium and vitamin D. A recombinant form of OPG is also being used to inhibit osteoclastogenesis in children, slowing the osteoclast activity. Juvenile Paget disease is being described as an OPG deficiency.

**IN SUMMARY**

In addition to its structural function, the skeleton is a homeostatic organ. Metabolic bone diseases such as osteoporosis, osteomalacia, rickets, and Paget disease are the result of a disruption in the equilibrium of bone formation and resorption. Osteoporosis, which is the most common of the metabolic bone diseases, occurs when the rate of bone resorption is greater than that of bone formation. It is seen frequently in postmenopausal women and is the major cause of fractures in people older than 45 years of age. Osteomalacia and rickets are caused by inadequate mineralization of bone matrix, primarily because of a deficiency of vitamin D. Paget disease results from excessive osteoclastic activity and is characterized by the formation of poor-quality bone. The success rate of the various drugs and hormones that are used to treat metabolic bone diseases varies. Further research is needed to clarify the cause, pathologic process, and treatment of these diseases.

**REVIEW EXERCISES**

1. A newborn girl was found to have DDH during a routine screening examination.
   - A. Describe the anatomic abnormalities that are present in the disorder.
   - B. Explain the need for early treatment of DDH.

2. A 12-year-old girl was noted to have asymmetry of the shoulders, scapular height, and pelvic height during routine physical examination. On x-ray examination, she is found to have a 30-degree curvature of the spine.
   - A. What possible treatments are available for this girl?
   - B. Describe the physical problems associated with progressive scoliosis.

3. A 60-year-old postmenopausal woman presents with a compression fracture of the vertebrae. She has also noticed increased backache and loss of height over the past few years.
   - A. Explain how the lack of estrogen and aging contribute to the development of osteoporosis.
   - B. What other factors should be considered when assessing the risk for development of osteoporosis?
   - C. What is one way to measure bone density?
   - D. Name the two most important factors in preventing osteoporosis.
   - E. What medications might be used to treat this woman’s condition?

Arthritis is a descriptive term applied to more than 100 rheumatic diseases, ranging from localized, self-limiting conditions to those that are systemic autoimmune processes. More than 27 million Americans have osteoarthritis.1 This type of arthritis impacts people in all age groups and is the leading cause of disability in the United States. Approximately 1.3 million Americans have rheumatoid arthritis and about 294,000 children under 18 years of age have juvenile arthritis or some type of rheumatic condition.1

The common use of the term arthritis can oversimplify the nature of the varied disease processes, the difficulty in differentiating one form of arthritis or rheumatic disease from another, and the complexity of treatment of these usually chronic conditions. All of these conditions share inflammation of the joint as a prominent or accompanying symptom. In the systemic rheumatic diseases—those affecting body systems in addition to the musculoskeletal system—the inflammation is primary, resulting from an immune response. In rheumatic conditions limited to a single or few diarthrodial joints, the inflammation is secondary, resulting from a degenerative process and the resulting joint irregularities that occur as the bone attempts to remodel itself. Although arthritis cannot be cured, much can be done to control its progress.

This chapter focuses on systemic autoimmune rheumatic diseases, arthritis associated with spondylitis, osteoarthritis syndrome, metabolic diseases associated with arthritis, and rheumatic disease in children and older adults.
Systemic autoimmune rheumatic diseases are a group of chronic disorders characterized by diffuse inflammatory lesions and degenerative changes in connective tissue. These disorders share similar clinical features and may affect many of the same organs. Rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), polymyalgia rheumatica, temporal arteritis, and juvenile arthritis and dermatomyositis, which share an autoimmune systemic pathogenesis, are discussed in this section.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic inflammatory disease that affects 1% to 2% of the population. Women are affected approximately three times more frequently than men. Although the disease occurs in all age groups, its prevalence increases with age. A new type of RA, elderly onset rheumatoid, has been identified. This type of RA occurs after the age of 65 years and seems to have a more limited impact on the body compared to RA that is acquired earlier in life.

Etiology and Pathogenesis

Although the cause of RA remains uncertain, evidence points to a genetic predisposition and the development of joint inflammation that is immunologically mediated. It has been suggested that the disease is initiated in a genetically predisposed person by the activation of a T cell–mediated response to an immune system trigger, such as a microbial agent (Fig. 59.1). The importance of genetic factors in the pathogenesis of RA is supported by the increased frequency of the disease among first-degree relatives. In addition, it is generally agreed that certain major histocompatibility complex (MHC) genes are expressed in a nonrandom manner in people with RA. An important genetic locus that predisposes to RA is present on the human leukocyte antigen (HLA) loci on the MHC class II molecules, with a specific focus on the DRB1 locus. This HLA-DRB1 gene, which forms a rheumatoid pocket on the HLA molecule, may influence the types of peptides that can be bound by the RA-associated HLA-DR molecules, thereby affecting the immune response.

The pathogenesis of RA can be viewed as an aberrant immune response that leads to synovial inflammation and destruction of the joint architecture. It has been suggested that the disease is initiated by the activation of helper T cells, release of cytokines (e.g., tumor necrosis factor [TNF], interleukin [IL]-1), and antibody formation. Approximately 70% to 80% of people with the disease have a substance called the rheumatoid factor (RF), which is an autologous (self-produced) antibody (Ig RF) that reacts with a fragment of immunoglobulin G (IgG) to form immune complexes. Immune complexes (Ig RF + IgG) and complement components are found in the synovium, synovial fluid, and extra-articular lesions of people with RA. Although people with RA may be seronegative (not have Ig RF in their serum), the presence of a high RF titer is frequently associated with severe and unremitting disease, mainly systemic complications. Evidence suggests that identification of anticyclic citrullinated peptide antibodies (anti-CCP antibodies) is a more specific diagnostic marker for predicting RA than the RF test.

The role of the autoimmune process in the joint destruction of RA remains obscure. At the cellular level, neutrophils, macrophages, and lymphocytes are attracted to the area. The neutrophils and macrophages phagocytize the immune complexes and, in the process, release lysosomal enzymes capable of causing destructive changes in the joint cartilage (see Fig. 59.1). The inflammatory response that follows attracts additional inflammatory cells, setting into motion a chain of events that perpetuates the condition. As the inflammatory process progresses, the synovial cells and subsynovial tissues undergo reactive hyperplasia. Vasodilation and increased blood flow cause warmth and redness. The joint swelling that occurs is the result of the increased capillary permeability that accompanies the inflammatory process.

Characteristic of RA is the development of an extensive network of new blood vessels in the synovial membrane that contributes to the advancement of the rheumatoid synovitis. This destructive vascular granulation tissue, which is called pannus, extends from the synovium to involve a region of unprotected bone at the junction between cartilage and the subchondral bone. Pannus is a feature of RA that differentiates it from other forms of inflammatory arthritis (Fig. 59.2C). The inflammatory cells found in the pannus have a destructive effect on the adjacent cartilage and bone. Eventually, pannus develops between the joint margins, leading to reduced joint motion and the possibility of eventual ankylosis. Evidence points to one of the collagen degrading matrix metalloproteinases (MMPs), MMP type 1, being essential for pannus to invade and destroy joints in RA, and, new research is being started to develop inhibiting drugs for MMP type 1 in an attempt to block MMP type 1 actions. With progression of the disease, joint inflammation and the resulting structural changes lead to joint instability, muscle atrophy from disuse, stretching of the ligaments, and involvement of the tendons and muscles. The effect of the pathologic changes on joint structure and function is related to the degree of disease activity, which can change at any time. Unfortunately, the destructive changes are irreversible.

Clinical Manifestations

RA often is associated with extra-articular as well as articular manifestations (see Fig. 59.2). It usually has an insidious onset marked by systemic manifestations such as fatigue, anorexia,
FIGURE 59.1 • Disease process in rheumatoid arthritis. (1) A virus or some trigger stimulates the synovial cells to proliferate. (2) The lymphocytes, plasma cells, and mast cells, along with neovascularization and edema, leads to hypertrophy and hyperplasia of the synovium. (3) Lymphoid nodules are present. (4) Proliferating synovium extends into the joint space, burrows into the bone beneath the articular cartilage, and covers the cartilage as a pannus. The articular cartilage is eventually destroyed by direct resorption or deprivation of its synovial fluid. The synovial tissue continues to proliferate in the subchondral region and joint. (5) Then the joint is destroyed and becomes fused, which is ankylosis. (From Rubin R., Strayer D. (Eds.) (2012). *Rubin's pathology: Clinicopathologic foundations of medicine* (6th ed., p. 1257). Philadelphia, PA: Lippincott Williams & Wilkins.)
weight loss, and generalized aching and stiffness. The disease, which is characterized by exacerbations and remissions, may involve only a few joints for brief durations, or it may become relentlessly progressive and debilitating.

**Joint Manifestations.** Joint involvement usually is symmetric and polyarticular. Any diarthrodial joint can be involved. The person may complain of joint pain and stiffness that lasts for 30 minutes and frequently for several hours. The limitation of joint motion that occurs early in the disease usually is because of pain; later, it is because of fibrosis. The most frequently affected joints initially are the fingers, hands, wrists, knees, and feet. Later, other diarthrodial joints may become involved.\(^7\) Spinal involvement usually is limited to the cervical region. In the hands, there usually is bilateral and symmetric involvement of the proximal interphalangeal (PIP)
and metacarpophalangeal (MCP) joints in the early stages of RA; the distal interphalangeal (DIP) joints rarely are affected. The fingers often take on a spindle-shaped appearance because of inflammation of the PIP joints.8

Progressive joint destruction may lead to subluxation (i.e., dislocation of the joint resulting in misalignment of the bone ends) and instability of the joint and limitation of movement. Swelling and thickening of the synovium can result in stretching of the joint capsule and ligaments. When this occurs, muscle and tendon imbalances develop, and mechanical forces applied to the joints through daily activities produce joint deformities (Fig. 59.3). In the MCP joints, the extensor tendons can slip to the ulnar side of the metacarpal head, causing ulnar deviation of the fingers (see Fig. 59.2A). Subluxation of the MCP joints may develop when this deformity is present. Hyperextension of the PIP joint and partial flexion of the DIP joint is called a swan neck deformity.9 After this condition becomes fixed, severe loss of function occurs because the person can no longer make a fist. Flexion of the PIP joint with hyperextension of the DIP joint is called a boutonnière deformity.8

The knee is one of the most commonly affected joints and is responsible for much of the disability associated with the disease.1,9 Active synovitis may be apparent as visible swelling that obliterates the normal contour over the medial and lateral aspects of the patella. The bulge sign, which involves milking fluid from the lateral to the medial side of the patella, may be used to determine the presence of excess fluid when it is not visible. Joint contractures, instability, and genu valgus (knock-knee) deformity are other possible manifestations. Severe quadriceps atrophy can contribute to the disability. A Baker cyst may develop in the popliteal area behind the knee. This is caused by enlargement of the bursa but does not usually cause symptoms unless the cyst ruptures, in which case symptoms mimicking thrombophlebitis appear.

Ankle involvement can limit flexion and extension, which can create difficulty in walking. Involvement of the metatarsophalangeal joints can cause subluxation, hallux valgus, and hammer toe deformities. Neck discomfort is common. In rare cases, long-standing disease can lead to neurologic complications such as occipital headaches, muscle weakness, and numbness and tingling in the upper extremities.

Extra-Articular Manifestations. Although characteristically a joint disease, RA can affect a number of other tissues. Extra-articular manifestations probably occur with a fair degree of frequency but usually are mild enough to cause only a few problems. They are most likely to occur in people who have RF. Because RA is a systemic disease, it may be accompanied by complaints of fatigue, weakness, anorexia, weight loss, and low-grade fever when the disease is active. The erythrocyte sedimentation rate (ESR), which commonly is elevated during inflammatory processes, has been found to correlate with the amount of disease activity.9 Anemia associated with a low serum iron level or low iron-binding capacity is common.1,10 This anemia usually is resistant to iron therapy.

Rheumatoid nodules are granulomatous lesions that develop around small blood vessels. The nodules may be tender or nontender, movable or immovable, and small or large. Typically, they are found over pressure points such as the extensor surfaces of the ulna. The nodules may remain unless surgically removed, or they may resolve spontaneously. Vasculitis, or inflammation of small and medium-sized arteries, is an uncommon manifestation of RA in people with a long history of active arthritis and high titers of RF. Manifestations include ischemic areas in the nail fold and digital pulp that appears as brown spots. Ulcerations may occur in the lower extremities, particularly around the malleolar areas. In some cases, neuropathy may be the only symptom of vasculitis. The visceral organs, such as the heart, lungs, and gastrointestinal tract, also may be affected.

Episcleritis and scleromalacia, which is due to scleral nodules and is capable of causing retinal detachment, pleuritis, and
pericarditis, are other possible extra-articular manifestations. A small number of people have splenomegaly and lymph node enlargement.

**KEY POINTS**

**RHEUMATOID ARTHRITIS**

- RA is a chronic systemic inflammatory disease with bilateral involvement of synovial or diarthrodial joints.
- The initial joint changes involve the synovial cells lining the joint. Inflammatory cells accumulate, and angiogenesis and formation of pannus, which proceed to cover the articular cartilage and isolate it from its nutritional synovial fluid, take place.

**Diagnosis**

The diagnosis of RA is based on findings of the history, physical examination, and laboratory tests. Information should be elicited regarding the duration of symptoms, systemic manifestations, stiffness, and family history. The criteria for RA developed by the American College of Rheumatology and the European League Against Rheumatism (EULAR) are useful in establishing the diagnosis of RA earlier than what has been done in the past. At least 6 out of 10 possible points must be present to make a diagnosis of RA. These criteria consisting of four categories (joint involvement, serology, acute phase reactants, and duration of symptoms) were developed for use in facilitating earlier recognition of RA so people could begin treatment earlier to prevent recurrences or decrease disease severity.

In the early stages, the disease often is difficult to diagnose. On physical examination, the affected joints show signs of inflammation, swelling, tenderness, and possibly warmth and reduced motion. The joints have a soft, spongy feeling because of synovial thickening and inflammation. Body movements may be guarded to prevent pain. Changes in joint structure usually are not visible early in the disease.

The RF test results are not diagnostic for RA, but they can be of value in differentiating RA from other forms of arthritis. A small percentage of healthy people have a positive RF. Also, a person can have RA without the presence of RF. Evidence suggests a stronger linkage of RA and anticitrullinated protein/peptide antibodies (ACPs), which are measured as anticyclic citrullinated peptide (anti-CCP) autoantibodies. This test has a higher specificity than RF and identification is possible very early in the RA process; also, it is capable of detecting erosive versus nonerosive forms of the disease. The term citrullination defines the posttranslational change of arginine into citrulline.

RA is linked with the HLA-DRB1 locus. The HLA-DRB1 alleles that coincide with RA have a sequence in the peptide-binding groove that is similar to that in specific autoantigenic peptides. Research demonstrated that the citrullinated peptides triggered specific T cell responses but the native peptides did not. Radiologic findings also are not diagnostic in RA because joint erosions often are not seen on radiographic images in the early stages of the disorder. Synovial fluid analysis can be helpful in the diagnostic process. The synovial fluid has a cloudy appearance, the white blood cell count is elevated as a result of inflammation, and the complement components are decreased due to the inflammatory process.

**Treatment**

The treatment goals for a person with RA are to prevent and/or reduce the pain, decrease stiffness and swelling, maximize mobility, and possibly halt the pathological process. The treatment plan includes education about the disease and its treatment, rest, therapeutic exercises, and medications. Because of the chronicity of the disease and the need for continuous, long-term adherence to the prescribed treatment modalities, it is important that the treatment be integrated with the person’s lifestyle.

Physical rest reduces joint stress. Rest of specific joints is recommended to relieve pain. For example, sitting reduces the weight on an inflamed knee, and the use of lightweight splints reduces undue movement of the hand or wrist. Emotional rest helps muscles relax and is often useful for people who find that emotional stress increases discomfort. Although rest is essential, therapeutic exercises also are important in maintaining joint motion and muscle strength. Range-of-motion exercises involve the active and passive movement of joints. Isometric (muscle-tensing) exercises may be used to strengthen muscles. These exercises are usually taught by a physical therapist and performed daily at home. The difference between normal activity and therapeutic exercise should be emphasized. Aerobic exercise and muscle-strengthening exercises can be an important component of the treatment regimen of selected people.

Instruction in the safe use of heat and cold modalities to relieve discomfort and in the use of relaxation techniques also is important. Proper posture, positioning, and body mechanics and the use of supportive shoes can provide further comfort. There often is a need for information about the principles of joint protection and work simplification. Some people may need assistive devices to reduce pain and improve their ability to perform activities of daily living.

The goals of pharmacologic therapy for RA are to reduce pain, decrease inflammation, maintain or restore joint function, and prevent bone and cartilage destruction. Medications used to achieve these goals are classified as those that provide relief from arthritis symptoms and those that have the potential for modifying the course of the disease. The trend in RA management is toward a more aggressive pharmacologic approach at an earlier stage in the disease. Ideally, disease-modifying antirheumatic drug (DMARD) therapy should be used when the diagnosis of RA is established and before erosive changes appear on radiography. Early treatment is
based on the theory that T cell–dependent pathways, which manifest early in the inflammatory process are more responsive to treatment than those that manifest later in the process, when disease progression is controlled by activated fibroblasts and macrophages, and the disease may be more resistant to treatment.

Nonsteroidal anti-inflammatory drugs (NSAIDs) usually are used early in the treatment of RA. The NSAIDs inhibit cyclooxygenase (COX)-mediated synthesis of prostaglandins, which have a damaging effect on joint structures. NSAIDs, including salicylates (e.g., aspirin), provide analgesic and anti-inflammatory effects. Effectiveness, side effects, cost, and dosing schedules are considered when selecting an NSAID. There is a wide range of responses to the various NSAIDs, and the particular NSAID that works best for any one person is not always predictable. The incidence of adverse reactions to the NSAIDs (e.g., gastric irritation and bleeding, fluid retention, kidney damage) tends to increase with age and long-term use.

Early treatment also includes the DMARDs. DMARDs include gold salts, hydroxychloroquine, sulfasalazine, methotrexate, and azathioprine. Methotrexate has become the drug of choice because of its potency, and it is relatively fast acting (i.e., improvement is seen in 1 month) compared with the slower-acting DMARDs, which can take 3 to 4 months to work. Methotrexate is thought to interfere with purine metabolism, leading to the release of adenosine, a potent anti-inflammatory compound. All of the DMARDs can be toxic and require close monitoring for adverse effects, especially those related to bone marrow suppression.

Corticosteroid drugs may be used to reduce discomfort. These agents interrupt the inflammatory and immune cascade at several levels, such as interfering with inflammatory cell adhesion and migration, impairing prostaglandin synthesis, and inhibiting neutrophil superoxide production. To avoid long-term side effects, they are used only in specific situations for short-term therapy at a low dose level. They may be used for unremitting disease with extra-articular manifestations. The corticosteroids do not modify the disease and are unable to prevent joint destruction. Intra-articular corticosteroid injections can provide rapid relief of acute or subacute inflammatory synovitis (after infection is excluded) in a few joints. They should not be repeated more than a few times each year.

Second-line antirheumatic drugs include anti-TNF drugs such as etanercept, infliximab, and adalimumab. Infliximab, etanercept, and adalimumab are biologic response–modifying agents or TNF inhibitors that block TNF-α, one of the key proinflammatory cytokines in RA. The anti–TNF-α agents have shown significant efficacy although they do have some potential adverse side effects. Evidence indicates that cardiovascular side effects are not different for TNF inhibitors than for the DMARDs. The TNF inhibitor agents have also been shown to inhibit radiologic disease progression and improve functional outcomes.

Another approach to RA treatment is combination DMARD therapy. This approach is a generally accepted one, and has been shown to be effective in several studies. Individual drugs with different mechanisms of action are given simultaneously to control the disease. The individual drugs are then tapered as symptoms subside and clinical remission is achieved.

Newer biologic response modifiers, abatacept and rituximab, have been used for treatment of persons with RA who have had an inadequate response to one or more of the DMARDs. Surgery also may be a part of the treatment of RA. Synovectomy may be indicated to reduce pain and joint damage when synovitis does not respond to medical treatment. The most common soft tissue surgery is tenosynovectomy (i.e., repair of damaged tendons) of the hand to release nerve entrapments. Total joint replacements (i.e., arthroplasty) may be indicated to reduce pain and increase motion. Arthrodesis (i.e., joint fusion) is indicated only in extreme cases when there is so much soft tissue damage and scarring or infection that a replacement is impossible. Significant positive results of surgery are more likely to occur when the surgical procedure is performed as soon as the initial symptoms are manifested.

**Systemic Lupus Erythematosus**

SLE is a chronic inflammatory disease that can affect virtually any organ system, including the musculoskeletal system. It is a major rheumatic disease, with approximately 1.5 million Americans and over 5 million people worldwide diagnosed with lupus. There is a female predominance of 10 to 1, and this ratio is closer to 30 to 1 during the childbearing years. SLE is more common in African Americans, Hispanics, and Asians than in whites, and the incidence in some families is higher than in others. There are four types of lupus erythematosus. The most common one is SLE, which includes about 70% of all people with lupus. Discoid lupus involves approximately 10% of people with a diagnosis of lupus. This type only affects the skin. Drug-induced lupus includes 10% and generally causes similar manifestations as SLE but once the drugs are stopped the person’s lupus completely resolves. The remaining 10% consists of a combination type of lupus of autoimmune rheumatologic disorders such as Sjögren syndrome or RA.

**Etiology and Pathogenesis**

The cause of SLE is unknown. It is characterized by the formation of autoantibodies and immune complexes. People with SLE appear to have B cell hyperreactivity and increased production of antibodies against self (i.e., autoantibodies) and nonself antigens. These B cells are polyclonal, each producing a different type of antibody. The autoantibodies can directly damage tissues or combine with corresponding antigens to form tissue-damaging immune complexes. Autoantibodies have been identified against an array of nuclear and cytoplasmic cell components (e.g., microtubules, ribosomes, RNA). Some autoantibodies that have been identified in SLE are anti-nuclear antibodies (ANA), including anti-deoxyribonucleic
SLE. Studies also suggest that an imbalance in sex hormone levels may play a role in the development of disease, especially because the disease is so prevalent among women. Genetic predisposition is evident by the occurrence of familial cases of SLE, especially among identical twins. The increased incidence among African Americans compared with whites also suggests genetic factors. As many as four genes may be involved in the expression of SLE in humans. Genes linked to the HLA-DR and HLA-DQ loci in the MHC class II molecules show strong support for a genetic link in the development of SLE. Studies also suggest that an imbalance in sex hormone levels may play a role in the development of the disease, especially because the disease is so prevalent among women. Androgens appear to protect against the development of SLE, whereas estrogens seem to favor its development. It has been suggested that an imbalance in sex hormone levels may lead to heightened helper T cell and weakened suppressor T cell immune responses that could in turn lead to the development of autoantibodies.

Possible environmental triggers include ultraviolet (UV) light, chemicals (e.g., drugs, hair dyes), some foods, and infectious agents (Fig. 59.4). UV light, specifically UVB associated with exposure to the sun or unshielded fluorescent bulbs, may trigger exacerbations. Photosensitivity occurs in approximately one third of people with SLE. Certain drugs may also provoke a lupus-like disorder in susceptible people, particularly in older adults. The most common of these drugs are hydralazine, minocycline, and procainamide. The disease usually recedes when the drug is discontinued.

Clinical Manifestations
SLE can manifest in a variety of ways. The disease has been called the great imitator because it has the capacity for affecting many different body systems, including the musculoskeletal system, the skin, the cardiovascular system, the lungs, the kidneys, the central nervous system (CNS), and the red blood cells and platelets (Fig. 59.5). The onset may be acute or insidious, and the course of the disease is characterized by exacerbations and remissions.

Arthralgias and arthritis are among the most commonly occurring early symptoms of SLE. Approximately 90% of all people with the disease complain of joint pain at some point during the course of their disease. The polyarthritis of SLE initially can be confused with other forms of arthritis, especially RA, because of the symmetric arthropathy. However, on radiologic examination, articular destruction rarely is found. Ligaments, tendons, and the joint capsule may be involved, causing varied deformities of people with the disease. Flexion contractures, hypertrophy of the interphalangeal joints, and subluxation of the carpometacarpal joints contribute to the deformity and subsequent loss of function in the hands. Other musculoskeletal manifestations of SLE include tenosynovitis, rupture of the intrapatellar and Achilles tendons, and avascular necrosis, frequently of the femoral head.

Skin manifestations can vary greatly and may be classified as acute, subacute, or chronic. The acute skin lesions include the classic malar or “butterfly” rash on the nose and cheeks (see Fig. 59.5). This rash is seen in SLE, but may be associated with other skin lesions, such as hives or livedo reticularis (i.e., reticular cyanotic discoloration of the skin, often precipitated by cold) and fingertip lesions, such as periungual erythema, nail fold infarcts, and splinter hemorrhages. Hair loss is common. Mucous membrane lesions tend to occur during periods of exacerbation. Sun sensitivity may occur in SLE even after mild sun exposure.

Renal involvement occurs in approximately 50% of people with SLE. Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous. Interstitial nephritis also may occur. Nephrotic syndrome causes proteinuria with resultant edema in the legs and abdomen, and around the eyes. Kidney biopsy is the best determinant of renal damage and the extent of treatment needed.

Pulmonary involvement in SLE is manifested primarily by pleural effusions or pleuritis. Less frequently occurring pulmonary problems include acute pneumonitis, pulmonary hemorrhage, chronic interstitial lung disease, and pulmonary embolism.

Pericarditis is the most common of the cardiac manifestations, and is often accompanied by pleural effusions. Myocarditis affects as much as 25% of those with SLE. Secondary heart disease also is a problem in those with SLE. Hypertension may be associated with lupus nephritis and long-term corticosteroid use. Ischemic heart disease can occur in older adults with longer-duration SLE.

The pathologic basis for the CNS symptoms is not entirely clear. It has been related to an acute vasculitis that impedes blood flow, causing strokes or hemorrhage; an immune response involving antineuronal antibodies that attack nerve cells; or production of antiphospholipid antibodies that damage blood vessels and cause blood clots in the brain. Seizures can occur and are more frequent when renal failure is present. Psychotic symptoms, including depression and unnatural euphoria, as well as decreased cognitive functioning, confusion, and altered levels of consciousness, may develop. More research is being done on the role of psychological factors in triggering the onset of SLE.

Hematologic disorders may manifest as hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia. Lymphadenopathy also may occur in many people with SLE. Discoid SLE involves plaque-like lesions on the head, scalp, and neck. These lesions first appear as red, swollen patches of skin, and later there can be scarring, depigmentation, and plugging of hair follicles. Most people with discoid lupus have disease that involves only the skin.
The diagnosis of SLE can be complicated and difficult. The 1982 American College of Rheumatology (updated in 1997) has defined 11 criteria to be considered in the diagnosis of the disease. If a person has at least 4 of these 11 criteria the individual has SLE. This tool has a 95% specificity and 85% sensitivity. However, these criteria are intended for use in clinical trials rather than for individual diagnosis. Diagnosis is based on a complete history, physical examination, and analysis of blood work. No single test can diagnose SLE in all people.

The most common laboratory test performed is the immunofluorescence test for ANA. Ninety-five percent of people with untreated SLE have high ANA levels. The ANA test is not specific for SLE, and positive ANA results may be found in various other disorders as well.

**KEY POINTS**

**CLINICAL MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS**

- SLE is a chronic autoimmune disorder characterized by production of a wide array of autoantibodies against nuclear and cytoplasmic cell components.
- SLE is often described as the great imitator because it can affect almost any organ system, including the joints of the musculoskeletal system, the skin, kidneys, lungs, nervous system, and the heart.
pleuritis. An antimalarial drug (e.g., hydroxychloroquine) is generally the next medication considered to treat cutaneous and musculoskeletal manifestations of SLE. Corticosteroids are used to treat more significant symptoms of SLE, such as renal and CNS disorders. High-dose corticosteroid treatment is used for acute symptoms, and the drug is tapered to the lowest therapeutic dose as soon as possible to minimize the adverse effects. Immunosuppressive drugs are used in cases of severe disease. Cyclophosphamide, under closely monitored circumstances, has been found to be beneficial in the treatment of lupus nephritis. A new drug that has shown positive effects in decreasing inflammatory exacerbations for people with SLE is Belimumab, which is a monoclonal antibody that inhibits the B lymphocyte stimulator.

**Systemic Sclerosis/Scleroderma**

Systemic sclerosis, sometimes called *scleroderma*, is an autoimmune disease of connective tissue characterized by excessive collagen deposition in the skin and internal organs such as the lungs, gastrointestinal tract, heart, and kidneys. In this disorder, the skin is thickened through fibrosis, with an accompanying fixation of subdermal structures, including the sheaths or fascia covering tendons and muscles. Systemic sclerosis affects women four times as frequently as men, with a peak incidence in the 25- to 50-year-old age group. The cause of this rare disorder is poorly understood. There is correlation between the development of autoantibodies of scleroderma and HLA-DQBI. There is evidence of both humoral and cellular immune system abnormalities.

**Clinical Manifestations**

Scleroderma presents as two distinct clinical entities: the diffuse or generalized form of the disease and the limited or CREST variant. CREST syndrome is an acronym for several different symptoms that tend to occur with scleroderma:

- **C** stands for calcinosis.
- **R** equals Raynaud’s phenomenon.
- **E** is esophageal dysmobility.
- **S** equals sclerodactyly.
- **T** stands for telangiectasias.

Recently another four letters have been added to the CREST acronym so that it is known now as ABCDCREST:

- **A** stands for autoantibodies.
- **B** stands for bibasilar pulmonary fibrosis.
- **C** stands for contractures of digital joints.
- **D** stands for dermal thickening proximal to wrists.

Generally a person would have to have four of these symptoms to be diagnosed with CREST type of scleroderma.

Diffuse scleroderma is characterized by severe and progressive disease of the skin and the early onset of organ involvement. The typical person has “stone facies” due to tightening of the facial skin with restricted motion of the mouth. Involvement of the esophagus leads to hypomotility...
and difficulty in swallowing. Malabsorption may develop if the submucosal and muscular atrophy affect the intestine. Pulmonary involvement leads to dyspnea and eventually respiratory failure. Vascular involvement of the kidneys is responsible for malignant hypertension and progressive renal insufficiency. Cardiac problems include pericarditis, heart block, and myocardial fibrosis.

**Diagnosis and Treatment**

Diagnostics for systemic scleroderma is more difficult than for the CREST variant. The measurement of the autoantibody, Scl-70, is most diagnostic, although only about 60% of people with systemic scleroderma have this.

Treatment of systemic sclerosis is largely symptomatic and supportive. Studies have indicated that if heart, lung, or kidney involvement is to become severe, it tends to do so early in the disease and is a predictor of shortened survival. Advances in treatment, primarily the use of angiotensin-converting enzyme (ACE) inhibitors in renal involvement, have led to a substantial decrease in the mortality from hypertensive renal disease.

**Polymyositis and Dermatomyositis**

Polymyositis and dermatomyositis are chronic inflammatory myopathies. The pathogenesis is multifactorial and includes cellular and humoral immune mechanisms. Systemic manifestations are common, and cardiac and pulmonary complications often adversely affect the outcome.24 These conditions are characterized by symmetric proximal muscle weakness and occasional muscle pain and tenderness. Sometimes symptoms of these myopathies are confused with chronic muscle weakness due to neuromuscular diseases or genetic disorders such as muscular dystrophies.25 Treatment for the inflammatory myopathies should seek to control inflammation and prevent long-term damage to muscles, joints, and internal organs. Corticosteroids are the mainstay of treatment for these conditions.

**IN SUMMARY**

Rheumatoid arthritis is a systemic inflammatory disorder that affects 1% to 2% of the population. Women are affected more frequently than men. This form of arthritis, the cause of which is unknown, has a chronic course and usually is characterized by remissions and exacerbations. Joint involvement is symmetric and begins with inflammatory changes in the synovial membrane. As joint inflammation progresses, structural changes can occur, leading to joint instability and eventual deformity. Systemic manifestations include weakness, anorexia, weight loss, and low-grade fever. Some extra-articular features include rheumatoid nodules and vasculitis. The treatment goals are to prevent and/or reduce the pain, decrease stiffness and swelling, maximize mobility, and possibly halt the pathological process.

SLE is a chronic autoimmune disorder that affects multiple body systems. There is no known cause of SLE, but the disease may result from an immunoregulatory disturbance brought about by a combination of genetic, hormonal, and environmental factors. Some drugs have been shown to induce SLE, especially in older adults. There is an exaggerated production of autoantibodies, which interact with antigens to produce an immune complex. These immune complexes produce an inflammatory response in affected tissues. Treatment focuses on preventing loss of organ function, controlling inflammation, and minimizing complications of medication therapy.

Systemic sclerosis, often prefixed by the term progressive, is sometimes called scleroderma. In this disorder, the skin is thickened through fibrosis with an accompanying fixation to the subdermal structures, including the sheaths or fascia covering tendons and muscles. Polymyositis and dermatomyositis are chronic inflammatory myopathies. Its pathogenesis is multifactorial and includes cellular and humoral immune mechanisms.

The spondyloarthropathies (SpA) are an interrelated group of multisystem inflammatory disorders that primarily affect the axial skeleton, particularly the spine. Typically, the inflammation begins at sites where tendon and ligament insert into bone rather than in the synovium. Sacroiliitis is a pathologic hallmark of the disorders.2 People with spondyloarthropathies may also have inflammation and involvement of the peripheral joints, in which case the signs and symptoms overlap with other inflammatory types of arthritis. Evidence suggests that people with spondyloarthropathies also have a high risk for developing thyroiditis and should have thyroid function testing conducted periodically especially as their SpA advances.26 Antithyroglobulin and antithyroid peroxidase antibodies tend to be high with SpA.26 Because there is an absence of RF, these disorders often are referred to as seronegative spondyloarthropathies and are recognized as specific disease entities.2

The seronegative spondyloarthropathies include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis in terms of cause, pathogenesis, and clinical manifestations.
joint involvement, there is clinical evidence of overlap between the various seronegative spondyloarthropathies. In none of these disorders is the cause or pathogenesis well understood. There is a striking association with the HLA-B27 antigen, but the presence of the HLA-B27 antigen by itself is neither necessary nor sufficient for the development of any of the diseases.

**Ankylosing Spondylitis**

Ankylosing spondylitis (AS) is a chronic, systemic inflammatory disease of the joints of the vertebral column and sacroiliac joints manifested by pain and progressive stiffening of the spine. The disease is more common than once was believed and is found in all races. Clinical manifestations usually begin in late adolescence or early adulthood and are slightly more common in men than in women. The disease usually evolves more slowly and is less severe in women. AS can occur later in life and, when it does, it tends to manifest in two ways:

1. Similar, but more severe, symptoms as in the younger person with AS.
2. Peripheral spondylarthropathy, which involves oligoarthritis of the lower limbs with pitting edema.

AS produces an inflammatory erosion of the sites where tendons and ligaments attach to bone. Typically, the disease process begins with bilateral involvement of the sacroiliac joints and then moves to the smaller joints of the posterior elements of the spine. The result is ultimate destruction of these joints with ankylosis or posterior fusion of the spine. The vertebrae take on a squared appearance and bone bridges fuse one vertebral body to the next across the intervertebral disks. Progressive spinal changes usually follow an ascending pattern beginning with the sacroiliac area and then moving up the spine to involve the costovertebral joints and cervical spine. Occasionally, large synovial joints (i.e., hips, knees, and shoulders) may be involved. The small peripheral joints usually are not affected. The disease spectrum ranges from an asymptomatic sacroiliitis to a progressive disease that can affect many body systems.

**Etiology and Pathogenesis**

Although the pathogenesis of AS has not been established, the presence of mononuclear cells in the acutely involved tissue suggests an immune response. Epidemiologic findings indicate that genetic and environmental factors play a role in the pathogenesis of the disease. Approximately 90% of those with AS possess the HLA-B27 antigen and nearly 100% of those who also have uveitis or aortitis have the marker; the HLA-B27 antigen also is present in approximately 8% of the normal population. Several theories have been advanced to account for the association between the HLA-B27 antigen and AS. One possibility is that the gene that determines the HLA-B27 antigen may be linked to other genes that determine the pathologic autoimmune phenomena or that lead to increased susceptibility to infections or environmental agents. A second theory postulates molecular mimicry. An autoimmune reaction to an antigenic determinant site in the host’s tissues may occur as a consequence of an immunologic response to an identical or closely related antigen of a foreign agent, usually an infectious agent.

**Clinical Manifestations**

The person with AS typically complains of lower back pain, which may be persistent or intermittent. The pain, which becomes worse when resting, particularly when lying in bed, initially may be attributed to muscle strain or spasm from physical activity. Lumbosacral pain also may be present, with discomfort in the buttocks and hip areas. Sometimes, pain can radiate to the thigh in a manner similar to that of sciatic pain. Prolonged stiffness is present in the morning and after periods of rest. Walking or exercise may be needed to provide the comfort needed to return to sleep. Muscle spasm also may contribute to discomfort.

Loss of motion in the spinal column is characteristic of the disease (Fig. 59.6). The severity and duration of disease.

**FIGURE 59.6** Clinical manifestations of ankylosing spondylitis.
activity influence the degree of mobility. Loss of lumbar lordosis occurs as the disease progresses, and this is followed by kyphosis of the thoracic spine and extension of the neck. A spine fused in the flexed position is the end result in severe AS. A kyphotic spine makes it difficult for the patient to look ahead and to maintain balance while walking. The image is of a person bent over looking at the floor and unable to straighten up. X-ray films show a rigid, bamboo-like spine. The heart and lungs are constricted in the chest cavity. Abnormal weight bearing can lead to degeneration and destruction of the hips, necessitating joint replacement procedures. Peripheral arthritis is more common in the hips and shoulders.

The most common extraskeletal involvement is acute anterior uveitis. Systemic features of weight loss, fever, and fatigue may be apparent. Sometimes, the fatigue is a greater problem than pain or stiffness. Osteoporosis can occur, especially in the spine, which contributes to the risk of spinal fracture. Fusion of the costovertebral joints can lead to reduced lung volume.

The disease process varies considerably among people. Exacerbations and remissions are common. The unpredictability of the disease can create uncertainty in planning daily activities and in setting goals. Fortunately, most of those affected are able to lead productive lives. The prognosis for AS in general is good. The first decade of disease predicts the remainder. Severe disease usually occurs early and is marked by peripheral arthritis, especially of the hip.

**Diagnosis**

The diagnosis of AS is based on history, physical examination, and x-ray examination. The early and precise diagnosis of AS is closely related to a favorable prognosis. Early recognition allows for implementation of a conservative and usually effective treatment program on a lifelong basis.

Several methods are available to assess mobility and detect sacroiliitis. These methods include pressure on the sacroiliac joints with the person in a forward-bending position to elicit pain and muscle spasm, measurement of the distance between the tips of the fingers and the floor in a bent-over position with straight knees, and a modified Schober test, which measures the movement of the lumbar vertebral column. Although these measures alone do not provide a diagnosis of AS or other spondyloarthropathies, they can provide useful measurements for monitoring the disease status. Measurement of chest expansion may be used as an indirect indicator of thoracic involvement, which usually occurs late in the disease course.

Laboratory findings frequently include an elevated ESR. The person also may have a mild normocytic normochromic anemia. HLA typing is not diagnostic of the disease and should not be used as a routine screening procedure. Radiologic evaluations help differentiate AS from sacroiliitis due to other diseases. However, x-ray images may be negative in early disease. Vertebrae normally are concave on the anterior border. In AS, the vertebrae take on a squared appearance (see Fig. 59.6).

**Treatment**

Treatment of AS is directed at controlling pain and maintaining mobility by suppressing inflammation. Proper posture and positioning are important. This includes sleeping in a supine position on a firm mattress and using one small pillow or no pillow. A bed board may be used to supply additional firmness. Therapeutic exercises are important to assist in maintaining motion in peripheral joints and in the spine. Muscle-strengthening exercises for extensor muscle groups also are prescribed. Heat applications or a shower or bath may be beneficial before exercise to improve ease of movement. Swimming is an excellent general conditioning exercise that avoids joint stress and enhances muscle tone. Immobilizing joints is not recommended. Maintaining ideal weight reduces the stress on weight-bearing joints. Smoking should be discouraged because it can exacerbate respiratory problems. Occupational counseling or job evaluation may be warranted because of postural abnormalities.

Pharmacologic treatment includes the use of NSAIDs to reduce inflammation, relieve pain, and reduce muscle spasm. DMARDs are potential second-line therapies, but their efficacy in AS is not known. Sulfasalazine and methotrexate have not shown benefit for spondylitis-associated back pain, but have shown efficacy for the peripheral joint involvement. Anti–TNF-α therapies, including etanercept, infliximab, and adalimumab, have demonstrated rapid effectiveness in reducing both the axial and peripheral symptoms of AS, as well as in improving quality-of-life measures.

**Reactive Arthopathies**

The reactive arthropathies may be defined as sterile inflammatory joint disorders that are distant in time and place from the initial inciting infective process. The infecting agents cannot be cultured and are not viable once they reach the joints. The list of triggering agents is continuously increasing and may be divided into urogenic, enterogenic, and respiratory tract associated, and the idiopathic arthritides.

Reactive arthritis also has been observed in people with acquired immunodeficiency syndrome (AIDS). Spondyloarthopathies such as Reiter syndrome and psoriatic arthritis are more severe and frequent in people infected with human immunodeficiency virus (HIV) than in the general population. It is thought that the immune response to HIV infection is selective and largely spares the natural killer cells, which may be quite significant in the pathology of reactive arthritis conditions. This is in contrast to RA and SLE, which dramatically improve as immunodeficiency develops. Reactive arthritis may also result from the presence of a foreign substance in the joint tissue, as in silicone implants in the small joints of the hands or feet or after exposure to industrial gases and oils. However, there is no evidence of antigenicity of the causative substance.

Similarities exist between reactive arthritis and bacterial arthritis. Several bacteria cause both diseases. When cultured bacteria are isolated from the synovial fluid, the diagnosis is
bacterial arthritis. When they cannot be isolated, even though there has been a preceding infection, the diagnosis of reactive arthritis is made.

Reactive arthritis may follow a self-limited course. It may involve recurrent episodes of arthritis or, in a small number of cases, it may follow a continuous and unremitting course. The treatment is largely symptomatic. NSAIDs are used in treating the arthritic symptoms. Vigorous treatment of possible triggering infections is thought to prevent relapses of reactive arthritis, but in many cases the triggering infection passes unnoticed or is mild, and the person contacts a physician only with the onset of definite arthritis. Short antibiotic courses at this time are not effective.

**Reiter Syndrome**

Reiter syndrome is considered to be a clinical manifestation of reactive arthritis that may be accompanied by extra-articular symptoms such as uveitis, bowel inflammation, and nonspecific urethritis. The disease often develops in a genetically susceptible host after a bacterial infection (e.g., a sexually transmitted infection).

**Psoriatic Arthritis**

Psoriatic arthritis is a seronegative inflammatory arthropathy that occurs in 7% of people with psoriasis. It is a heterogeneous disease with features of the spondyloarthropathies in some people, RA in others, and features of both coexisting in yet others.

**Etiology and Pathogenesis**

The etiology of psoriasis and psoriatic arthritis is unknown. Genetic, environmental, and immunologic factors appear to affect susceptibility and play a role in expression of the psoriatic skin disease and the arthritis. Environmental factors that may play a role in the pathogenesis of the disorder include infectious agents and physical trauma. T-cell–mediated immune responses seem to play an important role in the skin and joint manifestations of the disease, as indicated by the observation that there is improvement in disease status after treatment with immunosuppressant agents such as cyclosporine.

**Clinical Manifestations and Treatment**

Although the arthritis can antedate a detectable skin rash, the definitive diagnosis of psoriatic arthritis cannot be made without evidence of skin or nail changes typical of psoriasis. Psoriatic arthritis falls into five subgroups:

1. Oligoarticular or asymmetric
2. Spondylarthropathy
3. Polyarticular, or symmetric
4. Distal interphalangeal
5. Mutilans

This heterogeneous clinical presentation suggests more than one disease is associated with psoriasis or various clinical responses to a common cause. Some with psoriatic arthritis have an elevated serum level of uric acid. The abnormally elevated serum uric acid level is caused by the rapid skin turnover of psoriasis and the subsequent breakdown of nucleic acid followed by its metabolism to uric acid. This finding may lead to a misdiagnosis of gout. Psoriatic arthritis tends to be slowly progressive, but has a more favorable prognosis than RA.

Basic management is similar to the treatment of RA. Suppression of the skin disease may be important in controlling the arthritis. Often, affected joints are surprisingly functional and only minimally symptomatic. The biologic response modifiers, specifically the TNF inhibitors (e.g., etanercept, infliximab, and adalimumab), have been found to be beneficial in controlling arthritis as well as psoriasis in people with psoriatic arthritis.

**Enteropathic Arthritis**

Arthritis that is associated with an inflammatory bowel disease usually is considered an enteropathic arthritis because the intestinal disease is directly involved in the pathogenesis. Most cases of enteropathic arthritis are classified among the spondyloarthropathies. These include cases in which the arthritis is associated with inflammatory bowel disease (i.e., ulcerative colitis and Crohn disease), which is generally 20%, spondylitis (10%), and a few with the reactive arthritides triggered by bacterial infections of the gut, and Whipple disease.
Chapter 59 Disorders of Musculoskeletal Function: Rheumatic Disorders

AS is considered a prototype of this classification category. Bilateral sacroilitis is the primary feature of AS. The disease spectrum ranges from asymptomatic sacroilitis to a progressive disorder affecting many body systems. The cause remains unknown. However, a strong association between the HLA-B27 antigen and AS has been identified. Loss of motion in the spinal column is characteristic of the disease. Peripheral arthritis may occur in some persons. Another form of spondyloarthrits is reactive arthritis. Although there are overlapping features for each of the spondyloarthropathies, identifying etiologic differences and clinical manifestations is important for determining treatment.

Psoriatic arthritis is a seronegative arthropathy that occurs in approximately 7% of people with psoriasis. It is a heterogeneous disease with features of the spondyloarthropathies in some people, RA in others, and features of both coexisting in yet others.

**OSTEOARTHRITIS SYNDROME**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare rheumatoid arthritis and osteoarthritis in terms of joint involvement, level of inflammation, and local and systemic manifestations.
- Describe the pathologic joint changes associated with osteoarthritis.

Osteoarthritis (OA), formerly called degenerative joint disease, is the most prevalent form of arthritis and is a leading cause of disability and pain in older adults. OA is more of a disease process than a specific entity and is considered to have an inflammatory component along with the degenerative aspect. OA is a slowly progressive destruction of articular cartilage of weight-bearing joints and fingers of older adults and the joints of younger people who have experienced trauma. It can occur as a primary disorder or as a secondary disorder, although this distinction is not always clear. Primary variants of OA occur due to intrinsic defects in the articular cartilage that cause joint narrowing, subchondral bone thickening, and ultimately a painful joint. Secondary OA has a known underlying cause such as congenital or acquired defects of joint structures, trauma, infection, endocrinopathies, crystal deposits, osteonecrosis, metabolic disorders, or inflammatory diseases (Chart 59.1).

The joint changes associated with OA, which include a progressive loss of articular cartilage and synovitis, result from the inflammation caused when cartilage attempts to repair itself, creating osteophytes or spurs. These changes are accompanied by joint pain, stiffness, and limitation of motion, and in some cases by joint instability and deformity.

**Epidemiology and Risk Factors**

Age, gender, and race interact to influence the time of onset and the pattern of joint involvement in OA. Primary OA affects 4% of people between 18 and 24 years of age; 85% of people with OA are in their seventies. Men are affected more commonly at a younger age, such as 45 years. However, by 55 years of age, women are the more frequent gender affected by OA. Heredity influences the occurrence of hand OA in the DIP joint. Hand OA is more likely to affect white women, whereas knee OA is more common in black women. The incidence of hip OA is lower among the Chinese than among Europeans, perhaps representing the influence of other factors such as occupation, obesity, or heredity. Bone mass may also influence the risk of developing OA. In theory, thinner subchondral bone mass may allow a greater shock-absorbing function than denser bone, allowing less direct trauma to the cartilage.

Obesity is a particular risk factor for OA of the knee in women and a contributory biomechanical factor in the pathogenesis of the disease. Excess fat may have a direct metabolic effect on cartilage beyond the effects of excess joint stress.

**Pathogenesis**

The pathogenesis of OA resides in the homeostatic mechanisms that maintain the articular cartilage. Articular cartilage
plays two essential mechanical roles in joint physiology. First, the articular cartilage serves as a remarkably smooth weight-bearing surface. In combination with synovial fluid, the articular cartilage provides extremely low friction during movement of the joint. Second, the cartilage transmits the load down to the bone, dissipating the mechanical stress. If the subchondral bone protects the overlying articular cartilage, providing it with a pliable bed and absorbing the energy of the force (Fig. 59.7).

Cartilage is a specialized type of connective tissue. As with other types of tissue, it consists of cells (i.e., chondrocytes) nested in an extracellular matrix. In articular cartilage, the extracellular matrix is composed of water, proteoglycans, collagen, and ground substance. The proteoglycans, which are large macromolecules made up of disaccharides and amino acids, afford elasticity and stiffness, permitting articular cartilage to resist compression. The ground substance constitutes a highly hydrated, semisolid gel. Collagen molecules consist of polypeptide chains that form long, fibrous strands. They provide form and tensile strength. The primary function of the collagen fibers is to provide a rigid scaffold to support the chondrocytes and ground substance of cartilage. The hydrated proteoglycan molecules, because of their size and charge, are trapped in the collagen meshwork of the extracellular matrix and prevented from expanding to their maximum size. Due to this process there is high interstitial osmotic pressure and enough fluid available for joint lubrication. As in the case of adult bone, articular cartilage is not static. It undergoes turnover and its “worn out” matrix components are continually degraded and replaced. This turnover is maintained by the chondrocytes, which not only synthesize the matrix but also secrete matrix-degrading enzymes. Thus, the health of the chondrocytes determines joint integrity. In OA, this integrity can be disturbed by a number of influences.

Popularly known as wear-and-tear arthritis, OA is characterized by significant changes in both the composition and mechanical properties of cartilage. Early in the course of the disease, the cartilage contains increased water and decreased concentrations of proteoglycans compared with healthy cartilage. In addition, there appears to be a weakening of the collagen network, presumably caused by a decrease in the local synthesis of new collagen and an increase in the breakdown of existing collagen. It is thought that the injured articular cartilage is due to cytokine release, which triggers destruction of the joint (Fig. 59.8). The resulting damage predisposes the chondrocytes to more injury and impairs their ability to repair the damage by producing new collagen and proteoglycans. The combined effects of inadequate repair mechanisms and imbalances between the proteases and their inhibitors contribute further to disease progression.

The earliest structural changes in OA include enlargement and reorganization of the chondrocytes in the superficial part of the articular cartilage. This is accompanied by edematous changes in the cartilaginous matrix, principally the intermediate layer. The cartilage loses its smooth aspect and surface cracks or microfractures occur, allowing synovial fluid to enter and widen the crack (Fig. 59.9). As the crack deepens and clefts form it eventually extends through the articular surface and into the subchondral aspect of the bone. Portions of the articular cartilage eventually become completely eroded and the exposed surface of the subchondral bone becomes thickened and polished to an ivory-like consistency. Fragments of cartilage and bone often become dislodged, creating free-floating osteocartilaginous bodies (“joint mice”) that enter the joint cavity. As the disease progresses, the underlying trabecular bone becomes sclerotic in response to increased pressure on the surface of the joint, rendering it less effective as a shock absorber. Sclerosis, or formation of new bone and cysts, usually occurs at the joint margins, forming abnormal bony outgrowths called osteophytes, or spurs (Fig. 59.7). As the joint begins to lose its integrity, there is trauma to the synovial membrane, which results in nonspecific inflammation. Compared with RA, however, the changes in the synovium that occur in OA are not as pronounced, nor do they occur as early.

In secondary forms of OA, repetitive impact loading contributes to joint failure, accounting for the high prevalence of OA specific to vocational or avocational sites, such as the shoulders and elbows of baseball pitchers, ankles of ballet dancers, and knees of basketball players. Immobilization also can produce degenerative changes in articular cartilage. Cartilage degeneration due to immobility may result from loss of the pumping action of lubrication that occurs with joint movement. These changes are more marked and appear earlier in areas of contact but occur also in areas not subject to mechanical compression. Although cartilage atrophy is rapidly reversible with activity after a period of immobilization, impact exercise during the period of remobilization can prevent reversal of the atrophy. Therefore, slow and gradual remobilization may be important in preventing cartilage injury. Clinically, this has implications for instructions concerning the recommended level of physical activity after removal of a cast.
FIGURE 59.8 • Disease process in osteoarthritis. (A, B) The death of chondrocytes leads to a crack in the articular cartilage that is followed by an influx of synovial fluid and further loss of cartilage. (C) As a result of this process, cartilage is gradually worn away. Below the tidemark, new vessels grow in from the epiphysis, and fibrocartilage (D) is deposited. (E) The fibrocartilage plug is not mechanically sufficient and may be worn away, thus exposing the subchondral bone plate, which becomes thickened. If there is a crack in this region, synovial fluid leaks into the marrow space and produces a subchondral bone cyst. Focal regrowth of the articular surface leads to the formation of osteophytes. (From Rubin R., Strayer D. (Eds.) (2012). Rubin's pathology: Clinicopathologic foundations of medicine (6th ed., p. 1253). Philadelphia, PA: Lippincott Williams & Wilkins.)
Clinical Manifestations

The manifestations of OA may arise suddenly or insidiously. Initially, pain may be described as aching and may be somewhat difficult to localize. It usually worsens with use or activity and is relieved by rest. In later stages of disease activity, night pain may be experienced during rest. Pain can occur at rest, several hours after the use of the involved joints. Crepitus and grinding may be evident when the joint is moved. As the disease advances, even minimal activity may cause pain because of the limited range of motion resulting from intra-articular and periarticular structural damage.

The most frequently affected joints are the hips, knees, lumbar and cervical vertebrae, proximal and distal joints of the hands, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. Table 59.1 identifies the joints that commonly are affected by OA and the common clinical features correlated with the disease activity of each particular joint. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the initial joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in
contrast to the soft, spongy feeling characteristic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

**Diagnosis and Treatment**

The diagnosis of OA usually is determined by history and physical examination, x-ray studies, and laboratory findings that exclude other diseases. Although OA often is contrasted with RA for diagnostic purposes, the differences are not always readily apparent. Other rheumatic diseases may be superimposed on OA.

Characteristic radiologic changes initially include medial joint space narrowing, followed by subchondral bony sclerosis, formation of spikes on the tibial eminence, and osteophytes. The results of laboratory studies usually are normal because the disorder is not a systemic disease. The ESR may be slightly elevated in generalized OA or erosive inflammatory variations of the disease. If inflammation is present, there may be a slight increase in the white blood cell count. The synovial fluid usually is normal. The American College of Rheumatology (ACR) (2011) website has guidelines for classification of Hand, Knee, and Hip Criteria for Osteoarthritis.

Because there is no cure, the treatment of OA is symptomatic and includes physical rehabilitative, pharmacologic, and surgical measures. Physical measures are aimed at improving the supporting structures of the joint and strengthening opposing muscle groups involved in cushioning weight-bearing forces. This includes a balance of rest and exercise, use of splints to protect and rest the joint, use of heat and cold to relieve pain and muscle spasm, and adjusting the activities of daily living. Weight reduction is helpful when the knee is involved. The involved joint should not be further abused, and steps should be taken to protect and rest it. These include weight reduction (when weight-bearing surfaces are involved) and the use of a cane or walker if the hips and knees are involved.

Oral medications are aimed at reducing inflammation or providing analgesia. Popular medications used in the treatment of OA are the NSAIDs, many of which are available without a prescription. Ongoing research may confirm that some NSAIDs impede the repair mechanisms in early cartilage lesions. However, studies have shown that the pain of OA may arise from factors other than an inflamed synovium. These factors include stretching of the joint capsule, ligaments, or nerve endings in the periosteeum over osteophytes; non trabecular microfractures; intraosseous hypertension; bursts of tendinitis; and muscle spasm. In such cases, the analgesic effect of the NSAID may be able to successfully relieve the pain. For many people, acetaminophen may be as effective and less toxic than NSAIDs.

Intra-articular corticosteroid injections may be used when other treatment measures have been unsuccessful in adequately relieving symptoms. They are especially helpful in people who have an effusion of the joint. Injections usually are limited to a total of four and not more than three within 1 year because their use is thought to accelerate joint destruction.

Viscosupplementation is another treatment and is based on the hypothesis that joint lubrication is abnormal in OA. Hyaluronate is injected into the joint weekly for 3 to 5 weeks and indicates an equal result of pain management as using NSAIDs. Speculation that other agents (i.e., glucosamine and chondroitin sulfate) may be chondroprotective has prompted other studies, some of which demonstrated greater pain relief with treatment with either compound than with placebo, and others found little or no difference. The National Institutes of Health found that glucosamine hydrochloride was more efficacious than placebo. It is interesting to note, however, that some studies that used glucosamine sulfate rather than glucosamine hydrochloride reported greater pain relief in their treatment group than in their placebo group. Disease-modifying agents for OA are also being studied.

Surgery is considered when the person is having severe pain and joint function is severely reduced. Procedures include arthroscopic lavage and debridement, bunion resections, osteotomies to change alignment of the knee and hip joints, and decompression of the spinal roots in osteoarthritic vertebral stenosis. Total hip replacements have provided effective relief of symptoms and improved range of motion for many people, and have total knee replacements. Joint replacement is available for the first carpometacarpal joint. Arthrodesis (surgical stiffening of a joint) is used in advanced disease to reduce pain. However, this results in loss of motion.

Future management of OA lies in the development of techniques to identify and monitor cartilage lesions at an earlier stage. Potential approaches include bone scanning, magnetic resonance imaging, and arthroscopy.

**IN SUMMARY**

Osteoarthritis, the most common form of arthritis, is a localized condition affecting primarily the weight-bearing joints. Risk factors for OA progression include older age, OA in multiple joints, neuropathy, and, for knees, obesity. The disorder is characterized by degeneration of the articular cartilage and subchondral bone. It has been suggested that the cellular events responsible for the development of OA begin with some type of abnormal mechanical insult or stimulus, including hormones and growth factors, drugs, mechanical stresses, and the extracellular environment. Studies also implicate immunologic factors in the perpetuation and acceleration of the osteoarthritic change. As cartilage ages, biochemical events such as collagen fatigue and fracture occur with less stress. Attempts at repair by increased matrix synthesis and cellular proliferation maintain the integrity of the cartilage until failure of reparative processes allows the degenerative changes to progress. Joint enlargement usually results from new bone formation, which causes the joint to feel hard. Pain and stiffness are primary features of the disease. Inflammatory mediators (e.g., prostaglandins) may increase the inflammatory and degenerative response.
Treatment is directed toward the relief of pain and maintenance of mobility while preserving the articular cartilage. Although there is no known cure for OA, appropriate treatment can reduce pain, maintain or improve joint mobility, and limit functional disability.

**CRYSTAL-INDUCED ARTHROPATIES**

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the metabolism and elimination of uric acid to the pathogenesis of crystal-induced arthropathy.
- Describe the clinical manifestations, diagnostic measures, and methods used in the treatment of gouty arthritis.

Metabolic bone and joint disorders result from biochemical and metabolic disorders that affect the joints. Metabolic and endocrine diseases associated with joint symptoms include amyloidosis, osteogenesis imperfecta, diabetes mellitus, hyperparathyroidism, thyroid disease, AIDS, and hypermobility syndromes. The discussion in this chapter is limited to the crystal-induced arthropathy caused by monosodium urate deposition, or gout.

Crystal deposition in joints produces arthritis. In gout, monosodium urate or uric acid crystals are found in the joint cavity. Another condition in which calcium pyrophosphate dihydrate crystals are found in the joints sometimes is referred to as pseudogout or chondrocalcinosis. A brief discussion of pseudogout is found in the section on rheumatic diseases in older adults.

**Gout**

Gout is a group of disorders characterized by increased serum uric acid and urate crystal deposits in kidneys and joints.\(^2\) The majority of people with high serum uric acid are older men. However, younger men also experience high uric acid levels and some progress to being diagnosed with gout.\(^40\) All people diagnosed with a gout disorder have a high uric acid level greater than 6.8 mg/dL, but fewer than 15% of people with high serum uric acid have a gout disorder.\(^40\) Asymptomatic hyperuricemia is a laboratory finding and not a disease. Most people with hyperuricemia do not develop gout. Only one third of people with hyperuricemia have primary gout and the other two thirds have secondary gout.\(^2\)

Gout disorders include acute gouty arthritis with recurrent attacks of severe, periarticular inflammation; tophi or the accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage; gouty nephropathy or renal impairment; and uric acid kidney stones.

The term primary gout is used to designate cases in which the cause of the disorder is unknown or caused by an inborn error in metabolism and is characterized primarily by hyperuricemia and gout. Primary gout is predominantly a disease of men, with a peak incidence in the fourth to sixth decade.\(^2\) In secondary gout, the cause of the hyperuricemia is known but the gout is not the main disorder.

**Pathogenesis**

The pathogenesis of gout resides in an elevation of serum uric acid levels. Uric acid is the end product of purine (adenine and guanine from DNA and RNA) metabolism.\(^40\) Two pathways are involved in purine synthesis:

1. A de novo pathway in which purines are synthesized from nonpurine precursors.
2. The salvage pathway in which purine bases are recaptured from the breakdown of nucleic acids derived from exogenous (dietary) or endogenous sources.

The elevation of uric acid and the subsequent development of gout can result from overproduction of purines, decreased salvage of free purine bases, augmented breakdown of nucleic acids as a result of increased cell turnover, or decreased urinary excretion of uric acid (Fig. 59.10). Primary gout, which constitutes 90% of cases, may be a consequence of enzyme defects that result in an overproduction of uric acid; inadequate elimination of uric acid by the kidney; or a combination of the two.\(^40\) In most cases, the reason is unknown. In secondary gout, the hyperuricemia may be caused by the increased breakdown of nucleic acids, which occurs with rapid tumor cell lysis during treatment for lymphoma or leukemia. Other cases of secondary gout result from chronic renal disease. Some of the diuretics, including the thiazides, can interfere with the excretion of uric acid.

An attack of gout occurs when monosodium urate crystals precipitate in the joint and initiate an inflammatory response.

**FIGURE 59.10** Pathogenesis of hyperuricemia and gout. Purine nucleotides are synthesized from nonpurine precursors or derived from preformed purines in the diet. Purine nucleotides are catabolized to hypoxanthine or incorporated into nucleic acids. The degradation of nucleic acids and dietary purines also produces hypoxanthine, which is converted into uric acid and then excreted into the urine. (From Rubin R., Strayer D. (Eds.) (2012), Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 1260). Philadelphia, PA: Lippincott Williams & Wilkins.)
Chapter 59 Disorders of Musculoskeletal Function: Rheumatic Disorders

1519

gout, called chronic tophaceous gout, is characterized by more frequent and prolonged attacks, which often are polyarticular.

Clinical Manifestations
Gout is categorized into four phases:

1. The asymptomatic hyperuricemia.
2. Acute gout arthritis.
3. Intercritical gout.
4. Chronic tophaceous gout.

The first phase is sometimes not even identified or may be detected during an annual normal physical examination since the person has no symptoms. The typical acute attack of gout is monoarticular and usually affects the first metatarsophalangeal joint. The tarsal joints, insteps, ankles, heels, knees, wrists, fingers, and elbows also may be initial sites of involvement. Acute gout often begins at night and may be precipitated by excessive exercise, certain medications or foods, alcohol, or dieting. The onset of pain typically is abrupt, and redness and swelling are observed. The attack may last for days or weeks. Pain may be severe enough to be aggravated even by the weight of a bedsheet covering the affected area.

In the early stages of gout after the initial attack has subsided, the person is asymptomatic, and joint abnormalities are not evident. This is the third phase or the intercritical gout. After the first attack, it may be months or years before another attack. As attacks recur with increased frequency, joint changes occur and become permanent. This fourth phase is called chronic tophaceous gout.

Gout has been linked with cardiovascular disease, obesity, metabolic syndrome, and renal insufficiency. Many people with dyslipidemia also have gout. Therefore, all of these conditions need to be ruled out and, if they are ruled out, should be prevented.

Diagnosis and Treatment

Although hyperuricemia is the biochemical hallmark of gout, the presence of hyperuricemia cannot be equated with gout because many people with this condition never develop gout. A definitive diagnosis of gout can be made only when monosodium urate crystals are in the synovial fluid or in tissue sections of tophaceous deposits. Synovial fluid analysis is useful in excluding other conditions, such as septic arthritis, pseudogout, and RA. Diagnostic methods also include measures to determine if the disorder is related to overproduction or to underexcretion of uric acid. This is done through measurement of serum uric acid levels and collection of a 24-hour urine sample for determination of urate excretion in the urine. Only 10% of people with high serum uric acid have this due to overproduction of urate. Rather, 90% of people who have gout have an urate underexcretion.

The objectives for treatment of gout include the termination and prevention of the acute attacks of gouty arthritis and the correction of hyperuricemia, with consequent inhibition of further precipitation of sodium urate and absorption of urate crystal deposits already in the tissues.

Pharmacologic management of acute gout is directed toward reducing joint inflammation. Hyperuricemia and

Synovial fluid is a poorer solvent for uric acid than plasma, and uric acid crystals are even less soluble at temperatures below 37°C. Crystal deposition usually occurs in peripheral areas of the body, such as the great toe, where the temperatures are cooler than in other parts of the body. With prolonged hyperuricemia, crystals and microtophi (i.e., small, hard nodules with irregular surfaces that contain crystalline deposits of monosodium urate) accumulate in the synovial lining cells and in the joint cartilage. The released crystals are chemotactic to leukocytes and also activate complements. Phagocytosis of urate crystals by polymorphonuclear leukocytes occurs and leads to polymorphonuclear cell death with the release of lysosomal enzymes. As this process continues, the inflammation causes destruction of the cartilage and subchondral bone.

Repeated attacks of acute arthritis eventually lead to chronic arthritis and the formation of the large, hard nodules called tophi (Fig. 59.11). They are found most commonly in the synovium, olecranon bursa, Achilles tendon, subchondral bone, and extensor surface of the forearm and may be mistaken for rheumatoid nodules. Tophi usually do not appear until 10 years or more after the first gout attack. This stage of
related problems of tophi, joint destruction, and renal problems are treated after the acute inflammatory process has subsided. NSAIDs, particularly indomethacin and ibuprofen, are used for treating acute gouty arthritis. Alternative therapies include colchicine and intra-articular deposition of corticosteroids. Treatment with colchicine is used early in the acute stage. Colchicine produces its anti-inflammatory effects by inhibition of leukocyte migration and phagocytosis. The acute symptoms of gout usually subside within 48 hours after treatment with oral colchicine has been instituted and within 12 hours after intravenous administration of the drug. The NSAIDs are also effective during the acute stage when used at their maximum dosage and sometimes are preferred to colchicine because they have fewer toxic side effects. The corticosteroid drugs have not been systemically studied, but can be useful in the treatment of acute gout limited to a single joint or bursa.

After the acute attack has been relieved, the hyperuricemia is treated. Treatment of hyperuricemia is aimed at maintaining normal uric acid levels and is lifelong. One method is to reduce hyperuricemia through the use of allopurinol or a uricosuric agent. Allopurinol inhibits xanthine oxidase, an enzyme needed for the conversion of hypoxanthine to xanthine and xanthine to uric acid. Management of acute gout is directed first toward the reduction of joint inflammation, after which the hyperuricemia is treated. Hyperuricemia is treated with uricosuric agents, which prevent the tubular reabsorption of urate, or with medication that inhibits the production of uric acid. Although gout is chronic, most people can control it with appropriate lifestyle changes.

IN SUMMARY

Crystal-induced arthropathy is characterized by crystal deposition in the joint. Gout is the prototype of this group. Acute attacks of arthritis occur with gout and are characterized by the presence of monosodium urate crystals in the joint. The disorder is accompanied by hyperuricemia, which results from overproduction of uric acid or from the reduced ability of the kidney to rid the body of excess uric acid. Management of acute gout is directed first toward the reduction of joint inflammation, after which the hyperuricemia is treated. Hyperuricemia is treated with uricosuric agents, which prevent the tubular reabsorption of urate, or with medication that inhibits the production of uric acid. Although gout is chronic, most people can control it with appropriate lifestyle changes.

RHEUMATIC DISEASES IN CHILDREN AND OLDER ADULTS

After completing this section of the chapter, you should be able to meet the following objectives:

- List three types of juvenile arthritis and differentiate among their major characteristics.
- Name one rheumatic disease that affects only older adults.

Rheumatic Diseases in Children

Children can be affected with almost all of the rheumatic diseases. In addition to disease-specific differences, these conditions affect not only the child but also the family. Growth and development require special attention. Adherence to the treatment program requires intervention with the child and parents.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA), often referred to as Still disease or childhood arthritis, generally persists into adulthood and can cause significant disability. RA or other rheumatic conditions affect approximately 294,000 children younger than 18 years of age in the United States. It is characterized by synovitis and can influence epiphyseal growth by stimulating growth of the affected side. Generalized stunted growth also may occur. JIA can be regarded not as a single disease, but as a category of diseases with three principal types of onset:

1. Systemic-onset disease.
2. Pauciarticular arthritis.
3. Polyarticular disease.

The symptoms of systemic JIA include a daily intermittent high fever, which usually is accompanied by a rash, generalized lymphadenopathy, hepatosplenomegaly, leukocytosis, and anemia. Most of these children also have joint involvement, which develops concurrently with fever and rash. Systemic symptoms usually subside in 6 to 12 months. This form of JIA also can make an initial appearance in adulthood. Infections, heart disease, and adrenal insufficiency may cause death.

A second subgroup of JIA, pauciarticular arthritis, affects no more than four joints. Pauciarticular arthritis affects two distinct groups. The first group generally consists of girls younger than 6 years of age with chronic uveitis. The results of ANA testing in this group usually are positive. The second group, characterized by late-onset arthritis, is made up mostly of boys. The HLA-B27 test results are positive in more than one half of this group. They are affected by sacroiliitis, and the arthritis usually occurs in the lower extremities.

The third subgroup, accounting for approximately 40% of the total cases of JIA, is polyarticular disease. This third classification affects five or more joints during the first
6 months of the disease. This form of arthritis more closely resembles the adult form of the disease than the other two subgroups. RF sometimes is present and may indicate a more active disease process.

The prognosis for most children with JIA is good. NSAIDs are the first-line drugs used in treating JIA. Second-line agents are low-dose methotrexate and, less often, sulfasalazine. Biologic response modifiers and TNF-\( \alpha \) are also being used in JIA, depending on the symptoms and classification. Other aspects of treatment of children with JIA require careful attention to growth and development and nutritional issues.

**Systemic Lupus Erythematosus**

The features of SLE in children are similar to those in adults. The incidence in children is 0.5 to 0.6 cases per 100,000 in children younger than 15 years. African Americans, especially girls, are the most frequently affected by SLE. Most children who are diagnosed with SLE are 8 years or older, although SLE has been seen from infancy throughout the age cycle. The clinical manifestations of SLE in children reflect the extent and severity of systemic involvement. The best prognostic indicator in children is the extent of renal involvement, which is more common and more severe in children than in adults with SLE.

Children with SLE may present with constitutional symptoms, including fever, malaise, anorexia, and weight loss. Symptoms of the integumentary, musculoskeletal, central nervous, cardiac, pulmonary, and hematopoietic systems are similar to those in adults. Endocrine abnormalities include Cushing syndrome from long-term corticosteroid use and autoimmune thyroiditis.

Treatment of SLE in children is similar to that in adults. The use of NSAIDs, corticosteroids, antimalarial drugs, and immunosuppressive agents depends on the symptoms. Corticosteroids may cause stunting of growth and necrosis of femoral heads and other joints. Immunization schedules should be maintained using attenuated rather than live vaccines. The diversity of the clinical manifestations of SLE in the young requires the establishment of a comprehensive treatment or management program.

**Juvenile Dermatomyositis**

Juvenile dermatomyositis (JDMS) is a rare inflammatory myopathy primarily involving skin and muscle associated with a characteristic rash. This disorder affects only 2 to 3 children per 1 million children under 17 years of age. JDMS can affect children of all ages, with a mean age at onset of 8 years. There is an increased incidence among girls. The cause is not known. Symmetric proximal muscle weakness, elevated muscle enzymes, evidence of vasculitis, and electromyographic changes confirming an inflammatory myopathy are diagnostic for JDMS. Generalized vasculitis is not seen in the adult form of the disease. In children weak proximal muscles, a heliotrope rash around the eyes, and Gottron papules are often considered the triad of symptoms. The rash may precede or follow the onset of proximal muscle weakness. Periorbital edema, erythema, and eyelid telangiectasia are common. The criteria of Bohan and Pila are used to diagnose this disorder. A child must have three out of the five criteria (progressive proximal symmetrical weakness, increased muscle enzyme levels, abnormal muscle biopsy results, abnormal electromyogram [EMG] results, and compatible cutaneous disease) to be diagnosed with JDMS.

Calcifications can occur in 30% to 50% of children with JDMS and are by far the most debilitating symptom. The calcifications appear at pressure points or sites of previous trauma. JDMS is treated primarily with corticosteroids to reduce inflammation.

**Juvenile Spondyloarthropathies**

Ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and spondyloarthropathies associated with ulcerative colitis and regional enteritis can affect children as well as adults. In children, spondyloarthropathy manifests in peripheral joints first, mimicking pauciarticular JIA. There is no evidence of sacroiliac or spine involvement until later in the disease, such as months to years after onset. The spondyloarthropathies are more common in boys and commonly occur in children who have a positive family history. HLA-B27 typing is helpful in diagnosing children because of the unusual presentation of the disease.

Management of the disease involves physical therapy, education, and attention to school and growth and development issues. Medication includes the use of salicylates, NSAIDs, and biological modifiers.

**Rheumatic Diseases in Older Adults**

Arthritis is the most common complaint of older adults. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. Symptoms of the rheumatic diseases can also have an indirect effect on and even threaten the duration of life for older adults. The weakness and gait disturbance that often accompany rheumatic diseases can contribute to the likelihood of falls and fracture, causing suffering, increased health care costs, further loss of independence, and the potential for a decreased life span.

Older adults cope less well with mild to moderately severe disease, which, in younger people, is less likely to lead to serious disability for the same degree of impairment. Unfortunately, older adults, and often their health care providers, think the problems associated with arthritis are an inevitable consequence of aging and fail to take advantage of measures that can improve the quality of life.

Older adults often have multiple problems complicating diagnosis and management. The diagnosis of an older adult with a musculoskeletal problem must consider a wide variety of disorders that usually are regarded as outside the range of typical rheumatic disease. Among these are metastatic malignancy, multiple myeloma, musculoskeletal disorders accompanying endocrine or metabolic disorders, orthopedic conditions, and neurologic disease. The diagnosis may be missed if the assumption is that musculoskeletal problems in the older adult are caused by OA.
There is an increased incidence of false-positive test results for RF and ANA in the older adult population with or without rheumatic disease because older adults are better producers of autoantibodies than younger people. There are differences in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in older adults. The usual presentation of these conditions was discussed earlier in this chapter. One form of rheumatic disease that has a predilection for older adults is polymyalgia rheumatica, which generally affects individuals greater than 60 years of age.

**Rheumatoid Arthritis**

The prevalence of RA increases with advancing age possibly due to the decrease in T cell generation. Seropositive people are more likely to have had an acute onset with systemic features and higher disease activity. People with seronegative, elderly onset RA have a disease that usually follows a mild course. It may be that RA in older adults is a broad disorder that includes a number of distinct subsets with characteristic manifestations, courses, and outcomes.

**Systemic Lupus Erythematosus**

SLE is another condition with different manifestations in older adults. The disease is accompanied less frequently by renal involvement. However, pleurisy, pericarditis, arthritis, and symptoms closely resembling polymyalgia rheumatica are more common than in younger people. The characteristics of SLE in older adults closely resemble those of drug-induced SLE.

**Osteoarthritis**

OA is by far the most common form of arthritis among older adults. It is the greatest cause of disability and limitation of activity in older populations. It has been suggested that OA begins at a very young age, expressing itself in older adults only after a long period of latency.

**Crystal-Induced Arthropathies**

**Gout.** The incidence of clinical gout increases with advancing age, in part because of the increased involvement of joints after years of continued hyperuricemia. High serum urate levels rarely occur in women, especially before menopause, but they can occur after menopause. Gouty attacks in older adults are sometimes precipitated by the use of diuretics. The treatment of gout is often more difficult in older adults.

**Pseudogout.** As part of the tissue-aging process, OA develops with associated cartilage degeneration and the shedding of calcium pyrophosphate crystals into the joint cavity. These crystals may produce a low-grade chronic inflammation—the chronic pseudogout syndrome. The accumulation of calcium pyrophosphate and related crystalline deposits in articular cartilage is common in the elderly. There are no medications that can remove the crystals from the joints. Although it may be asymptomatic, presence of the crystals may contribute to more rapid cartilage deterioration. This condition may coexist with severe OA.

**Polymyalgia Rheumatica**

Polymyalgia rheumatica is an inflammatory condition of unknown origin characterized by aching and morning stiffness in the shoulder and pelvic areas. Of the forms of arthritis affecting older adults, it is one of the more difficult to diagnose and one of the most important to identify. Older women are especially at risk. Polymyalgia rheumatica is a common syndrome of older adults, rarely occurring before 50 years and usually after 60 years of age. The onset can be abrupt, with the person going to bed feeling well and awakening with pain and stiffness in the neck, shoulders, and hips.

Diagnosis is based on the pain and stiffness persisting for at least 1 month and an elevated eosinophil sedimentation rate (ESR). The diagnosis is confirmed when the symptoms respond dramatically to a small dose of prednisone, a corticosteroid. Biopsies have shown that the muscles are normal, despite the name, but that a nonspecific inflammation affecting the synovial tissue is present. It is possible that a number of people are erroneously diagnosed as having RA or OA. For symptomatic people with an elevated ESR, the diagnosis usually is made. Generally the person is given oral steroids. People with polymyalgia rheumatica typically exhibit striking clinical improvement approximately the second day of beginning the oral steroid. People with RA also show improvement, although usually not as quickly.

Treatment with NSAIDs provides relief for some people, but most require continuing therapy with prednisone, with gradual reduction of the dose over the course of 2 to 6 years, using the person’s symptoms as the primary guide. People need close monitoring during the maintenance phase with prednisone therapy. Because their symptoms are relieved, they often quit taking the prednisone and their symptoms recur, or doses are missed and the decreased dosage leads to an increase in symptoms. Unless careful assessment reveals the frequency of missed doses, the physician may be misled into increasing the dosage when it is not needed. Because of the side effects of the corticosteroids, the goal is to use the lowest dose of the drug necessary to control the symptoms. Weaning people off low-dose prednisone therapy after this length of time can be a difficult and extended process.

A certain percentage of people with polymyalgia rheumatica also develop giant cell arteritis (i.e., temporal arteritis) with involvement of the ophthalmic arteries. The two conditions are considered to represent different manifestations of the same disease. Giant cell arteritis, a form of systemic vasculitis, is a systemic inflammatory disease of large and medium-sized arteries. The inflammatory response seems to be a T cell response to an antigen.

Clinical manifestations of giant cell arteritis usually begin insidiously and may exist for some time before being recognized. It is potentially dangerous if missed or mis-treated, especially if the temporal artery or other vessels supplying the eye are involved, in which case blindness can ensue quickly without treatment. Initial treatment consists of large doses of prednisone. This dosage is continued for 4 to 6 weeks and then decreased gradually.
Management of Rheumatic Diseases in Older Adults

In addition to diagnosis-specific treatment, older adults require special considerations. Management techniques that rely on modalities other than drugs are particularly important. These include assistive devices, muscle-building exercise, and local heat. Muscle-strengthening and stretching exercises are particularly effective in the older adult with age-related losses in muscle function and should be instituted early.

Joint arthroplasty can also be used for pain relief and increased function. Chronicologic age is not a contraindication to surgical treatment of arthritis. In appropriately selected older candidates, survival and functional outcome after surgery are equivalent to those in younger age groups. The more sedentary activity level of the older adult makes them even better candidates for joint replacement because they put less stress and demand on the new joint.

IN SUMMARY

Rheumatic diseases that affect children can be similar to the adult diseases, but there are also manifestations unique to the younger population. Children with chronic diseases also have to be approached with different priorities than adults. Managing rheumatic diseases in children requires a team approach to address issues of the family, school, growth and development, and coping strategies and requires a comprehensive disease management program.

Arthritis is the most common complaint of the older adult population. The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. There is a difference in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in older adults compared with those in the younger population. OA is the most common form of arthritis among older adults. The prevalence of RA and gout increases with advancing age. One form of rheumatic disease that has a predilection for older adults is polymyalgia rheumatica. A certain percentage of people with polymyalgia rheumatica also have giant cell arteritis, frequently with involvement of the ophthalmic arteries. If this condition is untreated, it carries a serious threat of blindness.

120 IU/mL (nonreactive, 0 to 39 IU/mL; weakly reactive, 40 to 79 IU/mL; reactive, >80 IU/mL) and a positive anti-CCP antibody.
A. Describe the immunopathogenesis of the joint changes that occur with RA.
B. How do these changes relate to this woman’s symptoms?
C. What is the significance of her RF test results?
D. What is the significance of her + anti-CCP antibody test?
E. How do her complaints of general fatigue and weight loss relate to the RA disease process?

2. A 65-year-old obese woman with a diagnosis of osteoarthritis (OA) has been having increasing pain in her right knee that worsens with movement and weight bearing and is relieved by rest. Physical examination reveals an enlarged joint with a varus deformity; coarse crepitus is felt over the joint on passive movement.
A. Compare the pathogenesis and articular structures involved in OA with those of RA.
B. What is the origin of the enlargement of the affected joint, the varus deformity, and the crepitus that is felt on movement of the affected knee?
C. Explain the predilection for involvement of the knee in people such as this woman.
D. What types of treatment are available for this woman?

3. A 75-year-old woman is seen by her health care provider because of complaints of fever, malaise, and weight loss. She is having trouble combing her hair, putting on a coat, and getting out of chairs because of the stiffness and pain in her shoulders, hip, and lower back. Because of her symptoms, the health care provider suspects the woman has polymyalgia rheumatica.
A. What laboratory test can be used to substantiate the diagnosis?
B. What other diagnostic strategies are used to confirm the diagnosis?
C. How is the disease treated?

REVIEW EXERCISES

1. A 30-year-old woman, recently diagnosed with rheumatoid arthritis (RA), complains of general fatigue and weight loss along with symmetric joint swelling, stiffness, and pain. The stiffness is more prominent in the morning and subsides during the day. Laboratory measures reveal a rheumatoid factor (RF) of

References

Lauren Ronde, 18 years old, is a college freshman who presents with a growth on her lower right ear lobe and a rash on her fingers that she describes as “very itchy.” She explains that the rash started 2 days ago and it is really bothering her. After examining the rash, the nurse describes the rash as having an erythematous background, slightly swollen, nonpainful to touch, and papular with 1 mm vesicles. It is predominantly on her fingers bilaterally and a specimen is unable to be obtained for culture. Some of the blisters are intact but most have erupted and are resolving according to Lauren. After a thorough history and physical examination the rash is assumed to be a result of a hypersensitivity response to a chemical(s) she has just begun working with in her chemistry lab. The rash is presumed to be due to allergic contact dermatitis. She is told to wear gloves at all times in the chemistry lab and apply a slight film of hydrocortisone 1% cream to the rash after her shower every day and upon washing her hands after the lab session each day. A few days later she calls in to report that after following this process her rash has almost disappeared and that the hydrocortisone is effective with the itching.

The growth on her right lower ear lobe is irregularly shaped, elevated, and firm to the touch. It is located at the sight of her last ear piercing. She is told that this is a keloid and that it was caused by excessive formation of collagen corneum during the repair of the dermal connective tissue post earring piercing. It is her first piercing and she was scheduled for three more piercings. After hearing about the etiology of the keloid she has canceled her piercing appointments. She is told that there is nothing one can do about removing a keloid because doing so would require another incision, which would trigger more keloid formation. You will read more about Ms. Ronde in Chapters 60 and 61.
The skin, also called the integumentum, is one of the most versatile organs of the body, accounting for roughly 16% of the body’s weight. It forms the major interface between the internal organs and the external environment. The thickness of the skin can range from <1 to >5 mm. For example, the epidermal thickness on the eyelid is approximately 0.5 mm while the thickness on the sole of the foot is 1.5 mm. As the body’s first line of defense, the skin is continuously subjected to potentially harmful environmental agents, including solid matter, liquids, gases, sunlight, and microorganisms. Although it may become bruised, lacerated, burned, or infected, it has remarkable properties that allow for a continuous cycle of shedding, healing, and cell regeneration.

As the outer covering of the body, the skin may demonstrate outwardly what occurs inside the body. A number of systemic diseases are manifested by skin disorders (e.g., malar rash associated with systemic lupus erythematosus, bronze skin with Addison’s disease, and jaundice with liver disease). Thus, it is important to recognize that although skin eruptions are frequently caused by primary disorders of the skin, they may also represent manifestations of systemic disease.

**STRUCTURE AND FUNCTION OF THE SKIN**

**SKIN STRUCTURES**
- Epidermis
- Basement Membrane
- Dermis
- Subcutaneous Tissue

**SKIN APPENDAGES**
- Sweat Glands
- Sebaceous Glands
- Hair
- Nails

Functions of the Skin

**MANIFESTATIONS OF SKIN DISORDERS**
- Lesions and Rashes
- Pruritus
- Dry Skin
- Skin Variations in Dark-Skinned People

---

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the changes in a keratinocyte from its inception in the basal lamina to its arrival on the outer surface of the skin.
- Describe the following skin appendages and their functions: sebaceous gland, eccrine gland, apocrine gland, nails, and hair.
- Characterize the skin in terms of sensory and immune functions.
Chapter 60  Structure and Function of the Skin

**Skin Structures**

There are great variations in skin structure on different parts of the body. Therefore, “normal skin” on any one surface of the body is difficult to describe. Variations are found in the properties of the skin, such as the thickness of skin layers, the distribution of sweat glands, and the number and size of hair follicles. For example, the epidermis is thicker on the palms of the hands and soles of the feet than elsewhere on the body. The dermis, on the other hand, is thickest on the back, whereas the subcutaneous fat layer is thickest on the abdomen and buttocks. Hair follicles are densely distributed on the scalp, axillae, and genitalia, but they are sparse on the inner arms and abdomen. The apocrine sweat glands are confined to the axillae and the anogenital area. Nevertheless, certain structural properties are common to skin on all areas of the body.

The skin is composed of three layers:

1. Epidermis (outer layer)
2. Dermis (inner layer)
3. Subcutaneous fat layer

The basement membrane divides the first two layers. The subcutaneous tissue, a layer of loose connective and fatty tissues, binds the dermis to the underlying tissues of the body (Fig. 60.1).

**ORGANIZATION OF SKIN STRUCTURES**

- The epidermis, which is avascular, is composed of four to five layers of stratified squamous keratinized epithelial cells that are formed in the deepest layer of the epidermis and migrate to the skin surface to replace cells that are lost during normal skin shedding.
- The basement membrane is a thin adhesive layer that cements the epidermis to the dermis. This is the layer involved in blister formation.
- The dermis is a connective tissue layer that separates the epidermis from the underlying subcutaneous fat layer. It contains the blood vessels and nerve fibers that supply the epidermis.
Epidermis

The functions of the skin depend on the properties of its outermost layer, the epidermis. The epidermis covers the body. It is specialized in areas to form the various skin appendages, which include hair, nails, and glandular structures. The keratinocytes of the epidermis produce a fibrous protein called keratin, which is essential for the protective function of skin. In addition to the keratinocytes, the epidermis has three other types of cells that arise from its basal layer—melanocytes, Merkel cells, and Langerhans cells. Melanocytes produce a pigment called melanin, which is responsible for skin color, tanning, and protection against ultraviolet radiation. Merkel cells provide sensory information and Langerhans cells link the epidermis to the immune system. The epidermis contains openings for two types of glands—sweat glands, which produce watery secretions, and sebaceous glands, which produce an oily secretion called sebum.

Keratinocytes. The keratinocyte is the major cell of the epidermis, comprising 95% of the cells of this layer. The epidermis is composed of stratified squamous keratinized epithelium, which, when viewed under the microscope, is seen to consist of five distinct layers, or strata, that represent a progressive differentiation or maturation of the keratinocytes:

1. Stratum germinativum, or the basal layer
2. Stratum spinosum
3. Stratum granulosum
4. Stratum lucidum
5. Stratum corneum

The deepest layer, the stratum germinativum or stratum basale, consists of a single layer of basal cells that are attached to the basal lamina. The basal cells, which are columnar, undergo mitosis to produce new keratinocytes that move toward the skin surface to replace cells lost during normal skin shedding. Unlike the other layers of the epidermis, the basal cells do not migrate toward the skin surface, but remain stationary in the stratum germinativum.

The next layer, the stratum spinosum, is formed as the progeny of the basal cell layer move outward toward the skin surface. The stratum spinosum is two to four layers thick, and its cells become differentiated as they migrate outward. Because they develop a spiny appearance where their cell borders interconnect, the cells of this layer are commonly referred to as prickle cells.1

The stratum granulosum is only a few cells thick (thickness varies between one and three cells).1 It consists of granular cells that are the most differentiated cells of the living skin. The cells in this layer are unique in that two opposing functions occur simultaneously. While some cells lose cytoplasm and nuclear structures, others continue to synthesize keratin.

The stratum lucidum, which lies just superficial to the stratum granulosum, is a thin, transparent layer found primarily on the thick skin such as over the palms of the hands and soles of the feet.1 It consists of transitional cells that retain some of the functions of living skin cells from the layers below but otherwise resembles the cells of the stratum corneum.

The top or surface layer, the stratum corneum, consists of dead, keratinized cells. This layer contains the most cell layers and the largest cells of the epidermis. It ranges from 15 layers thick in areas such as the face to 25 layers or more on the arm. Specialized areas, such as the palms of the hands or soles of the feet, have 100 or more layers.

The keratinocytes that originate in the basal layer change morphologically as they are pushed toward the outer layer of the epidermis. For example, in the basal layer, the keratinocyte is round. As it is pushed into the stratum spinosum, the keratinocyte becomes flattened and is flattened and elongated in the stratum corneum (Fig. 60.2). Keratinocytes also change cytoplasmic structure and composition as they are pushed outward. This transformation from viable cells to the dead cells of the stratum corneum is called keratinization. The migration time of a keratinocyte from the basal layer to the stratum corneum is 20 to 30 days. The rate of production of new keratinocytes needs to be consistent with the rate of shedding old keratinocytes. When the rates are not in balance, skin anomalies occur.

The movement of the keratinocytes to the surface of the skin is best described as random or nonsynchronized. Keratinocytes pass other keratinocytes, melanocytes, and Langerhans cells as they migrate in a seemingly random fashion. However, the cells are connected by minute points of attachment called desmosomes. Desmosomes are localized patches or plaques that hold two cells tightly together. They are terminal end points on the cell walls of keratinocytes, made up of fibrous material that is bound into bundles, called tonofilaments. Desmosomes keep the cells from detaching and provide some structure to the skin while it is in perpetual motion. The basal layer provides the underlying structure and stability for the epidermis.
Besides desmosomes, there are three other types of cellular junctions that bind keratinocytes—adherens junctions, gap junctions, and tight junctions. Adherens junctions are specialized structures that provide strong mechanical connections between cells. They are responsible for adhesion between cells, communicate about the presence of neighboring cells, and anchor the skin cells. Gap junctions are cylindrical channels that permit ions and small molecules to pass between cells. They are composed of proteins called connexins.

Keratinocytes produce keratin, a complex protein that forms the surface of the skin and is also the structural protein of the hair and nails. Once believed to be passive cells passing through time while changing morphologically, keratinocytes are now known to be active secretory cells that play an important role in the immunobiology of the skin by communicating and regulating cells of the immune response and secreting cytokines and inflammatory mediators.

**Melanocytes.** Melanocytes are pigment-synthesizing cells that are scattered in the basal layer and are responsible for skin color.\(^1\) They function to produce pigment granules called melanin, the substance that gives skin its color. There are two major forms of melanin—eumelanin and pheomelanin. The two forms of eumelanin are brown and black; pheomelanin is yellow to red. The type of melanin produced depends on the stimulation of specific hormones or proteins and the binding of these substances to receptors on the melanocyte. Eumelanin is the most abundant in humans. Exposure to the sun’s ultraviolet rays increases the production of eumelanin, causing tanning to occur. The primary function of such melanin is to protect the skin by absorbing and scattering harmful ultraviolet rays, which are implicated in skin cancers. Localized concentrations of eumelanin are also responsible for the formation of freckles and moles.

Pheomelanin, the yellow to red pigment, is found in all humans. It is particularly concentrated in the lips, nipples, glans penis, and vagina. Besides the skin, it is found in hair, particularly red hair. It has been suggested that the reason fair-haired people are more susceptible to skin cancers may be due to the enhanced photoreactivity of pheomelanin, as compared with eumelanin.

The ability to synthesize melanin depends on the ability of the melanocytes to produce an enzyme called tyrosinase, which converts the amino acid tyrosine to a precursor of melanin. A genetic lack of this enzyme results in a clinical condition called albinism. People with this disorder lack pigmentation in the skin, hair, and iris of the eye. Tyrosinase is synthesized in the rough endoplasmic reticulum of the melanocytes and then routed to membranous vesicles in the Golgi complex called melanosomes. Melanin is subsequently synthesized in the melanosomes. Melanocytes have long, cytoplasm-filled dendritic processes that contain accumulated melanosomes and extend between the keratinocytes. Although the melanocytes remain in the basal layer, the melanosomes are transferred to the keratinocytes through their dendritic processes. The dendritic tip containing the melanosome is engulfed by a nearby keratinocyte, and the melanin is transferred (Fig. 60.3).

The amount of melanin in the keratinocytes determines a person’s skin color.\(^2\) Dark-skinned and light-skinned people have approximately the same number of melanocytes, but the production and packaging of pigment is different. In dark-skinned people, larger melanin-containing melanosome are produced and transferred individually to the keratinocyte. In light-skinned people, smaller melanosomes are produced and then packaged together in a membrane before being transferred to the keratinocyte. All people, regardless of skin color, have relatively few or no melanocytes in the epidermis of the palms of the hands or soles of the feet. In light-skinned people, the number of melanocytes decreases with age; the skin becomes lighter and is more susceptible to skin cancer when exposed to ultraviolet light. However, people with vitiligo, a skin problem where the melanocytes are destroyed, are not susceptible to nonmelanoma skin cancers, whereas people with albinism are.\(^4\)

**Merkel Cells.** Merkel cells are clear cells found in the stratum basale of the epidermis. They are connected to other skin cells by desmosomes. Each Merkel cell is connected to an afferent nerve terminal, forming a structure known as a Merkel disk. They are the sparsest cells of the epidermis and are found over the entire body, but are most plentiful in the basal layer of the fingers, toes, lips, and oral cavity, and in the outermost sheath of hair follicles (i.e., the touch areas). The exact function of Merkel cells is unclear, but they are believed to be neuroendocrine cells (i.e., they release hormones into the blood in response to neural stimuli) and function as specific, slowly adapting sensory touch receptors in cutaneous sensation.\(^1\) Merkel cells may also be involved in the metabolic support of their associated neurons, neuron development and regeneration after injury, and neurotransmission for autonomic nerves, blood vessels, and inflammatory cells.
Langerhans Cells. Langerhans cells are scattered in the suprabasal layers of the epidermis among the keratinocytes. They are less numerous (3% to 5% of epidermal cells) than the keratinocytes. They are derived from precursor cells originating in the bone marrow, and continuously repopulate the epidermis. Like melanocytes, they have a dendritic shape and clear cytoplasm. Birbeck granules that often resemble tennis racquets are their most distinguishing characteristic microscopically.1

Langerhans cells are the immunologic cells responsible for recognizing foreign antigens harmful to the body (Fig. 60.4). As such, Langerhans cells play an important role in defending the body against foreign antigens. Langerhans cells bind antigen to their surface and process it, and, bearing the processed antigen, migrate from the epidermis into lymphatic vessels and then into regional lymph nodes, where they are known as dendritic cells. During their migration in the lymph system, the Langerhans cells become potent antigen-presenting cells.2 Langerhans cells are innervated by sympathetic nerve fibers, which may explain why the skin’s immune system is altered under stress. An example of this is the exacerbations of acne seen in people under stress. Langerhans cells and the keratinocytes produce a number of cytokines that stimulate maturation of skin-localizing T lymphocytes.

Basement Membrane

The terms basement membrane and basal lamina are often used interchangeably. Technically, however, the basal lamina is a component of the basement membrane. The basement membrane is a layer of intercellular and extracellular matrices that serves as an interface between the dermis and the epidermis (Fig. 60.5). It separates the epithelium from the underlying connective tissue, it anchors the epithelium to the loose connective tissue underneath, and it serves as a selective filter for molecules moving between the two layers. It is also a major site of immunoglobulin and complement deposition in skin disease. The basement membrane is involved in skin disorders that cause bullae or blister formation.1

The basement membrane consists of three distinct zones or layers—lamina lucida, lamina densa, and lamina fibroreticularis—all of which contribute to the adhesion of the two skin layers. The lamina lucida is an electron-lucent layer where adherence proteins are located. It consists of fine anchoring filaments and a cell adhesion glycoprotein, called laminin, which plays a role in the organization of the macromolecules in the basement membrane zone and promotes attachment of cells to the extracellular matrix. The lamina densa contains an adhesive called type IV collagen as well as laminin. It is important in dermal–epidermal attachment. Combined, the lamina lucida and the lamina densa comprise what is known as the basal lamina. The lamina fibroreticularis then completes the basement membrane. This layer contains many anchoring microfibrils. These are short, curved structures that insert into the lamina densa and the upper part of the dermis (superficial dermis), where they are known as anchoring fibrils. Type VII collagen, another adherent substance, has been found in the anchoring fibrils and plaques. Another component of the lamina fibroreticularis are elastic fiber bundles that extend to the dermis.3

Hemidesmosomes are like half-desmosomes in both structure and function. They lie immediately at the basal plasma membrane and form the site or source of tonofilaments, which attach the dermis and epidermis (see Fig. 60.5).3 Because they form a continuous link between the intracellular keratin filament network and the extracellular basement membrane, they are also involved in relaying signals between the skin systems.

Dermis

The dermis is the connective tissue layer that separates the epidermis from the subcutaneous fat layer (see Fig. 60.1). It supports the epidermis and serves as its primary source of nutrition. The two layers of the dermis, the papillary dermis and the reticular dermis, are composed of cells, fibers, ground substances, nerves, and blood vessels. The main component of the dermis is collagen, a group of fibrous proteins. The collagen
the papillary dermis, forming rete ridges. Microscopically, the junction between the epidermis and the dermis appears like undulating ridges and valleys. It is believed that the dense structure of the dermal papillae serves to minimize the separation of the dermis and the epidermis. Dermal papillae contain capillaries, end arterioles, and venules that nourish the epidermal layers of the skin. This layer of the dermis is richly vascularized. Lymph vessels and nerve tissue also are found in this layer.

**Reticular Dermis.** The reticular dermis (pars reticularis) is the thicker area of the dermis and forms the bulk of the dermal layer. This is the tough layer in animal hides from which is enmeshed in a ground substance called hyaluronic acid.
Blood Vessels. The arterial vessels that nourish the skin form two plexuses (i.e., collections of blood vessels), one located between the dermis and the subcutaneous tissue and the other between the papillary and reticular layers of the dermis. The pink color of light skin results primarily from blood in the vessels of this latter plexus. Capillary flow that arises from vessels in this plexus also extends up and nourishes the overlying epidermis by diffusion. Blood leaves the skin through small veins that accompany the subcutaneous arteries. The lymphatic system of the skin, which aids in combating certain skin infections, also is limited to the dermis.

The skin is richly supplied with arteriovenous anastomoses in which blood flows directly between an artery and a vein, bypassing the capillary circulation. These anastomoses are important for temperature regulation. They can open up, letting blood flow through the skin vessels when there is a need to dissipate body heat, and close off, conserving body heat if the environmental temperature is cold.

Innervation. The innervation of the skin is complex. The skin, with its accessory structures, serves as an organ for receiving sensory information from the environment. The dermis is well supplied with sensory neurons as well as nerves that supply the blood vessels, sweat glands, and arrector pili muscles. The arrector pili muscles connect the dermis to the hair follicles.¹

The receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis. The papillary layer of the dermis is supplied with free nerve endings that serve as nociceptors (i.e., pain receptors) and thermoreceptors. The dermis also contains encapsulated pressure-sensitive receptors that detect pressure and touch. The largest of these are the pacinian corpuscles, which are widely distributed in the dermis and subcutaneous tissue. The afferent nerve endings of the pacinian corpuscle are surrounded by concentric layers of modified Schwann cells such that they resemble an onion when sectioned. Pacinian corpuscles are responsible for detecting gross pressure changes and vibrations. Pressure causes the pacinian corpuscle to change its shape, thereby triggering nerve impulses. Pacinian corpuscles are adaptive and they respond more to changes than to steady pressure or vibration.

Flat, encapsulated nerve endings found on the palmar surfaces of the fingers and hands and planter surfaces of the feet are called Meissner corpuscles and serve as touch receptors.¹ They are concentrated on the fingertips, palms, soles, lips, tongue, face, and genitalia. They are thick, laminated, ovoid capsules each containing up to six nerve endings. When the corpuscle is deformed by pressure, the nerve endings are stimulated, signaling the somatosensory portion of the cerebral cortex and informing the person about the location and strength of the stimulus. They are rapidly adapting and do not react to constant, steady stimulation.

The deep dermis is supplied with small, oval mechatoreceptors called Ruffini corpuscles. Ruffini corpuscles are located in the subcutaneous tissue of hairy and glabrous skin. Several expanded nerve endings branch from a single, myelinated afferent fiber.¹ They are slowly adapting receptors, responding to heavy pressure and joint movement. They are also believed to detect cold.

Most of the skin’s blood vessels are under sympathetic nervous system control. The sweat glands are innervated by cholinergic fibers but controlled by the sympathetic nervous system. Likewise, the sympathetic nervous system controls the arrector pili (pilomotor) muscles that cause elevation of hairs on the skin. Contraction of these muscles tends to cause the skin to dimple, producing “goose bumps or goose flesh.”¹

Subcutaneous Tissue

The subcutaneous tissue layer is the third layer of the skin and consists primarily of fat cells and connective tissues that lend
support to the vascular and neural structures supplying the outer layers of the skin. There is controversy about whether the subcutaneous tissue should be considered an actual layer of the skin. Because the eccrine glands and deep hair follicles extend to this layer and several skin diseases involve the subcutaneous tissue, the subcutaneous tissue may be considered part of the skin.

The subcutaneous layer may have varying levels of thickness depending on its location. The fascia may be thinner over a bony prominence and thicker when covering other organs. Therefore, if there is a break in the skin, which is more likely to occur over a bony prominence, and infection occurs in the subcutaneous tissue, the macrophages will proliferate to fight the infectious agents.\(^1\)\(^3\) Hence, the subcutaneous layer of the skin does contribute to the skin’s immunological function.

**Skin Appendages**

The skin houses a variety of appendages, including sweat glands, sebaceous glands, hair, and nails. The distribution and functions of the appendages vary.

**Sweat Glands**

There are two types of sweat glands—eccrine and apocrine. Eccrine sweat glands are simple tubular structures that originate in the dermis and open directly to the skin surface. They are numerous (several million), vary in density, and are located over the entire body surface except the lips and part of the external genitalia.\(^1\) Their purpose is to transport sweat to the outer skin surface to regulate body temperature. Apocrine sweat glands are less numerous than eccrine sweat glands. They are larger and located deep in the dermal layer. They open through a hair follicle, even though a hair may not be present, and are found primarily in the axillae and groin. The major difference between these glands and the eccrine glands is that apocrine glands secrete an oily substance. In animals, apocrine secretions give rise to distinctive odors that enable animals to recognize the presence of others. In humans, apocrine secretions are sterile until mixed with the bacteria on the skin surface. They then produce what is commonly known as “body odor.”

**Sebaceous Glands**

The sebaceous glands are located over the entire skin surface except for the palms, soles, and sides of the feet. They are part of the pilosebaceous unit. They secrete a mixture of lipids, including triglycerides, cholesterol, and wax. This mixture is called sebum, and it lubricates hair and skin.\(^1\) Sebum is not the same as the surface lipid film. Sebum prevents undue evaporation of moisture from the stratum corneum during cold weather and helps to conserve body heat. Sebum production is under the control of genetic and hormonal influences. Sebaceous glands are relatively small and inactive until people approach adolescence. The glands then enlarge, stimulated by the rise in sex hormones. Gland size directly influences the amount of sebum produced, and the level of androgens influences gland size. The sebaceous glands are the structures that become inflamed in acne.

**Hair**

Hair is a structure that originates from hair follicles in the dermis. Most hair follicles are associated with sebaceous glands, and these structures combine to form the pilosebaceous unit. The entire hair structure consists of the hair follicle, sebaceous gland, hair muscle (arrector pili), and, in some instances, the apocrine gland (Fig. 60.6). Hair is a keratinized structure that is pushed upward from the hair follicle. Growth of the hair is centered in the bulb (i.e., base) of the hair follicle, and the hair undergoes changes as it is pushed outward. Hair goes through three cyclic phases identified as anagen (the growth phase), catagen (the atrophy phase), and telogen (the resting phase, or no growth). Like most animals, human beings shed hair cyclically. However, human hair follicles work independently and therefore, unlike most animals, human beings shed hair asynchronously.

A vascular network at the site of the follicular bulb nourishes and maintains the hair follicle. Melanocytes in the bulb transfer melanosomes to the cells of the bulb matrix in much the same way as in the skin and are therefore responsible for the color of the hair. Similar to the skin, large melanosomes are found in the hair of darker-skinned people. Aggregated and encapsulated melanosomes are found in people with light skin. Red hair has spherical melanosomes, whereas gray hair is the result of a decreased number of melanosome-producing melanocytes. The arrector pili muscle, located under the sebaceous gland, provides a thermoregulatory function by contracting to cause goose bumps, thereby reducing the skin surface area that is available for the dissipation of body heat.
Nails

The nails are hardened keratinized plates, called *fingernails* and *toenails*, which protect the fingers and toes and enhance dexterity. The nails grow out from a curved transverse groove called the *nail groove*. The floor of this groove, called the *nail matrix*, is the germinal region of the nail plate (Fig. 60.7). The underlying epidermis, attached to the nail plate, is called the *nail bed*. Like hair, nails are the end product of dead matrix cells that are pushed outward from the nail matrix. Unlike hair, nails grow continuously rather than cyclically, unless permanently damaged or diseased. The epithelium of the fold of skin that surrounds the nail consists of the usual layers of skin. The stratum corneum forms the *eponychium* or cuticle. The nearly transparent nail plate provides a useful window for viewing the amount of oxygen in the blood, providing a view of the color of the blood in the dermal vessels. Changes or abnormalities of the nail can also serve to help diagnose skin or systemic diseases.

Functions of the Skin

The skin and its derivatives constitute a complex organ with many cell types. The diversity of cell types and their ability to work together provide a number of ways of protecting a person from the elements in the external environment. Microorganisms find it almost impossible to penetrate the skin from the outside, and water loss is limited from the inside. The skin surface is covered with a thin lipid film containing bactericidal fatty acids that protect against the entry of harmful microorganisms, and it harbors a constant flora of relatively harmless strains of microorganisms that protect against other, more virulent strains. The skin also plays an important role in immune regulation through skin-associated lymphoid tissues, including Langerhans cells, mast cells, and lymphocytes. Langerhans cells, the antigen-presenting cells of the epidermal skin, not only protect against harmful pathogens but also play an important role in the development of allergic skin conditions. As the antigen is phagocytized, it is evident on the Langerhans cell surface, and the cell moves to a regional lymph node where it interacts with T lymphocytes.¹

![FIGURE 60.7 • Parts of a fingernail.](image)

Key Points

**FUNCTIONS OF THE SKIN**

- The skin prevents body fluids from leaving the body, protects the body from potentially damaging environmental agents, and serves as an area for heat exchange. In addition, cells of the skin immune system provide protection against invading microorganisms.
- Receptors in the skin relay touch, pressure, temperature, and pain sensation to the central nervous system for localization and discrimination.

In Summary

The skin serves several other vital functions, including somatosensory function, temperature regulation, and vitamin D synthesis. The skin is richly innervated with pain, temperature, and touch receptors. Skin receptors relay the numerous qualities of touch, such as pressure, sharpness, dullness, and pleasure to the central nervous system for localization and fine discrimination. Most of the heat produced in the body is generated by deep organs, such as the liver, heart, and skeletal muscles, and then transferred to the skin, where it is lost to the surrounding environment. The rate at which heat is dissipated from the body is determined by constriction or dilation of the arterioles that supply blood to the skin and through evaporation of moisture and sweat from the skin surface. The skin also functions as an endocrine organ, in which 7-dehydrocholesterol, a substance normally found in epidermal cells, is converted to cholecalciferol (an inactive form of vitamin D), by ultraviolet rays from the sun. The skin is increasingly being understood as a complex and dynamic system involving neuroendocrine, immunologic, and cutaneous interactions.
in all five layers of the epidermis. The keratinocytes, which are the major cells of the epidermis, are transformed from viable keratinocytes to dead keratin as they move from the innermost layer of the epidermis (i.e., stratum germinativum) to the outermost layer (i.e., stratum corneum). The melanocytes are pigment-synthesizing cells that give skin its color. The dermis provides the epidermis with support and nutrition and is the source of blood vessels, nerves, and skin appendages (i.e., hair follicles, sebaceous glands, nails, and sweat glands). Sensory receptors for touch, pressure, heat, cold, and pain are widely distributed in the dermis. The skin serves as a first line of defense against microorganisms and other harmful agents. The epidermis contains Langerhans cells, which process foreign antigens for presentation to T cells, and the dermis contains macrophages, T cells, mast cells, and fibroblasts, all contributing to the body’s immune defenses.

**MANIFESTATIONS OF SKIN DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the following skin rashes and lesions—macule, patch, papule, plaque, nodule, tumor, wheal, vesicle, bulla, and pustule.
- Cite two physiologic explanations for pruritus.
- Describe the causes and treatment of dry skin.

No two skin disorders look exactly alike, nor do the same agents necessarily cause them. Excessive itching, infection, or the effects of self-treatment may further influence the appearance of many skin disorders. Skin color also may influence the appearance. Nevertheless, most skin disorders have some common characteristics that can be used to describe them. This section of the chapter covers lesions and rashes, dry skin, pruritus, skin disorders due to mechanical forces, and variations in dark skin.

**Lesions and Rashes**

Rashes are temporary eruptions of the skin, such as those associated with childhood diseases, heat, diaper irritation, or drug-induced reactions. The term lesion refers to a traumatic or pathologic loss of normal tissue continuity, structure, or function. The components of a rash often are referred to as lesions. Rashes and lesions may range in size from a fraction of a millimeter (e.g., the pinpoint spots of petechiae) to many centimeters (e.g., pressure ulcer). They may be blanched (white), erythematous (reddened), hemorrhagic or purpuric (containing blood), or pigmented (colored). Repeated rubbing and scratching can lead to lichenification (thickened, leathery, and roughened skin characterized by prominent markings) or excoriation (a raw, denuded area caused by breakage of the epidermis). Skin lesions may occur as primary lesions arising in previously normal skin, or they may develop as secondary lesions resulting from other disease conditions. Table 60.1 illustrates various types of skin lesions.

A **blister** is a vesicle or fluid-filled papule. Blisters of mechanical origin are caused by friction from repeated rubbing on a single area of the skin. Friction blisters most commonly occur on the palmar and plantar surfaces of the hands and feet where the skin is constantly exposed to mechanical trauma, such as from shoes and household tools and appliances. Blisters also develop in bullous skin disorders and from burns. Histologically, there is degeneration of the epidermal cells and a disruption of the intercellular junctions, causing the layers of the skin to separate. As a result, fluid accumulates and a noticeable bleb forms on the skin surface. Adhesive bandages and gauze can be used to protect friction blisters and prevent further irritation and rubbing. Breaking the skin of a blister to remove the fluid is inadvisable because of the risk of secondary infection.

A **callus** is a hyperkeratotic plaque of skin due to chronic pressure or friction. It represents hyperplasia of the dead, keratinized cells that make up the cornified or horny layer of the skin. Increased cohesion between cells results in hyperkeratosis and decreased skin shedding. A callus may be filed down but is likely to recur if pressure continues in the localized area.

**Corns** (helomas) are small, well-circumscribed, conical, keratinous thickenings of the skin. They usually appear on the toes from rubbing or ill-fitting shoes. The corn may be either hard (heloma durum) with a central hard, horny core or soft (heloma molle), as commonly seen between the toes. They may appear on the hands as an occupational hazard. The hard tissue at the center of the corn looks like a funnel with a broad top and a pointed bottom, hence the name “corn.” Corns on the feet often are painful, whereas corns on the hands may be asymptomatic. Corns may be abraded or surgically removed, but they recur if the causative agent is not removed.

**Pruritus**

Pruritus, or the sensation of itch, is a common symptom of skin disorders. Symptoms of pruritus range from mild to severe. In some people, the condition may be so severe that it interrupts sleep and the general quality of life. Although itching commonly occurs with skin disorders, it can also provide a valuable clue to internal disorders, such as chronic renal disease, diabetes, or biliary disease.

Despite the fact almost all skin diseases manifest in pruritus, very little is known about it. It is generally agreed that itch is a sensation that originates in free nerve endings in the skin, is carried by small myelinated type C nerve fibers to the dorsal horn of the spinal cord, and is then transmitted to the somatosensory cortex through the spinothalamic tract. Until recently, it was believed that pain and itch traveled along the same nerve pathways and that itch was a low-level pain response. It has now been demonstrated through micrographic recordings that there are itch-specific neuronal pathways in the

Plaque may be coalesced papules with that top  
• **Papules**: <0.5 cm  
• **Plaque**: >0.5 cm                                                                                   | Papules: Elevated nevi, warts, lichen planus  
Plaques: Psoriasis, actinic keratosis                                                                    |
| NODULE, TUMOR  | Elevated, palpable, solid mass that extends deeper into the dermis than a papule  
• **Nodule**: 0.5–2 cm; circumscribed  
• **Tumor**: >1–2 cm; tumors do not always have sharp borders                                                  | Nodules: Lipoma, squamous cell carcinoma, poorly absorbed injection, dermatofibroma  
Tumors: Larger lipoma, carcinoma                                                                        |
| VESICLE, BULLA | Circumscribed, elevated, palpable mass containing serous fluid  
• **Vesicle**: <0.5 cm  
• **Bulla**: >0.5 cm                                                                                   | Vesicles: Herpes simplex/zoster, chickenpox, poison ivy, second-degree bum (blister)  
Bulla: Pemphigus, contact dermatitis, large burn blisters, poison ivy, bullous impetigo          |
| WHEAL          | Elevated mass with transient borders; often irregular; size and color vary  
Caused by movement of serous fluid into the dermis; does not contain free fluid in a cavity (as, for example, a vesicle does) | Urticaria (hives), insect bites                                                                  |
| PUSTULE        | Pus-filled vesicle or bulla                                                                                                                      | Acne, impetigo, furuncles, carbuncles                                                             |

TABLE 60.1 PRIMARY AND SECONDARY SKIN LESIONS (Continued)

<table>
<thead>
<tr>
<th>LESION</th>
<th>DESCRIPTION</th>
<th>EXAMPLES</th>
</tr>
</thead>
</table>
| SCAR (CICATRIX)     | Skin mark left after healing of a wound or lesion; represents replacement by connective tissue of the injured tissue.  
* Young scars: red or purple  
* Mature scars: white or glistening | Healed wound or surgical incision                         |
| KEOlid             | Hypertrophied scar tissue secondary to excessive collagen formation during healing; elevated, irregular, red. Greater incidence among African Americans | Keloid of ear piercing or surgical incision             |
| ATROPHY            | Thin, dry, transparent appearance of epidermis; loss of surface markings; secondary to loss of collagen and elastin; underlying vessels may be visible | Aged skin, arterial insufficiency                        |
| LICHENIFICATION    | Thickening and roughening of the skin or accentuated skin markings that may be secondary to repeated rubbing, irritation, scratching | Contact dermatitis                                       |

spinothalamic tract and central nervous system that process peripheral itch stimuli. Evidence over the years has supported this finding. For example, it has been shown that itch and pain are antagonistic—pain and peripheral inflammation suppress itch, whereas opioids often provoke itch. Further, itch induces scratching, whereas pain induces withdrawal, and itch and pain can be simultaneously perceived. Finally, the belief in polymodal pain–itch receptors may be discounted by the knowledge that massaging or rubbing the skin, which are sensations conducted by nonitch fibers, often results in the sensation of itch. In other words, although rubbing a painful area tends to decrease pain sensations, it increases itch sensations.

Given these new findings, it has been postulated that itch exists both locally and centrally. That is, that in addition to localized itch, an “itch center” exists in the somatosensory cortex. For example, a mosquito bite on most people itches momentarily then subsides. However, a central itch may be similar to central pain in that it is perceived by the brain but does not exist locally.

Advances have also been made in understanding peripheral mediators (i.e., substances that cause itch) other than histamine. Mast cell tryptase may be an important itch mediator because it activates a specific receptor in the sensory nerves. Opioids operate centrally and peripherally in producing itch, whereas neuropeptides, such as substance P, induce itch by their effect on mast cells. Substances such as bradykinin and bile salts act locally to stimulate the itch sensation. Prostaglandins are modulators of the itch response, lowering the threshold for other mediators.

Scratching, the well-known response to itch, is a spinal reflex response that to varying degrees can be controlled by the person. Many types of itch are not easily localized or relieved by scratching. Excoriations and thickened papular areas develop at the site of repeated scratching or rubbing, and in some skin conditions, such as dry skin, scratching further activates itch sensations. Chronic forms of pruritus can severely affect the quality of a person’s life.

Most treatment measures for pruritus are nonspecific. Measures such as using the entire hand to rub over large areas
and keeping the fingernails trimmed often can relieve itch and prevent skin damage. Self-limited or seasonal cases of pruritus may respond to treatment measures such as moisturizing lotions, bath oils, and the use of humidifiers. Because vasodilation tends to increase itching, cold applications may provide relief. Cool showers before bed, light sleepwear, and cool home temperatures also may be helpful. Topical corticosteroids may be helpful in some cases, such as itch related to allergy-mediated urticaria. However, unlike for some other skin problems, there is no armamentarium of effective antipruritic drugs available. Another alternative method that has been effective in the treatment of eczema pruritus is the use of Herbavite, which is a combination of oil extracts from plants.6

Remember Ms. Ronde from the unit opener case study? She complained of her fingers being “very itchy” (pruritus) where the rash is. It seems she has a contact dermatitis secondary to the chemicals she has recently been working with in the chemistry laboratory. She readily offered, “I hardly ever wear gloves in the lab.” After using the steroid hydrocortisone 1% (which has anti-inflammatory properties) on her fingers for 24 hours, her pruritus was relieved.

Mild cutaneous disorders, such as bug bites, are mediated by histamine. Therefore, nondoning antihistamines tend to be the treatment of choice. However, because most cases of pruritus are not histamine related, their management should be directed at the underlying cause. For example, systemic antihistamines and corticosteroids may be indicated for people with severe pruritus or atopic dermatitis. Naltrexone has been shown to be an effective antipruritic medication for people with burns who have been refractory to all types of medications typically helpful for itching.7

Additionally, 80% to 100% of people experience severe pruritus postburn and generally use an antihistamine and emollient for pruritus management. However, one pilot study demonstrates effective pruritus management can be obtained just by using gabapentin without an antihistamine.8 Therefore, more studies need to be conducted to determine the best practices for managing pruritus. Topical capsaicin cream and topical aspirin have been used for localized chronic pruritic disorders. Opioid antagonists may be used for pruritus caused by opioid medications such as morphine. Other modalities that have been used for all cases of pruritus with varying degrees of success are phototherapy, acupuncture, antidepressant medications, behavior modification, and alternative therapies (herbal, nutritional, and reflex therapies). In people with pruritus due to a systemic cause, itching gradually recedes as the primary condition improves.

Given the recent advances in the science of pruritus, it is anticipated that health care professionals will have new, effective, and disease-specific antipruritic drugs available in the near future. Classification schemes for pruritus may also be forthcoming. Similar to pain scales, visual analog scales may be developed and used in the diagnosis and treatment of pruritus.

Dry Skin

Dry skin, also called xerosis, may be a natural occurrence, as in the drying of skin associated with aging, or it may be symptomatic of an underlying systemic disease or skin disorder such as contact dermatitis or diabetes mellitus. People with diabetes mellitus often experience xerosis especially on the extremities. It is often due to extreme winter weather when there is little humidity in the air.8 Most cases of dry skin are caused by dehydration of the stratum corneum. The effects of aging on skin dryness include a change in the composition of sebaceous gland secretions and a decrease in the secretion of moisture from the sweat glands. Aging is also accompanied by a decrease in skin capillaries as well as a flattening of the dermal rete ridges, resulting in less surface area for exchange of fluids between the dermis, epidermis, and skin surface.9

People with dry skin often experience severe pruritus and discomfort, most commonly of the extremities. Other commonly involved areas include the back, abdomen, and waist. Dry skin appears rough and scaly and there may be increased wrinkles or lines. Skin drying also predisposes the skin to scratching, resulting in cracking, fissuring, and a number of other skin maladies.

Some drugs used for other comorbidities can cause dry skin. For example, it has recently been found that epidermal growth factor receptor inhibitors (EGFRIs) frequently cause dermatologic adverse events such as xerotitis more so than systemic effects.10

Moisturizing agents are the cornerstone of treatment for dry skin. These agents exert their effects by repairing the skin barrier, increasing the water content of the skin, reducing transepidermal water loss, and restoring the lipid barrier’s ability to attract, hold, and redistribute water. Emollients are fatty acid–containing lotions that replenish the oils on the skin surface, but usually do not leave a residue on the skin. They have a short duration of action and need to be applied frequently. Humectants are the additives in lotions, such as alpha-hydroxy acids and urea, that draw out water from the deeper skin layers and hold it on the skin surface. However, the water that is drawn to the skin is transepidermal water, not atmospheric water. Thus, continued evaporation from the skin can actually exacerbate dryness. Alpha-hydroxy acids are derived from fruits, hence the abundance of fruit additives in shampoos and lotions in over-the-counter preparations. Urea is a nitrogenous substance that has been quite effective in reducing xerosis when combined with lotions. It is a humectant at lower concentrations (10%), but in higher concentrations (20% to 30%) it is mildly keratolytic. Occlusives are thick creams that contain petroleum or some other moisture-proof material that can form a barrier. They prevent water loss from the skin. They are the most effective agents for relieving skin dryness, but because of their greasiness and lack of cosmetic appeal, some people do not wish to use them.

Lotion or cream additives include corticosteroids or mild anesthetics, such as camphor, menthol, lidocaine, or
Skin Variations in Dark-Skinned People

Skin color is determined by the melanin produced by the melanocytes. Although the number of melanosomes in dark and white skin is the same, black skin produces more melanin more quickly than white skin. Because of their skin color, dark-skinned people are better protected against skin cancer, premature wrinkling, and aging of the skin that occurs with sun exposure.

Some skin disorders common to people of African, Hispanic, or East Indian descent are not commonly found in people of European descent. Similarly, some skin disorders, such as skin cancers, affect light-skinned people more commonly than dark-skinned people. Because of these differences, serious skin disorders may be overlooked, and normal variations in darker skin may be mistaken for anomalies.

A condition common in people with dark skin is too much or too little color. Areas of the skin may darken after injury, such as a cut or scrape, or after disease conditions such as acne. These darkened areas may take many months or years to fade. Dry or “ashy” skin also can be a problem for people with dark skin. It is very noticeable because it gives the skin an ashen or grayish appearance. It is also very uncomfortable. Although using a moisturizer may help relieve the discomfort, it may cause a worsening of acne in predisposed people.

Normal variations in skin structure and skin tones often make evaluation of dark skin difficult. The darker pigmentation can make skin pallor, cyanosis, and erythema more difficult to observe. Therefore, verbal histories must be relied on to assess skin changes. The verbal history should include the person’s description of her or his normal skin tones. Changes in skin color, in particular hypopigmentation and hyperpigmentation, often accompany the skin disorders of dark-skinned people.

In Summary

Skin lesions and rashes are the most common manifestations of skin disorders. Rashes are temporary skin eruptions. Lesions result from traumatic or pathologic loss of the normal continuity, structure, or function of the skin. Lesions may be vascular in origin. They may occur as primary lesions in previously normal skin or they may develop as secondary lesions resulting from primary lesions. Blisters, calluses, and corns result from rubbing, pressure, and frictional forces applied to the skin. Pruritus and dry skin are symptoms common to many skin disorders. Scratching because of pruritus can lead to excoriation, infection, and other complications. Normal variations in dark skin often make evaluation difficult and result in some disorders being overlooked. Changes in color, especially hypopigmentation or hyperpigmentation, often accompany the skin disorders of dark-skinned people.

The skin is a unique organ in that numerous signs of disease or injury are immediately observable on the skin. The skin serves as the interface between the body’s internal organs and the external environment. Therefore, skin disorders represent the culmination of environmental forces and the internal functioning of the body. Sunlight, insects, other arthropods, infectious organisms, chemicals, and physical agents all play a role in the pathogenesis of skin diseases. Although most disorders are intrinsic to skin, many are external manifestations of systemic disease. Thus, skin provides a valuable window for the recognition of many systemic disorders.

It is through the skin that warmth and other responses are given and received. The skin conveys a sense of health, beauty, integrity, and emotion. Human beings emphasize the body and, in particular, the skin to the degree that even slight imperfections may evoke a wide variety of responses.

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the pathogenesis of acne vulgaris and relate it to measures used in treating the disorder.
- Differentiate allergic and contact dermatitis and atopic and nummular eczema.
- Define the term papulosquamous and use the term to describe the lesions associated with psoriasis, pityriasis rosea, and lichen planus.
Primary skin disorders are those originating in the skin. They include pigmented skin disorders, infectious processes, acne, rosacea, papulosquamous dermatoses, allergic disorders and drug reactions, and arthropod infestations. Although most of these disorders are not life-threatening, they can affect the quality of life.

**KEY POINTS**

**PRIMARY SKIN DISORDERS**

- Infectious skin disorders are caused by viruses, bacteria, and fungi that invade the skin, incite inflammatory responses, and otherwise cause rashes and lesions that disrupt the skin surface.
- Allergic and hypersensitivity responses are caused by antigen–antibody responses resulting from sensitization to topical or systemic antigens.

**Pigmentary Skin Disorders**

Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase in melanin or some other pigment, as in mongolian spots or melasma. In either case, the emotional impact can cause much worry and anxiety.

**Vitiligo**

Vitiligo is a pigmented problem of concern to darkly pigmented people of all races. It also affects white-skinned people, but not as often, and the effects usually are not as socially debilitating as in people of all races. It also affects white-skinned people of all races. Worldwide, it affects people of all races regardless of gender.

**Etiology.** The cause of vitiligo is not known. However, there are many possible rationales for its etiology including genetics and autoimmunity. In some cases, vitiligo has been reportedly precipitated by emotional stress or physical trauma, such as sunburn. Evidence also suggests that high serum homocysteine (Hcy) levels may cause destruction of melanocytes and development of vitiligo. Additionally, vitiligo is associated with concurrent disease such as hypothyroidism, Graves' disease, Addison disease, pernicious anemia, type 2 diabetes mellitus, and melanoma.

**Clinical Manifestations.** The classic manifestation of vitiligo is the sudden appearance of white patches on the skin. The lesion is a depigmented macule with definite smooth borders on the face, axillae, neck, or extremities. The patches vary in size from small macules to ones involving large skin surfaces. The large macular type is more common. Depigmented areas appear white, pale colored, or sometimes grayish-blue. The depigmented sites may have melanocytes that no longer produce melanin or may not have any functioning melanocytes or very few. These areas sunburn easily and they enlarge over time. Vitiligo often is asymptomatic, although pruritus may occur.

There are two types of vitiligo: Vitiligo A and Vitiligo B. Vitiligo A is seen more frequently, and the white patches are symmetrical with discrete borders. Vitiligo A progresses slowly over years to cover first the backs of the hands, the face, and body folds. Vitiligo B is the segmental type, which means that the white patches are not symmetrical but rather randomly disseminated anywhere on the body. The onset of Vitiligo B occurs earlier in life than Vitiligo A.

**Treatment.** Although there are many treatment regimens for vitiligo, none is curative. Self-tanning lotions, skin stains, and cosmetics are used for camouflage. Corticosteroids administered topically, intralesionally, and orally have been used successfully. Broad-band (large area) and narrow-band (focused) ultraviolet B (UVB) irradiation has also been used successfully in the treatment of vitiligo.

A variety of skin grafting techniques have been used in people unresponsive to other therapies. Successful skin grafting techniques vary from minigrafting (2-mm full-thickness punch grafts transplanted to involved areas) to grafting melanocytes into involved areas. Micropigmentation (tattooing) has been done on smaller, recalcitrant areas, but it is often difficult to attain a correct color match.

If extensive skin surfaces are involved, the treatment may be reversed and the pigmented areas bleached to match the remainder of the skin color. A melanocytotoxic agent is used to remove remaining melanocytes from skin areas. This process, which is called depigmentation, is permanent and irreversible. People need to be apprised of this and their need to avoid the sun and use sunscreens for the remainder of their lives.

**Albinism**

Albinism, a genetic disorder in which there is complete or partial congenital absence of pigment in the skin, hair, and eyes, is found in all races. Although there are over 10 different types of albinism, the most common type is recessively inherited oculocutaneous albinism, in which there is a normal number of melanocytes, but they have little to no tyrosinase, the enzyme needed for synthesis of melanin. It affects the skin, hair, and eyes. People have pale or pink skin, white or yellow hair, and light-colored or sometimes pink eyes. People with albinism have ocular problems, such as extreme sensitivity to light, refractive errors, foveal hypoplasia, and nystagmus. The most severe form is OCA1A, which is tyrosinase negative since these people have a complete lack of tyrosinase. There is no cure for albinism. Treatment efforts for people with albinism are aimed at reducing their risk for skin cancer through protection from solar radiation and screening for malignant skin changes.

**Melasma**

Melasma is characterized by darkened facial macules. It is common in all skin types, but most prominent in brown-skinned people from Asia, India, and South America. It occurs in men but is more common in women, particularly during pregnancy.
or while using oral contraceptives.\textsuperscript{6,7} It may or may not resolve after giving birth or discontinuing hormonal birth control. Melasma is exacerbated by sun exposure.\textsuperscript{6–8} Treatment measures are palliative, mostly consisting of limiting exposure to the sun and using sunscreens. Bleaching agents, containing 2\% to 4\% hydroquinone, are standard treatments. Tretinoin cream and azelaic acid have been useful in treating severe cases.

**Infectious Processes**

The skin is subject to invasion by a number of microorganisms, including fungi, bacteria, and viruses. Normally, the skin flora, sebum, immune responses, and other protective mechanisms guard the skin against infection. Depending on the virulence of the infecting agent and the competence of the host’s resistance, infections may result.

**Superficial Fungal Infections**

Fungi are free-living, saprophytic plantlike organisms, certain strains of which are considered part of the normal skin flora. Some fungi cause deep infections and others are superficial. There are two types of fungi, yeasts, and molds. Yeasts, such as *Candida albicans*, grow as single cells and reproduce asexually.\textsuperscript{9} (See Fig. 61.1). Molds grow in long filaments, called hyphae.\textsuperscript{9} There are thousands of known species of yeasts and molds, but only about 100 of them cause disease in humans and animals.\textsuperscript{9} Fungal or mycotic infections of the skin are traditionally classified as superficial or deep. The superficial mycoses, more commonly known as *tinea* or ringworm, invade only the superficial keratinized tissue (skin, hair, and nails). Deep fungal infections involve the epidermis, dermis, and subcutis. Infections that typically are superficial may exhibit deep involvement in people who are immunosuppressed.\textsuperscript{4}

Most of the superficial mycoses, also called dermatophytes, are caused by the dermatophytes, a group of closely related fungi. These fungi are classified into three genera:

- Microsporum (*M. audouini*, *M. canis*, *M. gypseum*)
- Epidermophyton (*E. floccosum*)
- Trichophyton (*T. schoenleinii*, *T. violaceum*, *T. tonsurans*)\textsuperscript{4}

Two of these, *Microsporum* and *Trichophyton*, affect the hair.\textsuperscript{4}

Another way of classifying the dermatophytes is according to their ecologic origin—human, animal, or soil. Anthropophilic species (*M. audouini*, *M. tonsurans*, *T. violaceum*) are parasitic on humans and are spread by other infected humans. Zoophilic species (*M. canis* and *T. mentagrophytes*) cause parasitic infections in animals, some of which can be spread to humans. Geophilic species originate in the soil, but may infect animals, which in turn serve to infect humans.

**Pathogenesis and Clinical Manifestations.** The fungi that cause superficial mycoses live on the dead keratinized cells of the epidermis. They emit an enzyme that enables them to digest keratin, which results in superficial skin scaling, nail disintegration, or hair breakage, depending on the location of the infection.\textsuperscript{4} An exception to this is the invading fungus of *tinea versicolor*, which does not produce a keratolytic enzyme. Deeper reactions involving vesicles, erythema, and infiltration are caused by the inflammation that results from exotoxins liberated by the fungus. Fungi also are capable of producing an allergic or immune response.\textsuperscript{4} Superficial fungal infections affect various parts of the body, with the lesions varying according to site and fungal species. Tinea can affect the body (tinea corporis), face and neck (tinea faciale), scalp (tinea capitis), hands (tinea manus), feet (tinea pedis), nails (tinea unguium), or genitalia (tinea cruris).\textsuperscript{4}

**Diagnosis and Treatment.** Diagnosis of superficial fungal infections is primarily done by microscopic examination of skin scrapings for fungal spores, the reproducing bodies of fungi. Potassium hydroxide (KOH) preparations are used to prepare slides of skin scrapings. KOH disintegrates human tissue and leaves behind the threadlike filaments, or hyphae that grow from the fungal spores. Cultures also may be done using a dermatophyte test medium or a microculture slide that produces color changes and allows for direct microscopic identification. The Wood light (UV light) is another method that can assist with the diagnosis of tinea. Some types of fungi (e.g., *M. canis* and *M. audouini*) fluorescence yellow-green when the light is directed onto the affected area.\textsuperscript{3}

Superficial fungal infections may be treated with topical or systemic antifungal agents. Treatment usually follows diagnosis confirmed by KOH preparation or culture, particularly if a systemic agent is to be used. Topical agents, both prescription and over-the-counter preparations, are commonly used in the treatment of tinea infections. However, success often is limited because of the lengthy duration of treatment, poor compliance, and high rates of relapse at specific body sites.

The oral systemic antifungal agents include griseofulvin, the azoles, and the allylamines. Griseofulvin is a fungicidal agent derived from a species of *Penicillium* that is used only in the treatment of dermatophytoses. It acts by binding to the keratin of newly forming skin, protecting the skin from new infection. Because its action is to prevent new infection, it must be administered for 2 to 6 weeks to allow for skin replacement. The azoles are a group of synthetic antifungal...
Tinea corporis (ringworm) is a dermatophyte skin infection that is depicted as an annular lesion with a raised border and a central clearing. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 306). Philadelphia, PA: Lippincott Williams & Wilkins.)

**FIGURE 61.2** • Dermatophytosis—this fungal infection is superficial. Tinea corporis. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 864). Philadelphia, PA: Lippincott Williams & Wilkins.)

Drugs that act by inhibiting the fungal enzymes needed for the synthesis of ergosterol, which is an essential part of fungal cell membranes. The azoles are classified as either imidazoles or triazoles. The imidazoles consist of ketoconazole, miconazole, and clotrimazole. The latter two drugs are used only in topical therapy. The triazoles include itraconazole and fluconazole, both of which are used for the systemic treatment of fungal infections. Terbinafine, a synthetic allylamine, acts by interrupting ergosterol synthesis, causing the accumulation of a metabolite that is toxic to the fungus. In contrast to griseofulvin, the synthetic agents are fungicidal (i.e., kill the fungus) and therefore are more effective over shorter treatment periods. Some of the oral agents can produce serious side effects, such as hepatic toxicity, or interact adversely with other medications. A number of the synthetic fungicides (e.g., ketoconazole, miconazole, clotrimazole, and terbinafine) are available as topical preparations that produce less severe side effects. Topical corticosteroids may be used in conjunction with antifungal agents to relieve itching and erythema secondary to inflammation.

**Tinea of the Body or Face.** *Tinea corporis* (ringworm of the body) can be caused by any of the fungi but is most frequently caused by *M. canis* in the United States and by *T. rubrum* worldwide (Fig. 61.2). There has been an increase in *T. tonsurans* as the causative agent of tinea corporis as well. Although tinea corporis affects all ages, children seem most prone to infection. Transmission is most commonly from kittens, puppies, and other children who have infections.

The lesions vary, depending on the fungal agent. The most common types of lesions are oval or circular patches on exposed skin surfaces and the trunk, back, or buttocks. Less common are foot and groin infections. The lesion begins as a red papule and enlarges, often with a central clearing. Patches have raised red borders consisting of vesicles, papules, or pustules. The borders are sharply defined, but lesions may coalesce (see Fig. 61.3). Pruritus, a mild burning sensation, and erythema frequently accompany the skin lesion.

**Tinea faciale,** or ringworm of the face, is an infection caused by *T. mentagrophytes* or *T. rubrum.* Tinea faciale may mimic the annular, erythematous, scaling, pruritic lesions characteristic of tinea corporis. It also may appear as flat erythematous patches. Topical antifungal agents usually are effective in treating tinea corporis and tinea faciale. Oral antifungal agents may be used in resistant cases.

**Tinea of the Scalp.** There are two common types of *tinea capitis* (ringworm of the scalp): primary (noninflammatory) and secondary (inflammatory). In the United States, most of the cases of noninflammatory tinea capitis are caused by *T. tonsurans,* which does not fluoresce green with a Wood lamp. The infection is spread most often among household members who share combs and brushes on which the spores are shed and remain viable for long periods. Depending on the invading fungus, the lesions of the noninflammatory type can vary from grayish, round, hairless patches to balding spots, with or without black dots on the head. The lesions vary in size and are most commonly seen on the back of the head. Mild erythema, crust, or scale may be present. The individual usually is asymptomatic, although pruritus may exist.

The inflammatory type of tinea capitis is caused by virulent strains of *T. mentagrophytes,* *T. verrucosum,* and *M. gypseum.* The onset is rapid, and inflamed lesions usually are localized to one area of the head. The inflammation is believed to be a delayed hypersensitivity reaction to the invading fungus. The initial lesion consists of a pustular, scaly, round patch with broken hairs. A secondary bacterial infection is common and may lead to a painful, circumscribed, boggy, and indurated lesion called a *kerion.*

The treatment for both noninflammatory and inflammatory forms of tinea capitis is oral griseofulvin or synthetic antifungals. Griseofulvin has been the primary treatment for children because it was believed to have fewer side effects than the synthetic antifungals.
Tinea of the Foot and Hand. Tinea pedis (athlete’s foot) is the most common fungal dermatosis, primarily affecting the spaces between the toes, the soles, or sides of the feet. It is caused by T. mentagrophytes and T. rubrum. The lesions vary from a mildly scaling lesion to a painful, exudative, erosive, inflamed lesion with fissuring. Lesions often are accompanied by pruritus, pain, and foul odor. Some people are prone to chronic tinea pedis. Mild forms are more common during dry environmental conditions.

Tinea manu usually is a secondary infection with tinea pedis as the primary infection. In contrast to other skin disorders, such as contact dermatitis and psoriasis, which affect both hands, tinea manus usually occurs only on one hand. The characteristic lesion is a blister on the palm or finger surrounded by erythema. Chronic lesions are scaly and dry. Cracking and fissuring may occur. The lesions may spread to the plantar surfaces of the hand. If chronic, tinea manus may lead to tinea of the fingernails. Simple forms of tinea pedis and tinea manus are treated with topical applications of antifungals.

Tinea of the Nail. Tinea unguium is a dermatophyte infection of the nails. It is a subset of onychomycosis, which includes dermatophyte, nondermatophyte, and candidal infections of the nails. There is an increased incidence of fungal nail infections in recent years, probably reflecting better diagnostics, increased numbers of immunocompromised people who have greater susceptibility, increased use of immunosuppressive drugs, increasing numbers of older adults, worldwide travel, and increased use of communal bathing facilities.

Distal and lateral subungual onychomycosis, the most common form of tinea unguium, usually is caused by T. rubrum or T. mentagrophytes. Toenails are involved more commonly than fingernails because fingernails are more exposed to air. The infection often begins at the tip of the nail, where the fungus digests the nail keratin. In some cases, the infection may begin from a crushing injury to a toenail or from the spread of tinea pedis. Initially, the nail appears opaque, white, or silver. The nail then turns yellow or brown. The condition often remains unchanged for years. During this time, it may involve only one or two nails and may produce little or no discomfort. Gradually, the nail thickens and cracks as the infection spreads and includes the nail plate. Permanent discoloration and distortion result as the nail plate separates from the nail bed. Less common forms of tinea unguium are superficial white onychomycosis, in which areas of the nails become powdery white and erode, and proximal subungual onychomycosis, in which there is rapid invasion of the nail, leaving it white with no additional thickening of the nail. Although it is one of the less common forms of tinea unguium, proximal subungual onychomycosis has increased among people with human immunodeficiency virus (HIV) infection.

Treatment of tinea unguium usually requires oral antifungal therapy. Toenail infections are usually treated with itraconazole and terbinafine. Fluconazole has been effective, particularly if Candida is involved. Itraconazole is administered in pulses (intermittent weeks of therapy), whereas terbinafine or fluconazole is administered without interruption for 12 to 15 weeks. Fingernail infections are more easily treated, in part because the fingernails are more exposed to air. Itraconazole, terbinafine, and, to a lesser extent, griseofulvin have been effective in treating fingernail infections. All of the oral agents require careful monitoring for side effects. A new nail may require 3 to 12 months to grow. Thus, people being treated with antifungal agents need to be reminded that the resolution of the infection requires 4 to 6 months for fingernails and longer for toenails.

Although there has been an increase in the cure rate of toenail fungal infections, primarily because of the synthetic antifungals, recalcitrant cases remain. Some authorities recommend removal of the infected toenails. Many cases of tinea unguium would be prevented if primary infections of tinea pedis were diagnosed and treated promptly.

Tinea Versicolor. Tinea versicolor is a fungal infection involving the upper chest, the back, and sometimes the arms. It is caused by the dimorphic-lipophilic yeasts Pityrosporum orbiculare (round form) and P. ovale (oval form). The yeast lives within the stratum corneum and hair follicles in areas with sebaceous glands where it is easy to obtain triglycerides and free fatty acids. The characteristic lesion is a yellow, pink, or brown sheet of scaling skin (see Fig. 61.4). The name versicolor is derived from the multicolored variations of the lesion. The patches are depigmented and do not tan when exposed to UV light.

Selenium sulfide, found in several shampoo preparations, has been an effective fungistic treatment measure. Miconazole or ketoconazole creams or shampoos, because of their fungicidal properties, have become the drugs of choice. Oral antifungals are used for extensive cases. The infection may recur after drug therapy.

Tinea Incognito. Tinea incognito is a form of dermatophyte infection that developed with the widespread use of topical corticosteroids. It often is seen in cases where tinea infections are misdiagnosed as eczema and treated with corticosteroids. Because corticosteroids suppress inflammation, scaling and erythema may not be present or it may not resemble a fungal infection at all after several rounds of cortisone therapy. There
has been an increased incidence of tinea incognito in people with HIV infection. People with the disorder often present with thickened plaques with lichenification, papules, pustules, and nodules. Telangiectases, atrophy, and striae may be present. Tinea incognito is seen most often on the groin, the palms, or the dorsal aspect of the hand.

Treatment measures include discontinuing topical corticosteroids while using low-dose oral corticosteroids to prevent the flare-up associated with discontinuing potent topical steroids. Topical or oral antifungal agents are used, depending on the severity of the infection.

**Dermatophytid Reaction.** A secondary skin eruption may occur in people allergic to the fungus responsible for the dermatophytosis. This dermatophytid or allergic reaction may occur during an acute episode of a fungal infection. The most common reaction occurs on the hands in response to tinea pedis. The lesions are vesicles with erythema extending over the palms and fingers, sometimes extending to other areas. Less commonly, a more generalized reaction occurs, in which papules or vesicles erupt on the trunk or extremities. These eruptions may resemble tinea corporis. Lesions may become excoriated and infected with bacteria. Treatment is directed at the primary site of infection. The intradermal reaction resolves in most cases without intervention if the primary site is cleared.

**Candidal Infections.** Candidiasis (moniliasis) is a fungal infection caused by *C. albicans* and occasionally by a few other *Candida* species. This yeastlike fungus is a normal inhabitant of the gastrointestinal, tract, mouth, and vagina. The skin problems result from the release of irritating toxins on the skin surface. *C. albicans* is found almost always on the surface of the skin. It rarely penetrates to the deeper layers of the skin. Some people are predisposed to candidal infections by conditions such as diabetes mellitus, antibiotic therapy, pregnancy, oral contraceptive use, poor nutrition, and immunosuppressive diseases. Oral candidiasis may be the first sign of infection with HIV.

*C. albicans* thrives on warm, moist, intertriginous areas of the body. The rash is red with well-defined borders. Patches erode the epidermis, and there is scaling. Mild to severe itching and burning often accompany the infection. Severe forms of infection may involve pustules or vesiculopustules. In addition to microscopy, a candidal infection often can be differentiated from a tinea infection by the presence of satellite lesions. These satellite lesions are maculopapular and are found outside the clearly demarcated borders of the candidal infection. Satellite lesions often are diagnostic of diaper rash complicated by *Candida*. The appearance of candidal infections varies according to the site.

Diagnosis usually is based on microscopic examination of skin or mucous membrane scrapings placed in a KOH solution. Treatment measures vary according to the location. Preventive measures such as wearing rubber gloves are encouraged for people with infections of the hands. Intertriginous areas often are separated with clean cotton cloth and allowed to air dry as a means of decreasing the macerating effects of heat and moisture. Topical and oral antifungal agents, such as clotrimazole, econazole, and miconazole, are used in treatment depending on the site and extent of involvement.

**Bacterial Infections**

Bacteria are considered normal flora of the skin. Most bacteria are not pathogenic, but when pathogenic bacteria invade the skin, superficial or systemic infections may develop. Bacterial skin infections are commonly classified as primary or secondary infections. Primary infections are superficial skin infections such as impetigo or ecthyma. Secondary infections consist of deeper cutaneous infections, such as infected ulcers. Diagnosis usually is based on cultures taken from the infected site. Treatment measures include antibiotic therapy and measures to promote comfort and prevent the spread of infection.

**Impetigo.** Impetigo is a common, superficial bacterial infection caused by staphylococci or group A beta-hemolytic streptococci, or both. Impetigo is common among infants and young children, although older children and adults occasionally contract the disease. Its occurrence is highest during warm summer months or in warm, moist climates.

Impetigo initially appears as a small vesicle or pustule or as a large bulla on the face or elsewhere on the body. As the primary lesion ruptures, it leaves a denuded area that discharges a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust (Fig. 61.5). New vesicles erupt within hours. Pruritus often accompanies the lesions, and skin excoriations that result from scratching multiply the infection sites. Although a very low risk, a possible complication of untreated streptococcal impetigo is poststreptococcal glomerulonephritis. Topical mupirocin (Bactroban) is effective in treating impetigo and has few side effects. In most instances, it is the first choice but if a larger area is involved then a systemic antibiotic may be necessary.

Another form of impetigo exists, bullous impetigo, which is usually caused by *Staphylococcus aureus*. Bullous impetigo is common among children. It is due to the epidermolytic toxin and is not generally contaminated by streptococci. Thin bullae erupt that appear clear to cloudy and coalesce. The bullae open, leaving the original bullous rim with central thin, flat, honey-colored crusts, or in some cases denuded areas.

**FIGURE 61.5** • Impetigo of the face results from *S. aureus* commonly. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 304). Philadelphia, PA: Lippincott Williams & Wilkins.)
The face is often affected, but bullous impetigo may occur anywhere on the body. The treatment measures are the same as for nonbullous impetigo.

Ecthyma is an ulcerative form of impetigo, usually secondary to minor trauma. It is caused by group A beta-hemolytic streptococci, *S. aureus*, or *Pseudomonas* species. It frequently occurs on the buttocks and thighs of children. The lesions are similar to those of impetigo. A vesicle or pustule ruptures, leaving a skin erosion or ulcer that weeps and dries to a crusted patch, often resulting in scar formation. With extensive ecthyma, there is a low-grade fever and extension of the infection to other organs. Treatment usually involves the use of systemic antibiotics.

A less common form of *S. aureus* infection, called Ritter disease, manifests with a diffuse, scarlet fever–like rash, followed by skin separation and sloughing. It is also called *staphylococcal scalded skin syndrome* because the skin looks scalded (Fig. 61.6). Ritter disease usually affects children younger than 5 years of age. However, immunosuppressed adults also are at risk. The disorder, which is considered a deeper skin infection because the superficial layers of the epidermis are separated and shed in sheets, is caused by the hematologic spread of toxins from a focal infection, such as the nasopharynx or a superficial skin abrasion. The onset of the rash may be preceded by malaise, fever, irritability, and extreme tenderness over the skin. The conjunctiva is often inflamed, with purulent drainage. Although the fluid in the unbroken bullae is sterile, cultures usually are obtained from suspected sites of local infection and from the blood. Systemic antibiotics, either oral or parenteral, are used to treat the disorder. Healing usually occurs in 10 to 14 days without scarring.

**Cellulitis** is a deeper infection affecting the dermis and subcutaneous tissues. It is usually caused by group A beta-hemolytic streptococci or *S. aureus*, but can be caused by bacteria specific to certain activities, such as fish handling, swimming in fresh water, or swimming in salt water, or from animal bites or scratches. Preexisting wounds (e.g., ulcers, erosions) and tinea pedis are often portals of entry. Legs are the most common sites, followed by the hands and pinnae of the ears, but cellulitis may be seen on many body parts. The lesion consists of an expanding red, swollen, tender plaque with an indefinite border, covering a small to wide area (Fig. 61.7). Cellulitis is frequently accompanied by fever, erythema, heat, edema, and pain. Cellulitis often involves the lymph system and, once compromised, repeat infections may impair lymphatic drainage, leading to chronically swollen legs, and eventually dermal fibrosis and lymphedema. Incorrectly treated, it may result in septicemia, nephritis, or death. Treatment measures (oral and intravenous antibiotics) are aimed at the invasive organisms and the extent of the infection.

**Viral Infections**

Viruses are intracellular pathogens that rely on live cells of the host for reproduction. They have no organized cell structure but consist of a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) core surrounded by a protein coat. The viruses seen in skin lesion disorders tend to be DNA-containing viruses. Viruses invade the keratinocyte, begin to reproduce, and cause cellular proliferation or cellular death. The rapid increase in viral skin diseases has been attributed to the use of corticosteroid drugs, which have immunosuppressive qualities, and the use of antibiotics, which alter the bacterial flora of the skin. As the number of bacterial infections has decreased, there has been a proportional rise in viral skin diseases.

**Verrucae.** Verrucae, or warts, are common benign papillomas caused by the DNA-containing human papillomavirus (HPV). Transmission of HPV infection is largely by direct contact between individuals or by autoinoculation. As benign papillomas, warts represent an exaggeration of the normal skin structures. There is an irregular thickening of the stratum spinosum and greatly increased thickening of the stratum corneum. The classification of warts is based largely on morphology and location.

Although warts vary in appearance depending on their location, it is now recognized that the clinically distinct types of warts result not simply because of the anatomic sites in which they arise, but also because of the distinct types of HPV. There are almost 90 types of HPV found on humans that
cause several different kinds of warts, including skin warts and genital warts. Many of the HPV types that cause genital warts are sexually transmitted, some of which (types 6, 11, 16, and 18) may increase the risk of cervical cancer.

Nongenital warts often occur on the hands and feet. They are commonly caused by HPV types 1, 2, 3, 4, 27, and 57 and are not considered precancerous lesions. They are classified as common warts, flat warts, and plantar or palmar warts. Common warts, or verrucae vulgaris, are the most common type. The lesions can occur anywhere, but most frequently occur on dorsal surfaces of hands, especially the periungual area, where they appear as small, grayish-white to tan, flat to convex papules with a rough, pebble-like surface. Verrucae plana, or flat warts, are common on the face or dorsal surfaces of the hands. The warts are slightly elevated, flat, smooth, tan papules that are slightly larger than verrucae vulgaris (Fig. 61.8). Verrucae plantaris and verrucae palmaris (i.e., plantar and palmar warts, respectively) occur on the soles of the feet and palms of the hands, respectively. They appear as rough, scaly lesions that may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses. HPV transmission usually occurs through breaks in skin integrity.

Treatment is usually directed at inducing a "wart-free" period without producing scarring. Warts resolve spontaneously when immunity to the virus develops. The immune response, however, may be delayed for years. Because of their appearance or discomfort, people usually desire their removal, rather than waiting for immunity to develop. Removal is usually done by applying a keratolytic agent, such as salicylic acid gel or plaster that breaks down the wart tissue, or by freezing with liquid nitrogen. Salicylic acid works by dissolving intercellular cement and producing desquamation of the horny layer of skin without affecting normal epidermal cells. Various types of laser surgery, electrosurgery, cryotherapy, immunotherapy (e.g., oral zinc sulfate), and antiviral therapy (e.g., cidofovir) also have been successful in wart eradication.

**Herpes Simplex.** Herpes simplex virus (HSV) infections of the skin and mucous membrane (i.e., cold sore or fever blister) are common. Two types of HSV infect humans: type 1 and type 2. HSV-1 is usually associated with oropharynx infections, and the organism is spread by respiratory droplets or by direct contact with infected saliva. HSV-1 may also be transmitted to other parts of the body through occupational hazards, such as skin contact athletics, dentistry, and medicine. Genital herpes usually is caused by HSV-2. HSV-1 genital infections and HSV-2 oral infections are becoming more common.

Infection with HSV-1 may present as a primary or recurrent infection. Primary HSV-1 symptoms include fever; sore throat; painful vesicles; and ulcers of the tongue, palate, gingiva, buccal mucosa, and lips. The primary infection results in the production of antibodies to the virus so that recurrent infections are more localized and less severe. After an initial infection, the herpesvirus persists in the trigeminal and other dorsal root ganglia in the latent state, periodically reactivating in recurrent infections. It may be that reactivation of a herpes infection occurs both in the dorsal root ganglion and locally, where it has been found to exist in the epidermis and other organs. The symptoms of a primary HSV-1 infection most often occur in young children (1 to 5 years of age). It is likely that many adults were exposed to HSV-1 during childhood and therefore have antibodies to the virus.

Herpes Zoster. Herpes zoster (shingles) is an acute, localized vesicular eruption distributed over a dermatomal segment of the skin. It is caused by the same herpesvirus, varicella-zoster, which causes chickenpox. It is believed to be the result of reactivation of a latent varicella-zoster virus infection that was dormant in the sensory dorsal root ganglia since a primary childhood infection. During an episode of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome. Although herpes zoster is not as contagious as chickenpox, the reactivated virus can be transmitted to nonimmune contacts.

Herpes zoster occurs in 10% to 20% of all people. It can occur at any time during the lifespan, but tends to happen in older adults more frequently. The incidence is much less among African Americans. Other people at risk because of impaired T-cell–mediated immunity are those with conditions such as HIV infection and certain malignancies, chronic corticosteroid users, and those undergoing chemotherapy and radiation therapy.

The lesions of herpes zoster typically are preceded by a prodrome consisting of a burning pain, a tingling sensation, extreme sensitivity of the skin to touch, and pruritus along the affected dermatome. Among the dermatomes, the most frequently involved are the thoracic, the cervical, the trigeminal, and the lumbar. Prodromal symptoms may be present for 1 to 3 days or longer before the appearance of the rash. During this time, the pain may be mistaken for a number of other conditions, such as heart disease, pleurisy, musculoskeletal disorders, or gastrointestinal disorders.

The lesions appear as an eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia. In immunsuppressed people, the lesions may extend beyond the dermatome. Eruptions usually are unilateral in the thoracic region, trunk, or face. New groups of vesicles erupt for 3 to 5 days along the nerve pathway. The vesicles dry, form crusts, and eventually fall off. The lesions usually clear in 2 to 3 weeks, although they can persist up to 6 weeks in some older adults.

Serious complications can accompany eruptions. Eye involvement can result in permanent blindness and occurs in a large percentage of cases involving the ophthalmic division of the trigeminal nerve (Fig. 61.10). Postherpetic neuralgia, which is pain that persists longer than 1 to 3 months after the resolution of the rash, is an important complication of herpes zoster. It is seen most commonly in people older than 60 years of age, increasing age being the greatest risk factor. Given the aging population in the United States, the incidence of herpes zoster is expected to increase dramatically over the next two decades. Affected people complain of sharp, burning pain that often occurs in response to non-noxious stimuli. Even the slightest pressure of clothing and bedsheets may elicit pain. It usually is a self-limited condition that persists for months, with symptoms abating over time.

The treatment of choice for herpes zoster is the administration of an antiviral agent (e.g., acyclovir, valacyclovir, famciclovir). The treatment is most effective when started within 72 hours of rash development. When given in the acute vesicular stage, the antiviral drugs have been shown to decrease the amount of lesion development and pain. Narcotic analgesics, tricyclic antidepressants, gabapentin, anticonvulsant drugs, and nerve blocks have been used for management of postherpetic neuralgia. Local application of capsaicin cream or lidocaine patches may be used in selected cases. Zoster vaccine (Zostavax) is effective in either preventing or lessening the severity of herpes zoster. This vaccine is highly recommended for people greater than 50 years of age and anyone with high risk for herpes zoster.

Acne and Rosacea

Acne is a disorder of the pilosebaceous unit, which comprises a tiny vellus hair, hair follicle, and sebaceous gland. The hair follicle is a tubular invagination of the epidermis in which hair is produced. The sebaceous glands empty into the hair follicle, and the pilosebaceous unit opens to the skin surface through a widely dilated opening called a pore. The sebaceous glands produce a complex lipid mixture called sebum. Sebum consists of a mixture of free fatty acids, triglycerides, diglycerides, monoglycerides,
sterol esters, wax esters, and squalene. Sebum production occurs through what is called a holocrine process, in which the sebaceous gland cells that produce the sebum are completely broken down and their lipid contents emptied through the sebaceous duct into the hair follicle. The amount of sebum produced depends on two factors: the size of the sebaceous gland and the rate of sebaceous cell proliferation. The sebaceous glands are largest on the face, scalp, and scrotum but are present in all areas of the skin except for the soles and palms. Sebaceous cell proliferation and sebum production are uniquely responsive to direct hormonal stimulation by androgens. In men, testicular androgens are the main stimulus for sebaceous activity; in women, adrenal and ovarian androgens maintain sebaceous activity.

Acne lesions are divided into noninflammatory and inflammatory lesions.17

Remember Lauren from the unit opener case study who had presented with a “growth on the lower right ear lobe” and an itchy rash on her hands? She seems to think she may have an acne problem with this growth. She asks, “What exactly is this growth on my ear? They said it was a keloid, but I have never heard of anything like that before.” She is educated about the keloid that formed after her piercing and says, “Well, I guess it is not acne, but do you think it could be skin cancer?”

Noninflammatory lesions consist of comedones (whiteheads and blackheads). Blackheads are plugs of material that accumulate in sebaceous glands that open to the skin surface. The color of blackheads results from melanin that has moved into the sebaceous glands from adjoining epidermal cells. Whiteheads are pale, slightly elevated papules with no visible orifice. Inflammatory lesions consist of papules, pustules, nodules, and, in severe cases, cysts.17 Papules are raised areas less than 5 mm in diameter. Pustules have a central core of purulent material. Nodules are larger than 5 mm in diameter and may become suppurative or hemorrhagic. Suppurative nodules often are referred to as cysts because of their resemblance to inflamed epidermal cysts. The inflammatory lesions are believed to develop from the escape of sebum into the dermis and the irritating effects of the fatty acids contained in the sebum.

Two types of acne occur during different stages of the life cycle: acne vulgaris, which is the most common form among adolescents and young adults, and acne conglobata, which develops later in life. Other types of acne occur in association with various etiologic agents such as drugs (e.g., steroids, iodides), occupational compounds, cosmetics, and other irritating agents. Treatment measures for these acnes depend on the precipitating agent and the extent of the lesions.

Acne Vulgaris

Acne vulgaris is considered a chronic inflammatory disease of the pilosebaceous unit. It is a disorder of adolescents and young adults, affecting over 80% of people between the ages of 11 and 30 years in westernized countries.18 In women, acne may begin earlier and persist longer. However, overall, the incidence and severity of acne vulgaris is greater in men. Acne vulgaris lesions form primarily on the face and neck and, to a lesser extent, on the back, chest, and shoulders (Fig. 61.11). The lesions may consist of comedones (whiteheads and blackheads) or inflammatory lesions (pustules, nodules, and cysts).

Etiology. The cause of acne vulgaris remains unknown. However, there is a genetic factor. Multiple generations of family members often experience the disease. Several factors are believed to contribute to acne, including:

- Increased sebum production
- Increased proliferation of the keratinizing epidermal cells that form the sebaceous cells
- The colonization and proliferation of Propionibacterium acnes
- Inflammation

These factors are probably interrelated. Increased androgen production results in increased sebaceous cell activity, with resultant plugging of the pilosebaceous ducts. The excessive sebum provides a medium for the growth of P. acnes. The P. acnes organism contains lipases that break down the free fatty acids that produce the acne inflammation. In addition, there have been new findings regarding the physiology of acne (Fig. 61.12). One example is that P. acnes form a biofilm
Acne vulgaris. The pathogenesis of follicular distention, rupture, and inflammation is illustrated. Microcomedones (A) and closed (B) and open (C) comedones form. Excessive sebum can be secreted and the P. acnes proliferates. Neutrophilic enzymes are released, and the comedone ruptures causing a cycle of intense inflammation (D,E). (From Rubin R., Strayer D. (2012). Rubin’s pathology: Clinico-pathologic foundations of medicine (6th ed., p. 1145–1146). Philadelphia, PA: Lippincott Williams & Wilkins.)
an extracellular polysaccharide lining in which the bacteria are encased) that prevents antibiotic treatment. Given this and other discoveries, new drugs and therapies will emerge that selectively target such phenomena.

Over the years, several factors, such as poor hygiene, acne as an infectious process, diets high in fatty content, and certain foods (e.g., chocolate, fried foods) have been studied empirically and rejected as causal factors in the development of acne. Although general hygienic measures are important, obsessive scrubbing can traumatize the skin and worsen the condition. Instead, it is recommended that the affected areas be washed gently and patted dry.

**Diagnosis.** The diagnosis of acne is based on history and physical examination. Generally, the type and amount of lesions assists in determining the severity of the acne (mild, moderate, and moderately severe).\(^{15,18-20}\) **Mild acne** is usually characterized by the presence of a small number (generally <10) of open and closed comedones, with a few inflammatory papules. **Moderate acne** is characterized by the presence of a moderate number (10 to 40) of erythematous papules and pustules, usually limited to the face. **Moderately severe acne** is characterized by the presence of numerous papules and pustules (40 to 100) and occasionally larger, deeper, nodular inflamed lesions involving the face, chest, and back (see Fig. 61.13).
Chapter 61 Disorders of Skin Integrity and Function

and lotions containing keratolytic agents such as sulfur, salicylic acid, phenol, and resorcinol are available as over-the-counter preparations. These agents act chemically to break down keratin, loosen comedones, and exert a peeling effect on the skin.15,17

Benzoyl peroxide is a topical agent that has both antibacterial and comedolytic properties. It is the topical agent most effective in reducing the P. acnes population. Bacterial proteins are oxidized by the oxygen-free radicals released from the metabolism of benzoyl peroxide on the skin. Because of its mechanism of action, bacterial resistance does not develop to benzoyl peroxide. The irritant effect of the drug also causes vasodilation and increased blood flow, which may hasten resolution of the inflammatory lesions. Azelaic acid, derived from wheat, rye, and barley, has actions similar to benzoyl peroxide. It decreases the proliferation of keratinocytes and has antibacterial actions against P. acnes. Azelaic cream is moisturizing and causes only minimal skin irritation.

Topical tretinoin (Retin-A), an acid derivative of vitamin A, acts locally to decrease the cohesiveness of epidermal cells and increase epidermal cell turnover. This is thought

Figure 61.13 • (A) Acne of the face and (B) acne of the chest. (From Hall B.J., Hall J. C. (2010). Sauer’s manual of skin diseases (10th ed., p. 152). Philadelphia, PA: Lippincott Williams & Wilkins.)

Treatment. Treatment of acne focuses on clearing up existing lesions, preventing new lesions, and limiting scar formation. Depending on the severity of the acne, a treatment plan could include topical and/or systemic drugs. Long-term treatment usually is required. Significant improvement may not be apparent for 4 weeks after initiation of treatment, and maximum effects may not be apparent for months. Some people will not have an effective response to any of the treatments that are available. However, acne is the most common skin condition in the world.19 Therefore, it is realistic to believe that new and more effective treatment measures will continue to be developed.

A number of topical agents are available for the treatment of acne, including retinoids, benzoyl peroxide, azelaic acid, and antibiotics. Topical retinoids, benzoyl peroxide, and azelaic acid are effective treatments for mild acne. Moderate to severe acne often requires combination therapy with a topical agent and systemic antibiotics. The type of topical (cream, gel, or lotion) may be an important consideration in the selection of an agent. People with drier skin may benefit from creams, whereas people with oily skin may have better results using a gel or lotion. Many acne creams and lotions containing keratolytic agents such as sulfur, salicylic acid, phenol, and resorcinol are available as over-the-counter preparations. These agents act chemically to break down keratin, loosen comedones, and exert a peeling effect on the skin.15,17

Benzoyl peroxide is a topical agent that has both antibacterial and comedolytic properties. It is the topical agent most effective in reducing the P. acnes population. Bacterial proteins are oxidized by the oxygen-free radicals released from the metabolism of benzoyl peroxide on the skin. Because of its mechanism of action, bacterial resistance does not develop to benzoyl peroxide. The irritant effect of the drug also causes vasodilation and increased blood flow, which may hasten resolution of the inflammatory lesions. Azelaic acid, derived from wheat, rye, and barley, has actions similar to benzoyl peroxide. It decreases the proliferation of keratinocytes and has antibacterial actions against P. acnes. Azelaic cream is moisturizing and causes only minimal skin irritation.

Topical tretinoin (Retin-A), an acid derivative of vitamin A, acts locally to decrease the cohesiveness of epidermal cells and increase epidermal cell turnover. This is thought
to result in an increased extrusion of open comedones and a transformation of closed comedones into open ones. Tretinoin is inactivated by UV light and oxidized to benzoyl peroxide and should be applied only at night and not with benzoyl peroxide. All tretinoin formulations are irritating to the skin, an effect that is increased with sun exposure. Another form of tretinoin, Retin-A Micro, works by entrapping the drug in microspheres that move into the follicle and serve as reservoirs for drug release. Other retinoid drugs, such as adapalene and tazarotene, have actions similar to tretinoin. Adapalene appears to be as effective as tretinoin, but may be less irritating to the skin.

Topical antibiotics also are effective in treating mild to moderate acne. Topical tetracycline, erythromycin, and clindamycin are used most commonly. They do not affect existing lesions but prevent future lesions by decreasing the amount of *P. acnes* on the skin, thereby reducing subsequent inflammation formed from the presence of sebaceous fatty acid metabolites. Treatment failure can result from development of antibiotic resistance. Combination drugs such as benzoyl peroxide and erythromycin or minocycline also have been effective.

Oral antibiotics are indicated for moderate to severe disease, and for the treatment of acne on the chest, back, or shoulders. Low-dose tetracycline has been used effectively for many years. Tetracycline has no effect on sebum production, but it decreases bacterial growth and the amount of free fatty acids produced. Tetracycline requires a sufficient treatment period to establish effective blood levels. Side effects are minimal, which is why the drug has remained so useful. However, it does have teratogenic effects on skeletal and tooth development and should not be given to those who are pregnant or lactating, or to children. The tetracycline derivatives, minocycline and doxycycline, are better tolerated than tetracycline. Doxycycline may cause photosensitivity reactions. Erythromycin also is effective in acne treatment, especially when tetracycline and its derivatives cannot be used.

Isotretinoin (Accutane), an orally administered synthetic retinoid or acid form of vitamin A, revolutionized the treatment of recalcitrant cases of acne and cystic acne. In carefully planned doses, oral isotretinoin has cleared major cases of acne and initiated long-term remissions of the disease. It is administered for 3- to 4-month treatment periods. Although the exact mode of action is unknown, it decreases sebaceous gland activity, prevents new comedones from forming, reduces the *P. acnes* count through sebum reduction, and has an anti-inflammatory effect. However, because of its many side effects, it is used only in people with severe acne and only when no other treatment is effective. Side effects include dryness of the mouth and other mucous membranes, conjunctivitis, and musculoskeletal system abnormalities. Although not confirmed by population-based studies, there have been case reports of depression and suicide attempts by people taking isotretinoin. Careful clinical and laboratory monitoring is necessary because the drug can produce elevated serum lipid levels, abnormal liver enzyme test results, and hematologic disorders. Isotretinoin is a teratogen that causes brain, heart, and ear malformations. Women taking isotretinoin are strongly advised not to become pregnant.

Estrogens reduce the size and secretion of the sebaceous gland, but because of the high dosages required, they are contraindicated in men. In women, oral contraceptive agents that combine estrogen with a progestin that has low androgenic activity may be used.

Other treatment measures for acne include surgery, UV irradiation, cryotherapy (e.g., freezing with carbon dioxide slushes, liquid nitrogen), laser therapy, and intralesional corticosteroid injection. Intralesional injection of corticosteroids using a syringe or needleless injector is limited to severe nodulocystic forms of acne. It has been effective in promoting cyst healing, but usually has to be repeated frequently.

### Acne Conglobata

Acne conglobata occurs later in life and is a chronic form of severe cystic acne. Comedones, papules, pustules, nodules, abscesses, cysts, and scars occur on the back, buttocks, and chest. Lesions occur to a lesser extent on the abdomen, shoulders, neck, face, upper arms, and thighs. The comedones or cysts have multiple openings, large abscesses, and interconnecting sinuses. Inflammatory nodules are not uncommon. Their discharge is odoriferous, serous or mucoid, and purulent. Healing often leaves deep keloidal lesions. Affected people have anemia with elevated white blood cell counts, erythrocyte sedimentation rates, and neutrophil counts. When people with acne conglobata also have leukocytosis, fever, and arthralgia, this type of acne is diagnosed as acne fulminans. The treatment often includes debridement, systemic corticosteroid therapy, oral retinoids, and systemic antibiotics.

### Rosacea

Rosacea is a chronic inflammatory process that occurs in adults between the ages of 40 and 60 years of age. It is easily confused with acne and may coexist with it. Rosacea is more common in fair-skinned people. Rosacea affects an estimated 16 million people in the United States. Most people with rosacea are white women older than 30 years of age.

#### Etiology

The cause of rosacea is unknown. However, it is believed to be an inflammatory process accompanied by vascular instability with leakage of fluid and inflammatory mediators into the dermis. It often is accompanied by gastrointestinal symptoms and, although *Helicobacter pylori* infection has been implicated as a possible cause, some evidence does not support this finding. In addition to microorganisms, other causes postulated have been genetic, environmental, and vascular.

#### Types and Clinical Manifestations

Rosacea has now been classified into four types:
1. Erythematotelangiectatic (flushing and persistent central facial erythema)
2. Papulopustular (inflammatory)
3. Phymatous (thickening of the skin with irregular surface nodularities and enlargement)
4. Ocular (involving the eyes)\(^{26}\)

In the early stage of rosacea development, there are repeated episodes of blushing. The blush eventually becomes a permanent dark red erythema on the nose and cheeks that sometimes extends to the forehead and chin. This stage often occurs before 20 years of age. Ocular problems occur in at least 50% of people with rosacea, which may lead to visual losses. Prominent symptoms include eyes that are itchy, burning, or dry; a gritty or foreign body sensation; and erythema and swelling of the eyelid.\(^{26}\) As the person ages, the erythema persists, and telangiectases with or without acne components (e.g., comedones, papules, pustules, nodules, erythema, edema) develop. After years of affliction, acne rosacea may develop into an irregular bullous hyperplasia (thickening of the skin) of the nose, known as rhinophyma.\(^{16}\) The sebaceous follicles and openings of the nose enlarge, and the skin color changes to a purple-red, resulting in hypertrophy of the nose and impaired breathing. Although rosacea is more common in women, rhinophyma is more common in men. People with rosacea are heat sensitive. They are instructed to avoid vascular stimulating agents such as heat, sunlight, hot liquids, foods, and alcohol.

**Treatment.** Treatment measures are similar to those used for acne vulgaris. Topical metronidazole and azelaic acid have been effective. Topical antibiotics (e.g., clindamycin, erythromycin) have been useful, as well as systemic antibiotics (e.g., tetracycline and its derivatives). Rhinophyma can be treated by a number of surgical methods, including electrosurgery, laser ablation, dermabrasion, cryosurgery, and excision.

### Allergic and Hypersensitivity Dermatoses

Allergic and hypersensitivity dermatoses involve the inflammatory response to multiple exogenous and endogenous agents. The disorders, which are usually characterized by epidermal edema with separation of epidermal cells, include irritant contact dermatitis, allergy contact dermatitis, atopic and nummular eczema, urticaria, and drug-induced skin eruptions.

**Contact and Allergic Dermatitis**

Contact dermatitis is a common inflammation of the skin. There are two types of contact dermatitis: allergic and irritant contact dermatitis.

**Allergic Contact Dermatitis.** Allergic contact dermatitis results from a cell-mediated, type IV hypersensitivity response brought about by sensitization to an allergen such as the toxin in poison ivy. More than 2000 allergens have been identified as capable of producing an inflammatory skin response. Crude forms of many naturally occurring substances are in general less allergenic than alloys and synthetic products. Additives such as dyes and perfumes account for the major sources of known allergens. Some of the common topical agents causing allergic rashes are antimicrobial agents (especially neomycin), antihistamines, local anesthetic agents (benzocaine), preservatives (e.g., parabens), and adhesive tape. Additional examples are poison ivy, poison oak, and metal alloys found in jewelry. Also of concern is the increased incidence of contact dermatitis from the heavy use of synthetic latex products, specifically latex gloves and condoms used to prevent communicable diseases.

The top 10 causes of allergic contact dermatitis in order of frequency are nickel, gold (jewelry), balsam of Peru (perfume fragrance), thimerosal (preservative in cosmetics), neomycin sulfate, fragrance mix (eight fragrances used for testing fragrance allergies), formaldehyde (preservative in paper, paint, medications, fabrics), cobalt chloride (metal in medical products, hair dye, antiperspirants), and bacitracin.\(^{27,28}\)

The lesions of allergic contact dermatitis range from a mild erythema with edema to vesicles or large bullae (Fig. 61.14). Secondary lesions from bacterial infection may occur. Lesions can occur almost anywhere on the body, and the many variations of eczema are often classified according to their location (e.g., ear eczema, hand eczema). The location and pattern often help in identifying causative agents. For example, the typical poison ivy lesion consists of vesicles or bullae in a linear pattern (from swiping the plant) on exposed areas. The vesicles and bullae break and weep, leaving an excoriated area.

**Irritant Contact Dermatitis.** Chemicals (soaps, detergents, organic solvents) that irritate the skin cause irritant contact dermatitis. It can occur from mechanical means such as rubbing (e.g., wool, fiberglass), chemical irritants (e.g., household cleaning products), or environmental irritants (e.g., plants, urine). In contrast to allergic contact dermatitis, no allergens can be identified.

**FIGURE 61.14** Contact dermatitis. A classic erythematous and pruritic rash on the arm due to an inflammatory response to an antigen that had contact with the skin of the arm. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 307). Philadelphia, PA: Lippincott Williams & Wilkins.)
A history of atopic dermatitis, either in the past or concurrent, is a major risk for the development of irritant contact dermatitis. Four types of irritant contact dermatitis exist: subjective, acute, chronic, and chemical burns. Subjective cases have no clinical manifestation, but the person reports burning or stinging sensations when exposed to the irritant, and the effect can be reproduced. Acute episodes are often due to single exposures to the irritant.

There may be dryness and erythema or edema, inflammation, and vesicles. Chronic irritant dermatitis results from continued exposure to the irritant. Even when the irritant is removed, the reaction may continue for several years. In addition to dryness and erythema, there may be scales, fissures, and vesicles (Fig. 61.15).

**Diagnosis and Treatment.** With both allergic and irritant contact dermatitis, the location of the lesions is of great benefit in diagnosing the causative agent. Patch testing, in which a small amount of the suspected antigen is applied to the skin, is used to identify the allergens.29 Treatment measures for both types of contact dermatitis are aimed at removing the source of the irritant or allergen. Minor cases are treated by washing the affected areas to remove further contamination by the irritant or allergen, applying antipruritic creams or lotions, and bandaging the exposed areas. Topical corticosteroids may be helpful in these cases. Systemic treatment regimens differ according to the type of irritant or allergen and the severity of the reaction. Moderate to extreme cases are treated with wet dressings, oral antihistamines, and systemic corticosteroids.

**Atopic Dermatitis and Nummular Eczema**

**Atopic Dermatitis.** Atopic dermatitis (atopic eczema) is an itchy, inflammatory skin disorder that is characterized by poorly defined erythema with edema, vesicles, and weeping at the acute stage and skin thickening (lichenification) in the chronic stage.30 Although often described as an immunoglobulin E (IgE)-mediated hypersensitivity (atopic) disease, allergic causation is difficult to document, and the disorder is increasingly viewed as a skin disease that predisposes to allergies.30 Greater than 50% of children with atopic dermatitis develop asthma and allergies in adolescence and adulthood.31

Atopic dermatitis presents differently at different ages (infantile and adult) and in people of different races. Approximately 70% of cases of atopic allergy start in children younger than 5 years of age.32 The infantile form of atopic dermatitis is characterized by vesicle formation, oozing, and crusting with excoriations. It usually begins on the cheeks and may progress to involve the scalp, arms, trunk, and legs (Fig. 61.16). The skin of the cheeks may be paler, with extra creases under the eyes, called Dennie-Morgan folds. The infantile form may become milder as the child ages, often disappearing by the age of 15 years. However, many people...
have resultant eczematous disorders and rhinitis symptoms throughout life.

Adolescents and adults usually have dry, red patches affecting the face, neck, and upper trunk, but without the thickening and discrete demarcation associated with psoriasis. The bends of the elbows and knees are usually involved. In chronic cases, the skin is dry, leathery, and lichenified. People with dark skin may have a papular eruption and poorly demarcated hypopigmentation patches on the cheeks and extremities. In people with black skin, pigmentation may be lost from lichenified skin. Acute flares may present with red patches that are weepy, shiny, or lichenified (i.e., thickened, with more prominent markings), and with plaques and papules. Itching may be severe and prolonged with both childhood and adults forms of atopic dermatitis. Secondary infections are common.

Treatment of atopic eczema is designed to target the underlying abnormalities: dryness, pruritus, infection, and inflammation. The guidelines derived consensually from and endorsed by North American and European expert teams include a stepwise approach for the management of atopic dermatitis based on the intensity of the disease process. Underlying all treatment measures is a comprehensive education program regarding the cause of the disorder, treatment measures, and avoidance of temperature changes and stress to minimize vascular and sweat responses. Basic therapy begins with optimal skin care, addressing the skin barrier defect with continuous use of emollients and skin hydration, along with avoiding exposure to environmental irritants and foods that cause exacerbations of the symptoms. Contacts with water should be minimized. The person should bathe with warm water and mild soap. Bathing dries the skin, yet it is important to maintain a low level of microorganisms to prevent infection. Although there is no evidence that emollients improve atopic dermatitis directly, they are widely used to relieve the problem of dry skin and pruritus. A key feature of atopic dermatitis is severe dryness of the skin caused by dysfunction of the skin barrier with transepidermal water loss. This is accompanied by intense pruritus and inflammation.

Topical corticosteroids remain an important treatment for acute flare-ups but can cause local and systemic side effects. Potency of topical corticosteroids is classified by the potential for vasoconstriction. In general, only preparations that have weak or moderate potency are used on the face and genital areas, whereas those that have moderate or high potency are used on other areas of the body. Lower-potency corticosteroids may be sufficient on all areas of the body in younger children. One of the main concerns of topical corticosteroid use is skin thinning. Another concern is secondary adrenal suppression and the suppression of growth in children resulting from systemic absorption.

Wet-wrap therapy, in which a wet dressing is applied over emollients in combination with topical antiseptics (e.g., triclosan, chlorhexidine) or topical corticosteroids, has been shown to be beneficial in some cases of severe atopic dermatitis. Secondary infection with \textit{S. aureus} is common and usually treated with short courses of antibiotics. Short-term corticosteroids are also used during acute flare-ups with adult patients. Cyclosporine and azathioprine, both immunosuppressive agents, may also be used, keeping in mind their potentially harmful effects. Antihistamines are useful for their sedative effects and may be helpful during severe pruritus episodes. Phototherapy alone or in combination with corticosteroids during acute flares is often practiced, with beneficial results.

Less studied is the use of probiotics, foods containing live microorganisms, such as \textit{Lactobacillus acidophilus} or \textit{Bifidobacterium bifidum}. Probiotics are believed to reduce IgE-mediated reactions. These foods include hydrolyzed cow’s milk formula (predigested peptides of whey and casein), whey formulas, and yogurts.

**Nummular Eczema.** The lesions of nummular eczema are coin shaped (hence its other name, \textit{discoid eczema}), papulovesicular patches mainly involving the arms and legs. Lichenification and secondary bacterial infections are common. It is not unusual for the initial lesions seemingly to heal, followed by a secondary outbreak of mirror-image lesions on the opposite side of the body. Nummular eczema is mostly chronic, with weeks to years between exacerbations. Exacerbations are more frequent in the cold winter months. The exact cause of nummular eczema is unknown, although many people have a history of atopy (allergy-related disorders), and there is heavy colonization of lesions with staphylococci. Ingestion of iodides and bromides usually aggravates the condition and should be avoided. Treatment is similar to that for other types of dermatitis. Frequent bathing and stress should be reduced, whereas environmental humidity should be increased. Topical emollients, corticosteroids, coal tar preparations, and UV light treatments may be prescribed as necessary.

**Urticaria**

Urticaria, or hives, are pale, raised, itchy papules or plaques that occur in the most superficial aspect of the dermis anywhere on the skin. These small wheals blanch with pressure and vary in size from a few millimeters to centimeters (Fig. 61.17). They occur as either an immunologic reaction to an antigen in an IgE hypersensitivity response or a nonimmunologic reaction to something that is not known. Angioedema is when the swelling occurs in the deeper dermis and result in large
wheals.  

Etiology and Pathogenesis. Urticaria can be acute or chronic and due to known or unknown causes. Numerous factors, both immunologic and nonimmunologic, can be involved in its pathogenesis. The urticarial wheal results from liberation of histamine from mast cells and basophils. Histamine causes hyperpermeability of the microvessels of the skin and surrounding tissue, allowing fluid to leak into the tissues, causing edema and wheal formation.

The most common causes of acute urticaria are foods or drinks, medications (most notably penicillin and cephalosporin), insect stings, viral infections, dust mites, and exposure to pollens or chemicals. Food is the most common cause of acute urticaria in children.

Chronic urticaria affects primarily adults and is twice as common in women as in men. Usually its cause cannot be determined despite extensive laboratory tests. It appears to be an autoimmune disorder in a substantial number of people. Approximately one half of people with chronic urticaria have circulating IgG antibodies, which trigger the release of histamine by mast cells. In rare cases, urticaria is a manifestation of underlying disease, such as certain cancers, collagen diseases, and hepatitis. It is thought there may be a connection between urticaria and having an autoimmune disease of the thyroid gland. Additionally, a genetic deficiency of a C1 (complement 1) inhibitor also can cause urticaria and angioedema.

The physical urticarias constitute another form of chronic urticaria. Physical urticarias are intermittent; usually last less than 2 hours; are produced by exercise, cold, sunlight, vibration, heat, or delayed pressure; have distinctive appearances and locations; and are seen most frequently in young adults.

Diagnosis and Treatment. Appropriate challenge tests (e.g., application of an ice cube to the skin to initiate development of cold urticaria) are used to differentiate physical urticaria from chronic urticaria due to other causes.

Most types of urticaria are treated with second-generation antihistamines that block histamine type 1 (H1) receptors. These drugs do not cause drowsiness so they are recommended over the first generation. They control urticaria by inhibiting vasodilation and the escape of fluid into the surrounding tissues. They also relieve the pruritis. If the antihistamines are not effective, leukotriene receptor blockers (zafirlukast and montelukast) are used. Colloid-type (e.g., Aveeno) baths may be used as comfort measures. People who experience angioedema of the larynx and pharynx are strongly encouraged to carry an EpiPen. Oral corticosteroids may be used in the treatment of refractory urticaria.

Drug-Induced Skin Eruptions

Most drugs can cause a localized or generalized skin eruption. Topical drugs are usually responsible for localized contact dermatitis types of rashes, whereas systemic drugs cause generalised skin lesions. Although many drug-induced skin eruptions are morbilliform (i.e., measles-like) or exanthematous, they may mimic most of the skin disorders described in this chapter. Because the lesions vary greatly, the diagnosis depends almost entirely on an accurate patient history. Management of mild cases is aimed at eliminating the offending drug while treating the symptoms. Severe cases require prompt medical attention and treatment with systemic corticosteroids and antihistamines.

Some drug reactions result in epidermal skin detachment and formation of bullous lesions. Three types of drug reactions that result in bullous skin lesions are erythema multiforme minor (Fig. 61.18), Stevens-Johnson syndrome, and toxic epidermal necrolysis (TEN).

Etiology and Pathogenesis. Erythema multiforme minor is usually self-limiting, and manifestations vary from a few ring-like erythematous macules and blisters. If the reaction involves a systemic ulceration of all mucous membranes and skin, it is called erythema multiforme major, or Stevens-Johnson syndrome, which may be a reaction to either a drug or a virus such as HSV. The third disease-causing bullous skin lesions triggered by a medication adverse reaction is TEN or Lyell disease, which is life threatening.

Erythema multiforme minor is self-limiting, with a small amount of skin detachment at the lesion sites. Stevens-Johnson syndrome and TEN are caused by hypersensitivity reaction to drugs, the most common being sulfonamides, anticonvulsants, nonsteroidal anti-inflammatory drugs, antimarials, and allopurinol. Recovery is based on the severity and quick, aggressive treatment.

The skin detachment seen with bullous skin lesions is different from the desquamation (i.e., peeling) that occurs with other skin disorders. For example, with scarlet fever, there is peeling of the dead keratinized layer of the stratum corneum. In the bullous disorders, there is full-thickness detachment of
the entire epidermis from the dermis. This leaves the person vulnerable to multiple problems, including loss of body fluids and electrolytes, impaired body temperature control, and a greatly increased risk of infection.

**Clinical Manifestations.** The lesions of erythema multiforme minor and Stevens-Johnson syndrome are similar. The primary lesion of both is a round, erythematous papule, resembling an insect bite. Within hours to days, these lesions change into several different patterns. The individual lesions may enlarge and coalesce, producing small plaques, or they may change to concentric zones of color appearing as “target” or “iris” lesions. The outermost rings of the target lesions usually are erythematous; the central portion usually is opaque white, yellow, or gray (dusky). In the center, small blisters on the dusky purpuric macules may form, giving them their characteristic target-like appearance. Although there is wide distribution of lesions over the body surface area, there is a propensity for them to occur on the face and trunk.

TEN is the most serious drug reaction. The person experiences a prodromal period of malaise, low-grade fever, and sore throat. Within a few days, widespread erythema and large, flaccid bullae appear, followed by the loss of the epidermis, leaving a denuded and painful dermis. The skin surrounding the large denuded areas may have the typical target-like lesions seen with Stevens-Johnson syndrome. Lateral pressure causes the surrounding skin to separate easily from the dermis (Nikolsky sign). Usually, the epithelium of mucosal surfaces, especially the mouth and eyes, is also involved and may lead to blindness.

**Treatment.** Treatment of erythema multiforme minor and less severe cases of Stevens-Johnson syndrome includes relief of symptoms using compresses, antipruritic drugs, and topical anesthetics. Recurrent cases of erythema multiforme have been prevented with continuous acyclovir therapy, given the fact it is triggered often by HSV. Corticosteroid therapy may be indicated in moderate cases, although its use is controversial. For severe cases of Stevens-Johnson syndrome and TEN, hospitalization is required for fluid replacement, respiratory care, administration of antibiotics and analgesics, and application of moist dressings. When large areas of skin are detached, the care is similar to that for people with thermal burn injuries. Intravenous immunoglobulin may hasten the healing response of the skin. Generally, healing is a slow process, taking 6 weeks or more to regenerate skin. The mucous membranes heal slowly, and follow-up treatment is often needed for ophthalmologic and mucous membrane sequelae.

Avoidance of the responsible drug and chemically related compounds is essential.

**Psoriasis**

Psoriasis is a common, chronic inflammatory skin disease characterized by circumscribed, red, thickened plaques with an overlying silvery-white scale. Psoriasis occurs worldwide, although the incidence is lower in warmer, sunnier climates. In the United States and England, it affects 2% to 3% of the population. The average age of onset is in the third decade, and its prevalence increases with age.

**Etiology.** Approximately one third of people have a genetic history, indicating a hereditary factor. Childhood onset of the disease is more strongly associated with a family history than psoriasis occurring in adults older than 30 years of age. The disease, which can persist throughout life and become exacerbated at unpredictable times, is classified as a chronic ailment. A few cases, however, have been known to clear and not recur. There appears to be an association between psoriasis and arthritis.

The primary cause of psoriasis is uncertain. It is thought that activated T lymphocytes (mainly CD4+ helper cells) produce chemical messengers that stimulate abnormal growth of keratinocytes and dermal blood vessels. Accompanying inflammatory changes are caused by infiltration of neutrophils and monocytes. Skin trauma is a common precipitating factor in people predisposed to the disease. The reaction of the skin to an original trauma of any type is called the Köbner reaction. Stress, infections, trauma, xerosis, and use of medications such as angiotensin-converting enzyme inhibitors, β-adrenergic blocking drugs, lithium, and the antimalarial agent, hydroxychloroquine (Plaquenil), may precipitate or exacerbate the condition.

**Pathogenesis.** Histologically, psoriasis is characterized by increased epidermal cell turnover with marked epidermal thickening, a process called hyperkeratosis. The granular layer (stratum granulosum) of the epidermis is thinned or absent, and neutrophils are found in the stratum corneum. There also is an accompanying thinning of the epidermal cell layer that overlies the tips of the dermal papillae (suprapapillary plate), and the blood vessels in the dermal papillae become tortuous and dilated. These capillary beds show permanent damage even when the disease is in remission or resolved. The close proximity of the vessels in the dermal papillae to the hyperkeratotic scale accounts for multiple, minute bleeding points that are seen when the scale is lifted.

**Types of Psoriasis.** There are several variants or types of psoriasis, including plaque-type psoriasis, guttate psoriasis, pustular psoriasis (localized and generalized), and erythrodermic psoriasis. Plate-type psoriasis (psoriasis vulgaris), which is the most common type, is a chronic stationary form of psoriasis. The lesions may occur anywhere on the skin, but most often involve the elbows, knees, and scalp (Fig. 61.19). The primary lesions are sharply demarcated, thick, red plaques with a silvery scale that vary in size and shape. In darker-skinned people, the plaques may

**Papulosquamous Dermatoses**

Papulosquamous dermatoses are a group of skin disorders characterized by scaling papules and plaques. Among the major papulosquamous diseases are psoriasis, pityriasis rosea, and lichen planus.
appear purple. There may be excoriation, thickening, or ooze from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed, which is known as the **Auspitz sign**.

**Guttate psoriasis** occurs in children and young adults and is characterized by teardrop-shaped, pink to salmon, scaly lesions. Its lesions are usually limited to the upper trunk and extremities. This form of psoriasis usually is brought on by a streptococcal infection. It generally responds to treatments such as UVB phototherapy, only to return with recurrent streptococcal infections. **Pustular psoriasis** is characterized by papules or plaques studded with pustules (Fig. 61.20). Localized pustular psoriasis usually is limited to the palms of the hands and soles of the feet. Generalized pustular psoriasis is characterized by more general involvement and may be associated with systemic symptoms such as fever, malaise, and diarrhea. The person may or may not have had preexisting psoriasis.

---

Erythrodermic psoriasis is a rare form of psoriasis affecting all body surfaces, including the hands, feet, nails, trunk, and extremities. It is characterized by a process in which the lesions scale and become confluent, leaving much of the body surface bright red, with continuous skin shedding. Severe itching and pain often accompany it. Severe complications may develop related to loss of body fluids, proteins, and electrolytes and disturbances in temperature regulation.

**Treatment.** There is no cure for psoriasis. The goal of treatment is to suppress the signs and symptoms of the disease: hyperkeratosis, epidermal inflammation, and abnormal keratinocyte differentiation. Treatment depends on the severity of the disease, as well as on the person’s age, sex, treatment history, and level of treatment compliance. There is no standardized tool to assess severity of psoriasis. Treatment measures are divided into topical and systemic approaches. Usually, topical agents are used first in any treatment regimen and when less than 5% of the body surface is involved. Combination therapies tailored to the needs of the client are most effective. Also, rotating various therapies may decrease the side effects of any one therapy.

Topical agents include emollients, keratolytic agents, coal tar products, anthralin, corticosteroids, and calcipotriene. Emollients hydrate and soften the psoriatic plaques. Petroleum-based products are more effective than water-based, but they are less often acceptable cosmetically to persons with psoriasis. Keratolytic agents are peeling agents. Salicylic acid is the most widely used. It softens and removes plaques. It has been used alone or in conjunction with other topical agents. Coal tar, the byproduct of the processing of coke and gas from coal, is one of the oldest yet more effective forms of treatment. The skin is covered with a film of coal tar for up to several weeks. The exact mechanism of action of tar products is unknown, but side effects of the treatment are few.

Anthralin, a synthesized product of Goa powder from Brazilian araroba tree bark, has remained a topical treatment of choice. It has been effective in resolving lesions in approximately 2 weeks. A disadvantage to anthralin is that it stains the uninvolved skin and clothes brown or purple. A treatment variation, called the Ingram method, involves coal tar applications and UVB radiation, followed by anthralin paste application.

Topical corticosteroids are widely used and relatively effective. They are generally more acceptable because they do not stain and are easy to use. Topical corticosteroids are available as low-, medium-, and high-potency preparations. Treatment usually is started with a medium-potency agent. Low-potency drugs usually are used on the face and areas of the body, such as the groin and axillary areas, where the skin tends to be thinner. High-potency preparations are reserved for treatment of thick chronic plaques that do not respond to less potent preparations. Although the corticosteroids are rapidly effective in the treatment of psoriasis, they are associated with flare-ups after discontinuation and they have many potential side effects. Their effectiveness is increased when used under occlusive dressings, but there is an increase in side effects. Calcipotriene, a topical vitamin D derivative, has been effective for the treatment of psoriasis. It inhibits epidermal cell proliferation and enhances cell differentiation. Tazarotene, a synthetic retinoid, also has been effective, but it is teratogenic and should be avoided in women of childbearing age.

Systemic treatments include phototherapy, photochemotherapy, methotrexate, retinoids, corticosteroids, and cyclosporine. The positive effects of sunlight have long been established. Phototherapy with UVB is a widely used treatment. Photochemotherapy involves using a light-activated form of the drug methoxsalen.

Systemic corticosteroids have been effective in treating severe or pustular psoriasis. However, they cause severe side effects, including Cushing syndrome. Intralesional injection of triamcinolone has proved effective in resistant lesions. The retinoids are another class of systemic psoriasis therapy. These drugs, which are derivatives of vitamin A, are only moderately effective as a monotherapy and are associated with numerous mucocutaneous side effects such as hair loss, cheilitis, and thinning of the nails. Teratogenicity limits use of retinoids in women of childbearing potential.

Methotrexate, which is used for cancer treatment, is an antimetabolite that inhibits DNA synthesis and prevents cell mitosis. Oral methotrexate has been effective in treating psoriasis when other approaches have failed. The drug has many side effects, including nausea, malaise, leukopenia, thrombocytopenia, and liver function abnormalities. Cyclosporine is a potent immunosuppressive drug used to prevent rejection of organ transplants. It suppresses inflammation and the proliferation of T cells in people with psoriasis. Its use is limited to severe psoriasis because of serious side effects, including nephrotoxicity, hypertension, and increased risk of cancers. Intralesional cyclosporine also has been effective. Biologic agents (e.g., infiximab, etanercept, efalizumab, and alefacept) that target the activity of T lymphocytes and cytokines responsible for the inflammatory nature of psoriasis have proven effective, not only with the skin lesions, but in halting the effects of the associated arthritis of psoriasis.

**Pityriasis Rosea**

Pityriasis rosea is a rash that primarily affects children and young adults. The origin of the rash is unknown, but is hypothesized to be triggered by a viral infection. Numerous viruses have been investigated, thus far with no conclusive evidence except for some support for human herpes virus 6 (HHV-6) or 7 (HHV-7). The incidence is highest in spring and fall. Cases occur in clusters and among people who live or work closely together, indicating an infectious spread. However, there are no data to support communicability. It may be an immune response to any number of agents.

The characteristic lesion is an oval macule or papule with surrounding erythema (Fig. 61.21). The lesion spreads with central clearing, much like tinea corporis. This initial lesion is a solitary lesion called the herald patch and is usually on the trunk or neck. However, there is not always a herald patch.
As the lesion enlarges and begins to fade (2 to 10 days), successive crops of lesions appear on the trunk and neck over the next 2 to 3 weeks. The lesions on the back have a characteristic “Christmas tree branch” pattern over the back. The extremities, face, and scalp may be involved more so with children and people of color. Mild to severe pruritus may occur. The disease is self-limited and usually disappears within 6 to 8 weeks. Treatment measures are palliative and include topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases.

**Lichen Planus**

Lichen planus is a skin disorder characterized by small (2 to 10 mm), flat-topped, violaceous papules with irregular, angulated borders (Fig. 61.22). Lichen planus is an uncommon chronic pruritic disease. It involves inflammation and papular eruption of the skin and mucous membranes. There are variations in the pattern of lesions (e.g., annular, linear) and differences in the sites (e.g., mucous membranes, genitalia, nails, scalp). The characteristic lesion is a purple, polygonal papule covered with a shiny, white, lacylike pattern. The lesions appear most frequently on the wrist, ankles, and trunk of the body. Most people who have skin lesions also have oral lesions, appearing as milky white lacework on the buccal mucosa or tongue. Other mucosal surfaces, such as the genital, nasal, laryngeal, otic, gastric, and anal areas, may also be affected. As with psoriasis, lichen planus lesions can develop on scratches or skin injuries and so can be secondary or primary lesions.

The etiology of lichen planus is unknown, but it is believed to be an abnormal immune response in which epithelial cells are recognized as foreign. The disorder involves the epidermal–dermal junction, with damage to the basal cell layer. Some cases of lichen planus have been linked to hepatitis C or B virus infections.

Diagnosis is based on the clinical appearance of the lesions and the histopathologic findings from a punch biopsy. For most people, lichen planus is a self-limited disease. Treatment measures include discontinuation of all medications, followed by treatment with topical corticosteroids and occlusive dressings. Occlusion may be used to enhance the effect of topical medications. Antipruritic agents are helpful in reducing itch. Systemic corticosteroids may be indicated in severe cases. Intraleional corticosteroid injections also may be used. Acitretin, an orally administered retinoid agent, also may be effective. Because retinoids are teratogenic, they should be avoided in women of childbearing age. Cyclosporine, tacrolimus, and other immunosuppressive agents have been helpful.

**Lichen Simplex Chronicus**

Lichen simplex chronicus or circumscribed neurodermatitis is a localized lichenoid pruritic dermatitis resulting from repeated rubbing and scratching. The term lichen simplex denotes the absence of a known predisposing skin disorder in the affected person. It is characterized by the occurrence of itchy, reddened, thickened, and scaly patches of dry skin. People with the condition may have a single or, less frequently, multiple lesions. The lesions are seen most commonly at the nape of the neck, wrists, ankles, or anal area. Women can experience this dermatosis on the vulva and complain of distressing vulvar pruritis that they worsen by constant itching.

The condition usually begins as a small pruritic patch, which after a repetitive cycle of itching and scratching develops into a chronic dermatosis. Because of the chronic itching and scratching, excoriations and lichenification with thickening of the skin develops, often giving the appearance of tree bark. Treatment consists of measures to decrease scratching of the area. A moderate-potency corticosteroid is often prescribed to decrease the itching and subsequent inflammatory process.

**Arthropod Infestations**

The skin is susceptible to a variety of disorders as a result of an invasion or infestation by arthropods, including mites and lice. The type of rash or sometimes singular lesion depends on the causative agent.

**Scabies**

A mite, *Sarcoptes scabiei*, which burrows into the epidermis, causes scabies. After a female mite is impregnated, she burrows into the skin and lays two to three eggs each day for 4 or 5 weeks. The eggs hatch after 3 to 4 days, and the larvae migrate to the skin surface. At this point, they burrow into the skin only for food or protection. The larvae molt and become nymphs; they molt once more to become adults. After the new adult females are impregnated, the cycle is repeated. Scabies is transmitted by person-to-person contact, including sexual
Types of Scabies. There are two types of scabies: Classic scabies and Norwegian (crusted) scabies. Classic scabies is characterized by a small burrow (e.g., 2 mm) lesion that may be red to reddish-brown. Small vesicles may cover the burrows. The areas most commonly affected are the interdigital web of the finger, flexor surface of the wrist, inner surface of the elbow, axilla, nipple, penis, belt line, and gluteal crease (Fig. 61.23). Pruritus is common and may result from the burrows, the fecal material of the mite, or both. Excoriations may develop from scratching, leaving the host vulnerable to secondary bacterial infections and severe skin lesions if left untreated. A second type of scabies is Norwegian or crusted scabies, which is a severe form of scabies that involves millions of mites. It differs from common contact. It also is transmitted by contact with mite-infested sheets in hospitals and nursing homes because the mite can live up to 2 days on sheets or clothing.

scabies in the large number of mites living on the host and a crust ing over of the infested region.44

**Diagnosis and Treatment** Diagnosis is done by skin scrapings. A positive diagnosis relies on the presence of mites, ova, or feces. The treatment is simple and curative. After bathing, permethrin, malathion, or other effective mite-killing agents are applied over the entire skin surface for 12 hours. Repeated applications may be recommended in certain cases, but one treatment usually is sufficient. Care must be taken to ensure that close contacts are treated. Clothes and towels are disinfected with hot water and detergent, or they can be isolated in a dark bag for 2 weeks. If symptoms persist after treatment, the person should be advised not to re-treat the condition without consulting a health care provider. Oral ivermectin, a broad-spectrum antiparasitic agent, has also been used successfully.

**Pediculosis**

_Pediculosis_ is the term for infestation with lice (genus _Pediculus_). Lice are gray, gray-brown, or red-brown, oval, wingless insects that live off the blood of humans and animals (Fig. 61.24). Lice are host specific; lice that live on animals do not transfer to humans and vice versa. Lice also are host dependent; they cannot live apart from the host beyond a few hours.

Three types of lice affect humans: _Pediculus humanus corporis_ (body lice), _Pthirus pubis_ (pubic lice), and _Pediculus humanus capitis_ (head lice).4 Although these three types differ biologically, they have similar life cycles. The life cycle of a louse consists of a “nit” or unhatched egg, three molt stages, an adult reproductive stage, and death. Before adulthood, lice live off the host and are incapable of reproduction. After fertilization, the female louse lays her eggs along hair shafts. The nits appear pearl-gray to brown. Depending on the site, a female louse can lay between 150 and 300 nits in her life. The life span of a feeding louse is 30 to 50 days.4 Lice are equipped with styles that pierce the skin. Their saliva contains an anticoagulant that prevents the host’s blood from clotting while the louse is feeding. A louse takes up to 1 mL of blood during a feeding.

**Pediculosis Corporis.** _Pediculosis corporis_ is infestation with _P. humanus corporis_, or body lice. The lice are transferred chiefly through contact with an infested person, clothing, or bedding. The lice live in clothes fibers, coming out only to feed—usually at night, causing nocturnal pruritus. Unlike pubic and head lice, the body louse can survive 10 to 14 days without the host.

The typical lesion is a macule at the site of the bite. Papules and wheals may develop. The infestation is pruritic and evokes scratching that brings about a characteristic linear excoriation. Eczematous patches are found frequently. Secondary lesions may become scaly and hyperpigmented and leave scars. Areas typically affected are the shoulders, trunk, and buttocks. The presence of nits in the seams of clothes confirms a diagnosis of body lice.

Treatment measures consist of eradicating the louse and nits on the body and on clothing. Dry cleaning, washing in hot water, or steam pressing clothes are recommended methods. Merely storing clothing in plastic bags for 2 weeks also rids clothes of lice. Many health care providers prefer

Pediculosis Pubis. Pediculosis pubis, the infestation known as crabs or pubic lice, is a disease spread by intimate contact with someone harboring P. pubis. The lice and nits are usually found in the pubic area of men and women, where their bites produce itching and erythematous lesions. Occasionally, they may be found in sites of secondary sex characteristics, such as the beard in men or the axillae in both sexes. Symptoms include intense itching and irritation of the skin. Diagnosis is made on the basis of symptoms and microscopic examination. The treatment is the same as for head lice.

Pediculosis Capitis. The incidence of pediculosis capitis, or infestation with head lice, is higher among girls, although hair length has not been indicated as a contributing factor. Infestations of head lice usually are confined to the nape of the neck and behind the ears. Less frequently, head lice are found on the beard, pubic areas, eyebrows, and body hairs. Although head lice can be transmitted by sharing combs and hats, they usually are spread from hair shaft to hair shaft through close personal contact. A positive diagnosis depends on the presence of firmly attached nits or live adult lice on hair shafts. Pruritus and scratching of the head are the primary indicators that head lice may be present. The scalp may appear red and excoriated from scratching (Fig. 61.25). In severe cases, the hair becomes matted together in a crusty, foul-smelling “cap.” An occasional morbilliform rash, which may be misdiagnosed as rubella, may occur with lymphadenopathy.

Head lice are treated with permethrin or malathion shampoos. Repeated treatments may be needed to eliminate the hatching nits. Dead nits may be removed with a fine-toothed comb or over-the-counter nit removal hair rinses. Over the years, permethrin- and malathion-resistant lice have evolved.

IN SUMMARY

Primary disorders of the skin include pigmentary skin disorders, infectious processes, inflammatory conditions, immune disorders, allergic reactions, and arthropod infestations. Pigmentary skin disorders include vitiligo, albinism, and melasma. Although the causes of the disorders vary, all involve changes in the amount of melanin produced by the melanocytes. These disorders appear in people of every skin type. However, the manifestations of the disorders vary among light-skinned and dark-skinned people.

Superficial fungal infections are called dermatophytooses and are commonly known as tinea or ringworm. Tinea can affect the whole body (tinea corporis), face and neck (tinea faciale), scalp (tinea capitis), hands (tinea manus), feet (tinea pedis), or nails (tinea unguium). The deep fungal infections invade the skin more deeply and go into living tissue and are also capable of involving other organs. Impetigo, which is caused by staphylococci or beta-hemolytic streptococci, is the most common superficial bacterial infection. Viruses are responsible for verrucae (warts), herpes simplex type 1 lesions (cold sores or fever blisters), and herpes zoster (shingles).

Noninfectious inflammatory skin conditions, such as acne, lichen planus, psoriasis, and pityriasis rosea, are of unknown origin. They usually are localized to the skin and are rarely associated with a specific internal disease. Allergic skin responses involve the body’s immune system and are caused by hypersensitivity reactions to allergens such as environmental agents, drugs, and other substances. They include contact dermatitis, atopic dermatitis, and drug-induced skin eruptions (erythema multiforme, Stevens-Johnson syndrome, and TEN).

The skin is also subject to invasion or infestation by a number of arthropod species, including scabies, which is caused by a mite (S. scabiei), and pediculosis, which is caused by lice. There are three types of lice that affect humans: P. humanus corporis (body lice), Phthirus pubis (pubic lice), and P. humanus capitis (head lice).
Skin Damage Caused by Ultraviolet Radiation

The skin is the protective shield against harmful UV rays from the sun. Skin cancers and other skin disorders such as early wrinkling and aging of the skin have been attributed to the damaging effects of sunlight.

Sunlight is measured in wavelengths of nanometers (nm; one billionth of a meter) ranging from approximately 290 nm in the UV region up to approximately 2500 nm in the infrared region. UV radiation (UVR) is divided into three types: UVC, UVB, and UVA. UVC rays are short (100 to 290 nm) and do not pass through the earth’s atmosphere. However, they can be produced artificially and are damaging to the eyes. UVB rays are 290 to 320 nm. Commonly referred to as sunburn rays, they are responsible for nearly all the skin effects of sunlight, including photoaging—the wrinkles, pigmented changes, dryness, and loss of skin tone that occur with and are enhanced by exposure to sunlight. UVA rays are 320 to 400 nm and can pass through window glass. They are further divided into short-wave UVAII (320 to 339 nm) and long-wave UVA1 (340 to 400 nm). Nonetheless, UVA, particularly UVA2, contributes greatly to skin alterations. Artificial sources of UVA, such as tanning salons and therapeutic solar interventions (PUVA) for certain skin conditions, also produce the same effects as UVB radiation.

The acute effects of UVA and UVB are short lived and reversible. They include erythema, pigmentation, and injury to Langerhans cells and keratinocytes in the epidermis. These reactions differ depending on whether the inciting agent is UVA or UVB. For example, UVA-induced erythema occurs immediately, fades within 2 hours, and is believed to be due to the “heat load.” UVB-induced erythema has a delayed response, peaking within 6 to 24 hours after exposure to sunlight and fading over 1 or 2 days. Pigmentation or tanning induced by UVA and UVB is due to a delayed increase in the number of melanocytes, elongation and extension of the dendritic processes, and transfer of melanin to keratinocytes. For tanning to occur, there must be UVA-induced erythema. Tanning induced by UVB is protective against subsequent exposures, whereas tanning induced by UVA provides limited protection.

Skin damage induced by UVB is believed to be caused by the generation of reactive oxygen species and by damage to melanin. This type of damage is referred to as photoaging. Solar elastosis is due to a large amount of abnormal, elastotic material in the upper dermis, which causes epidermal thickening and loss of elasticity. This causes deep and coarse wrinkles that never disappear. Cellular proteins and DNA are primarily damaged because of their abundance and ability to absorb UVR. Both UVA and UVB also deplete Langerhans cells and immune cells. Both UVA and UVB are now considered causes of cancer. UVA may actually be more carcinogenic than UVB. Although it causes less sunburn, UVA is present during all daylight hours, year-round. UVB, on the other hand, varies by season, location, and time of day. UVA penetrates deeply and causes greater damage in the keratinocytes, where most skin cancers arise.

Drug-Induced Photosensitivity

Some drugs are classified as photosensitive drugs because they produce an exaggerated response to UVR when the drug is taken in combination with sun exposure. Examples include some of the anti-infective agents (sulfonamides, tetracyclines, nalidixic acid), antihistamines (cyproheptadine, diphenhydramine), antipsychotic agents (phenothiazines, haloperidol), diuretics (thiazides, acetazolamide, amiloride), hypoglycemic agents (sulfonylureas), and nonsteroidal anti-inflammatory drugs (phenylbutazone, ketoprofen, naproxen).

Stopping the drug and switching to a non-photosensitivity-inducing drug can generally manage drug-induced sun damage. However, in some cases, the photosensitivity can continue for months to years even after the medication has been discontinued.

Sunburn

Sunburn is caused by excessive exposure of the epidermal and dermal layers of the skin to UVR, resulting in an erythematous inflammatory reaction. Sunburn ranges from mild to severe. Mild sunburn consists of various degrees of skin redness. The burn can continue to develop for another 1 or 2 days, occasionally followed by peeling skin. Some peeling and itching may continue for several weeks. Inflammation, blistering, weakness, chills, fever, malaise, and pain often accompany severe forms of sunburn. Scaling and peeling follow any overexposure to sunlight. Dark skin also burns and may appear grayish or gray-black. Severe sunburns are those that cover large portions of the body with blisters or are accompanied by a high fever or intense pain.

Mild to moderate sunburns are treated with anti-inflammatory medications, such as aspirin or ibuprofen, until redness and pain subside. Cold compresses, cool baths, and applying a moisturizing cream, such as aloe, to affected skin help treat the symptoms. Blisters should not be broken to preserve the protective layer of the skin, hasten the healing process, and decrease the risk of infection. Extensive
second- and third-degree burns may require hospitalization and specialized burn care techniques.

 prevented Skin Damage Caused by Ultraviolet Radiation
The UV rays of sunlight or other sources can be completely or partially blocked from the skin by sunscreens. There are three primary types of sunscreens available on the market: those that reduce or prevent UV erythema chemically, which causes the chemicals in the sunscreen to absorb the UVR; those that work physically by reflecting the UVR; and those that work biologically to block the inflammatory reaction.

Sunscreen products no longer contain para-aminobenzoic acid (PABA), a chemical blocking agent that protects against UVB, because of its allergenic and staining properties. However, PABA derivatives are used widely, but protect only against UVB. Broad-spectrum sunscreen products protect against both UVA and UVB. Sunscreen should be used diligently and according to the person’s tendency to burn rather than tan. Sunless suntan creams, such as dihydroxyacetone, produce a tan without exposure to the sun. They come in various tones, with emollients or humectants added for moisturizing or gel or alcohol-based products for drying.

Thermal Injury
About 450,000 people in the United States require medical care for burns each year, with 45,000 requiring hospitalization. The effects and complications of burns fully illustrate the essential function that the skin performs as it protects the body from the damaging elements in the environment while serving to maintain the constancy of the body’s internal environment. The massive loss of skin tissue not only predisposes to attack by microorganisms that are present in the environment, it allows for the massive loss of body fluids and their contents, it interferes with temperature regulation, it challenges the immune system, and it imposes excessive demands on the metabolic and reparative processes that are needed to restore the body’s interface with the environment.

Burns are caused by a number of sources. Flame burns occur because of exposure to direct fire. Scald burns result from hot liquids spilled or poured on the skin surface. In a child, a scald burn may be indicative of child abuse. Chemical burns occur from industrial agents used in occupational sites. Electrical burns occur from contact with live electrical wires in fields or in the home. Electrical burns are usually more extensive because of internal tissue injury and the presence of entrance and exit wounds. Lightning, electromagnetic radiation, and ionizing radiation also can cause skin burns.

Classification of Burns
Burns are typically classified according to the depth of involvement as first-degree, second-degree, and third-degree burns (see Fig. 61.26A). The depth of a burn is largely influenced by the duration of exposure to the heat source and the temperature of the heating agent.

First-Degree Burns. First-degree burns (superficial partial-thickness burns) involve only the outer layers of the epidermis. They are red or pink, dry, and painful. There usually is no blister formation. A mild sunburn is an example. The skin maintains its ability to function as a water vapor and bacterial }

**FIGURE 61.26** Classification of burns. Burns are classified according to thickness. (A) and (B) The rule of nines. (From McConnell T. H., Hull K. L. (2011). Human form human function: Essentials of anatomy & physiology (p. 159). Philadelphia, PA: Lippincott Williams & Wilkins.)
barrier and heals in 3 to 10 days. First-degree burns usually require only palliative treatment, such as pain relief measures and adequate fluid intake. Extensive first-degree burns on infants, older adults, and people who receive radiation therapy for cancer may require more care.

**Second-Degree Burns.** Second-degree burns involve both the epidermis and dermis. Second-degree partial-thickness burns involve the epidermis and various degrees of the dermis. They are painful, moist, red, and blistered. Underneath the blisters is weeping, bright pink or red skin that is sensitive to temperature changes, air exposure, and touch. The blisters prevent the loss of body water and superficial dermal cells. Excluding excision of large burn areas, it is important to maintain intact blisters after injury because they serve as a good bandage and may promote wound healing. These burns heal in approximately 1 to 2 weeks.

Second-degree full-thickness burns involve the entire epidermis and dermis. Structures that originate in the subcutaneous layer, such as hair follicles and sweat glands, remain intact. These burns can be very painful because the pain sensors remain intact. Tactile sensation may be absent or greatly diminished in the areas of deepest destruction. These burns appear as mottled pink, red, or waxy white areas with blisters and edema. The blisters resemble flat, dry tissue paper, rather than the bullous blisters seen with superficial partial-thickness injury. After healing, in approximately 1 month, these burns maintain their softness and elasticity, but there may be the loss of some sensation. Scar formation is usual. These burns heal with supportive medical care aimed at preventing further tissue damage, providing adequate hydration, and ensuring that the granular bed is adequate to support reepithelialization.

**Third-Degree Burns.** Third-degree full-thickness burns extend into the subcutaneous tissue and may involve muscle and bone. Thrombosed vessels can be seen under the burned skin, indicating that the underlying vasculature is involved. Third-degree burns vary in color from waxy white or yellow to tan, brown, deep red, or black. These burns are hard, dry, and leathery. Edema is extensive in the burn area and surrounding tissues. There is no pain because the nerve sensors have been destroyed. However, there is no such thing as a “pure” third-degree burn. Third-degree burns are almost always surrounded by second-degree burns, which are surrounded by an area of first-degree burns. The injury sometimes has an almost target-like appearance because of the various degrees of burn. Full-thickness burns wider than 1.5 inches usually require skin grafts because all the regenerative (i.e., dermal) elements have been destroyed. Smaller injuries usually heal from the margins inward toward the center, the dermal elements regenerating from the healthier margins. However, regeneration may take many weeks and leave a permanent scar, even in smaller burns (Table 61.1).

**Extent of the Burn.** In addition to the depth of the wound, the extent of the burn also is important. Extent is measured by estimating the amount of total body surface area (TBSA) involved. Several tools exist for estimating the TBSA. For example, the rule of nines counts anatomic body parts as multiples of 9% (the head is 9%, each arm 9%, each leg 18%, anterior trunk 18%, posterior trunk 18%), with the perineum 1% (see Fig. 61.26B). Other factors, such as age, location, other injuries, and preexisting conditions, must be assessed in order to manage best practice of the burn injury. These factors can increase the assessed severity of the burn and the length of treatment. For example, a first-degree burn is reclassified as a more severe burn if other factors are present, such as burns to the hands, face, and feet; inhalation injury; electrical burns; other trauma; or existence of psychosocial problems. Genital burns almost always require hospitalization because edema may cause difficulty urinating and the location complicates maintenance of a bacteria-free environment.

**Systemic Complications**

Burn victims often experience multiple life-threatening complications such as hemodynamic instability, respiratory failure, infection, and even multiple-organ dysfunction (MOD). The magnitude of the response is proportional to the extent of injury, usually reaching a plateau when approximately 60% of the body is burned. In addition to loss of skin, people with burns often have associated injuries or illnesses. The treatment challenge is to provide immediate resuscitation efforts and long-term maintenance of physiologic function. Pain and emotional problems are additional challenges faced by people with burns.

**Hemodynamic Instability.** Hemodynamic instability begins almost immediately with injury to capillaries in the burned area and surrounding tissue. Fluid is lost from the vascular, interstitial, and cellular compartments. Because of a loss of vascular volume, people with major burns often present in the emergency department in a form of hypovolemic shock known as burn shock. Evidence suggests that lactate serum level at admission can predict which people in burn shock are going to benefit from therapeutic plasma exchange (TPE). The person has a decrease in cardiac output, increased peripheral vascular resistance, and impaired perfusion of vital organs. Electrical injuries that cause burns can produce cardiac arrhythmias that require immediate attention.

**Respiratory System Dysfunction.** Another injury commonly associated with burns is smoke inhalation and postburn lung injury. People often are trapped in a burning structure and inhale significant amounts of smoke, carbon monoxide, and other toxic fumes. Water-soluble gases, such as ammonia, sulfur dioxide, and chlorine that are found in smoke from burning plastics and rubber react with mucous membranes to form strong acids and alkalis that induce ulceration of the mucous membrane, bronchospasm, and edema. Lipid-soluble gases, such as nitrous oxide and hydrogen chloride, are transported to the lower airways, where they damage lung tissue. There also may be thermal injury to the respiratory passages. Manifestations of inhalation injury include hoarseness, drooling, an inability to handle secretions, hacking cough, and

Labored and shallow breathing. Serial blood gases show a fall in the partial pressure of arterial oxygen (PO$_2$). Signs of mucosal injury and airway obstruction often are delayed for 24 to 48 hours after a burn. It is necessary continually to monitor the patient for early signs of respiratory distress. Other pulmonary conditions, such as pneumonia, pulmonary embolism, or pneumothorax, may occur secondarily to the burn.

**Hypermetabolic Response.** The stress of burn injury increases metabolic and nutritional requirements. Secretion of stress-related hormones such as catecholamines and cortisol is increased in an effort to maintain homeostasis. Heat production is increased in an effort to balance heat losses from the burned area. Hypermetabolism, characterized by increased oxygen consumption, increased glucose use, and protein and fat wasting, is a characteristic response to burn trauma and infection. The hypermetabolic state peaks at approximately 7 to 17 days after the burn, and tissue breakdown diminishes as the wounds heal. Nutritional support is essential to recovery from burn injury. Enteral and parenteral hyperalimentation may be used during this time to deliver sufficient nutrients to prevent tissue breakdown and postburn weight loss.

**Dysfunction of Other Organ Systems.** Burn shock results in impaired perfusion of vital organs. The person may have impaired function of the kidneys, the gastrointestinal tract, and the nervous system. Although the initial insult often is one of hypovolemic shock and impaired organ perfusion, sepsis may contribute to impaired organ function after the initial resuscitation period.

Renal insufficiency can occur in people with burns as a result of the hypovolemic state, damage to the kidneys at the
time of the burn, or drugs that are administered. Immediately after the burn, a person goes into a short period of relative anuria, followed by a phase of hypermetabolism characterized by increased urine output and nitrogen loss.

The effects of burn injury on the gastrointestinal tract include increased secretion, increased motility, and decreased peristalsis. These effects are compounded by immobilization and narcotic analgesics. People with burns are observed carefully for vomiting and fecal impaction. Acute ulceration of the stomach and duodenum (called *Curling ulcer*) is a potential complication in burn victims and is thought to be the result of stress and gastric ischemia. It is largely controlled by the prophylactic administration of proton pump inhibitors. Enteral feeding tubes are inserted almost immediately. Tube feeding is intended to mitigate ulcer formation, maintain the integrity of the intestinal mucosa, and provide sufficient calories and protein for the hypermetabolic state.

Neurologic changes can occur from periods of hypoxia. Neurologic damage may result from head injuries, drug or alcohol abuse, carbon monoxide poisoning, fluid volume deficits, and hypovolemia. With an electrical burn, the brain or spine can be directly injured. The responses to neurologic damage may include confusion, memory loss, insomnia, lethargy, and combative ness.

Musculoskeletal effects include fractures that occur at the time of the accident, deep burns extending to the muscles and bone, hypertrophic scarring, and contractures. The hypermetabolic state increases tissue catabolism and produces severe protein and fat wasting.

**Sepsis.** A significant complication of the acute phase of burn injury is sepsis. It may arise from the burn wound, pneumonia, urinary tract infection, infection elsewhere in the body, or the use of invasive procedures or monitoring devices. Immunologically, the skin is the body’s first line of defense. When the skin is no longer intact, the body is open to bacterial infection. Destruction of the skin also prevents the delivery of cellular components of the immune system to the site of injury. There also is loss of normal protective skin flora and a shift to colonization by more pathogenic flora.

**Emergency and Long-Term Treatment**

Regardless of the type of burn, it is first priority to stop the fire and provide relief to the affected people. The heat source should be removed, and flames should be doused with water or smothered with a blanket. Active cooling removes the heat and prevents progression of the burn. Immersion or irrigation with lukewarm water for at least 20 minutes can be extremely helpful. This period should be increased for those with chemical burns. Immediate submersion is more important than removal of clothing, which may delay cooling the involved areas. The application of ice or cold water is not recommended because it can further limit blood flow to an area, turning a partial-thickness into a full-thickness burn.

Depending on the depth and extent of the burn, medical treatment is necessary. Emergency care consists of resuscitation and stabilization with intravenous fluids while maintaining cardiac and respiratory function. Once hospitalized, the immediate treatment regimen focuses on continued maintenance of cardiorespiratory function, pain alleviation, wound care, and emotional support. Intermediate and long-term treatments depend on the extent of injury.

After hemodynamic and pulmonary stability have been established, treatment is directed toward initial care of the wound. Treatment of the burn wound focuses on protection from desiccation and further injury of those burn areas that reepithelialize in 7 to 10 days (superficial second-degree burns). "Nature’s own blister" is the best protection for these burns. Topical antimicrobial preparations (*e.g.*, silver sulfadiazine) and dressings are used to cover the wound when the blister has been broken. Wounds that will not heal spontaneously in 7 to 10 days (deep second-degree and third-degree burns) are usually treated by excision and skin grafts. The sloughed tissue, or eschar, produced by the burn is excised as soon as possible. This decreases the chance of infection and allows the skin to regenerate faster.

Burns that encircle the entire surface of the body or a body part (*e.g.*, arms, legs, torso) act like tourniquets and can cause major tissue damage to the muscles, tendons, and vasculature under the area of the leathery eschar skin. These burns are called *circumferential burns*. The eschar is incised longitudinally (escharotomy), and sometimes a fasciectomy (surgical incision through the fascia of the muscle) is performed. The timing of these incisions is important. Incision is done after the patient’s circulatory condition stabilizes to some degree, thereby limiting some of the massive fluid loss. However, the incisions must be done before eschar formation can cause hypoxia and necrosis of the underlying tissues and organs. This is extremely important when torso burns occur because the pressure placed on the chest can result in an inability to breathe and decreased blood return to the heart.

Systemic infection remains a leading cause of morbidity among persons with extensive burns. Continuous microbiologic surveillance is necessary; protective isolation measures are often instituted. There is an increasing trend toward use of prophylactic antibiotic treatment in persons with major burns.

Skin grafts are surgically implanted as soon as possible, often at the same time the burn tissue is excised, to promote new skin growth, limit fluid loss, and act as a dressing. Skin grafts can be permanent or temporary, and split thickness or full thickness. Permanent skin grafts are used over newly excised tissue. Temporary skin grafts are used to cover a burned area until the tissue underneath it has healed.

**Various sources of skin grafts exist:** autograft (skin obtained from the person’s own body), homograft (skin obtained from another human being, alive or recently dead), and heterograft (skin obtained from another species, such as pigs). The best choice is autografting when there is enough uninterrupted skin on the person’s body. The thickness of these grafts depends on the donor site and the needs of the burn patient. A split-thickness skin graft is one that includes the epidermis and part of the dermis. A split-thickness skin...
Methods for preventing pressure ulcers include frequent position change, meticulous skin care, and frequent and conscientious shift of body weight to redistribute pressure on the skin. The same is true for sitting for any length of time. The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

**Mechanisms of Development**

Multiple factors contribute to the development of pressure ulcers including other comorbidities such as type 2 diabetes, pressure from positioning and body weight, sweating and/or incontinence are just to name a few. External pressures that exceed capillary pressure interrupt blood flow in the capillary beds. When the pressure between a bony prominence and a support surface exceeds the normal capillary filling pressure, capillary flow essentially is obstructed. If this pressure is applied constantly for 2 hours, oxygen deprivation coupled with an accumulation of metabolic end products leads to irreversible tissue damage. People with impaired circulation will require less pressure to interrupt circulation so they are at even higher risk of developing a pressure ulcer. The same amount of pressure causes more damage when it is distributed over a small area than over a larger area.

Whether a person is sitting or lying down, the weight of the body is borne by tissues covering the bony prominences. Most pressure ulcers are located on the lower part of the body, most often over the sacrum and on bony prominences. Pressure over a bony area is transmitted from the surface to the underlying dense bone, compressing all of the intervening tissue. As a result, the greatest pressure occurs at the surface of the bone and dissipates outward in a conelike manner toward the surface of the skin. Thus, extensive underlying tissue damage can be present when a small superficial skin lesion is first noticed.

Altering the distribution of pressure from one skin area to another prevents tissue injury. Pressure ulcers most commonly occur in people with conditions such as spinal cord injury in which normal sensation and movement to effect redistribution of body weight are impaired. Normally, people unconsciously shift their weight to redistribute pressure on the skin and underlying tissues. For example, during the night, people turn in their sleep, preventing ischemic injury of tissues that overlie the bony prominences that support the weight of the body; the same is true for sitting for any length of time. The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

**Shearing forces** are caused by the sliding of one tissue layer over another with stretching and angulation of blood vessels, causing injury and thrombosis. Shear occurs when the skeleton moves, but the skin remains fixed to an external surface, such as occurs with transfer from a stretcher to a bed or pulling a person up in bed. The same thing happens when the head of the bed is elevated, causing the torso to move toward the foot of the bed while friction and moisture cause the skin to remain fixed to the bed linens. **Friction** contributes to pressure ulceration by damaging the skin at the epidermal–dermal interface. It occurs as persons who are bedridden use their elbows and heels to aid in movement. **Moisture** contributes to pressure ulcer formation by weakening the cell wall of individual skin cells and by changing the protective pH of the skin. This makes the skin more susceptible to pressure, shear, and friction injury.

**Prevention**

The prevention of pressure ulcers is preferable to their treatment. The Agency for Healthcare Research and Quality is firm in its conviction that using the Prevention of Pressure Ulcers Tool kit will be effective in decreasing the number of decubitus ulcers.48

Risk factors identified as contributing to the development of pressure ulcers were those related to sensory perception (i.e., ability to respond meaningfully to pressure-related discomfort), level of skin moisture, urine and fecal incontinence, nutrition and hydration status, mobility, circulatory status, and presence of shear and friction forces.

Methods for preventing pressure ulcers include frequent position change, meticulous skin care, and frequent and conscientious shift of body weight to redistribute pressure on the skin.
with little exudate are treated with semipermeable or occlusive dressings. The occlusive dressing can assist with epithelial cell migration by keeping the wound fluid. Wound fluid is thought to contain a variety of growth factors that enhance wound healing. Occlusive dressings may also relieve wound pain and prevent bacterial contamination. There are several types of occlusive dressings available, including polymer films, hydrogels, hydrocolloids, biomembranes, and absorbing granules. The available products differ in their permeability to water vapor and wound protection, and each has advantages and disadvantages.

Necrotic debris increases the possibility of bacterial infection and delays wound healing. Stage III ulcers with exudate and necrotic debris and stage IV ulcers usually require debridement (i.e., removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes. Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

Careful observation to detect early signs of skin breakdown. Moisture macerates and injures skin. Sources of moisture include sweat, wound drainage, urine, and feces. Both urinary and fecal incontinence increase the risk of pressure ulcers. Food crumbs, intravenous tubing, and other debris in the bed can greatly increase local skin pressure points. The prevention of dehydrating the patient improves the circulation. It also decreases the concentration of urine, thereby minimizing skin irritation in people who are incontinent, and it reduces urinary problems that contribute to incontinence. Maintenance of adequate nutrition is important (see Table 61.2). Anemia and malnutrition contribute to tissue breakdown and delay healing after tissue injury has occurred.

**Staging and Treatment**

Pressure ulcers can be staged using four categories. Stage I ulcers are characterized by a defined area of persistent redness in lightly pigmented skin or an area of persistent redness with blue or purple hues in darker skin. Stage II ulcers represent a partial-thickness loss of skin involving the epidermis or dermis, or both. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater. Stage III ulcers represent a full-thickness skin loss involving damage and necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer manifests as a deep crater with or without undermining of adjacent tissue. Stage IV ulcers involve full-thickness skin loss and necrosis with extensive destruction or damage to the underlying subcutaneous tissues that may extend to involve muscle, bone, and supporting structures (e.g., tendon or joint capsule) (Table 61.3).

After skin breakdown has occurred, special treatment measures are needed to prevent further ischemic damage, reduce bacterial contamination and infection, and promote healing. Stage I ulcers usually are treated with frequent turning and measures to remove pressure. Stage II or III ulcers with little exudate are treated with semipermeable or occlusive dressings. The occlusive dressing can assist with epithelial cell migration by keeping the wound fluid. Wound fluid is thought to contain a variety of growth factors that enhance wound healing. Occlusive dressings may also relieve wound pain and prevent bacterial contamination. There are several types of occlusive dressings available, including polymer films, hydrogels, hydrocolloids, biomembranes, and absorbing granules. The available products differ in their permeability to water vapor and wound protection, and each has advantages and disadvantages.

Necrotic debris increases the possibility of bacterial infection and delays wound healing. Stage III ulcers with exudate and necrotic debris and stage IV ulcers usually require debridement (i.e., removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes. Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

**Repeated exposure to the UV rays of the sun predisposes to**

sunburn, premature aging of the skin (wrinkling, solar elastosis, and irregularities in pigmentation), and skin cancer. Solar and artificial sources of UVR, such as from a tanning parlor, contribute to the amount of radiation to which human beings are exposed. Sunburn, which is caused by excessive exposure to UVR, is an erythematos inflammatory reaction, ranging from mild to severe. Photosensitive drugs can also produce an exaggerated response to UVR when they are taken in combination with sun exposure. Sunscreens are protective agents that work by either reflecting sunlight or preventing its absorption.

Burns cause damage to skin structures, ranging from first-degree burns, which damage the epidermis, to third-degree full-thickness burns, which extend into the subcutaneous tissue and may involve muscle and bone. The extent of injury is determined by the thickness of the burn and the TBSA involved. In addition to skin involvement, burn injury can cause hemodynamic instability with hypovolemic shock, inhalation injury with respiratory involvement, a hypermetabolic state, organ dysfunction, immune suppression and sepsis, pain, and emotional trauma. Treatment methods vary with the severity of injury and include immediate resuscitation and maintenance of physiologic function, wound cleaning and debridement, application of antimicrobial agents and dressings, and skin grafting. Efforts are directed toward preventing or limiting disfigurement and disability.
Pressure ulcers are caused by ischemia of the skin and underlying tissues. They result from external pressure, which disrupts blood flow, or shearing forces, which cause stretching and injury to blood vessels. Pressure ulcers are divided into four stages, according to the depth of tissue involvement. The prevention of pressure ulcers is preferable to their treatment. The goals of prevention should include identifying at-risk persons who need prevention along with the specific factors placing them at risk; maintaining and improving tissue tolerance to pressure to prevent injury; and protecting against the adverse effects of external mechanical forces (i.e., pressure, friction, and shear).

**NEVI AND SKIN CANCERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the origin of nevi and state their relationship to skin cancers.
- Compare the appearance and outcome of basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and malignant melanoma.

**Nevi**

Nevi, or moles, are common congenital or acquired tumors of the skin that are benign. Almost all adults have nevi, some in greater numbers than others. Nevii can be pigmented or nonpigmented, flat or elevated, and hairy or nonhairy.

**Nevocellular nevi** are pigmented skin lesions resulting from proliferation of melanocytes in the epidermis or dermis. Nevocellular nevi are tan to deep brown, uniformly pigmented, small papules with well-defined, rounded borders (Fig. 61.27). They are formed initially by melanocytes with long dendritic extensions that are normally interspersed among the basal keratinocytes. The melanocytes are transformed into round or oval melanin-containing cells that grow in nests or clusters along the dermal–epidermal junction. Because of their location, these lesions are called **junctional nevi** or active nevi. Eventually, most junctional nevi grow into the surrounding dermis as nests or cords of cells. **Compound nevi** contain epidermal and dermal components. In older lesions, the epidermal nests may disappear entirely, leaving a **dermal nevus**. Compound and dermal nevi usually are more elevated than junctional nevi.

Another form of nevus, the **dysplastic nevus**, is important because of its capacity to transform into malignant melanoma. Dysplastic nevi are usually larger than other nevi (often >5 to 15 mm in diameter). Their appearance is a flat, slightly raised plaque with a pebbly surface, or a target-like lesion with a darker, raised center and irregular border. They vary in shade from brown and red to flesh tones. A person may have hundreds of these lesions. Unlike other moles or nevi, they occur on both sun-exposed and covered areas of the body. Dysplastic nevus syndromes have been documented in multiple members of families prone to development of malignant melanoma, and the condition is referred to as familiar atypical malignant melanoma (FAMM). Whereas a person who has this syndrome without a family history are classified as sporadic atypical malignant melanoma (SAMM). People with this syndrome tend to have larger nevi with irregular borders, and the color of the nevus is a random blending of tan, black, pink, and brown.

Because of the possibility of malignant transformation, any mole that undergoes a change warrants immediate medical attention. The changes to observe and report are changes in size, thickness, or color, itching, and bleeding.

**Skin Cancer**

There has been an alarming increase in skin cancers over the past several decades. In 2011, there were approximately 70,230 new cases of melanoma with 40,010 in men and 30,200 in women in the United States. There were also approximately 2.2 million cases per year of highly curable nonmelanoma (basal cell and squamous cell) cancers. The rising incidence of skin cancer has been attributed to increased sun exposure associated with social and lifestyle changes. The thinning of the ozone layer in the earth’s stratosphere is thought to be another factor in this increased incidence. Society’s emphasis on sun tanning also is implicated. People tend to have more leisure time and spend increasing amounts of time in the sun with uncovered skin.

Although the factors linking sun exposure to skin cancer are not completely understood, both total cumulative exposure and altered patterns of exposure are strongly implicated. BCC and SCC are often associated with total cumulative exposure to UVR. Thus, BCC and SCC occur more commonly on maximally sun-exposed parts of the body, such as the face and back of the hands and forearms. Melanomas occur most commonly on areas of the body that are exposed to the sun intermittently, such as the back in men and the lower legs in women.
Malignant Melanoma

Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. The dramatic increase in the incidence of malignant melanoma over the past several decades has been credited to increased UVR exposure, including tanning salons. Public health screening measures, early diagnosis, increased knowledge of precursor lesions, and greater public knowledge of the disease may account for earlier intervention.

The risk is greatest in fair-skinned people, particularly those with blond or red hair who sunburn and freckle easily. Other risk factors include a family history of malignant melanoma, presence of marked freckling on the upper back, history of three or more blistering sunburns before 20 years of age, and presence of actinic keratoses. Still other significant risk factors for melanoma are atypical mole/dysplastic nevus syndrome, immunosuppression, and prior PUVA therapy.

Severe, blistering sunburns in early childhood and intermittent intense sun exposures contribute to increased susceptibility to melanoma in young- and middle-aged adults. Roughly 90% of malignant melanomas in whites occur on sun-exposed skin. However, in darker-skinned people, melanomas often occur on non–sun-exposed areas, such as the mucous membranes and subungual, palmar, and plantar surfaces.

Clinical Manifestations. Malignant melanomas differ in size and shape. Usually, they are slightly raised and black or brown. Borders are irregular and surfaces are uneven. Most seem to arise from preexisting nevi or new mole-like growths. There may be surrounding erythema, inflammation, and tenderness. Periodically, melanomas ulcerate and bleed. Dark melanomas are often mottled with shades of red, blue, and white. These three colors represent three concurrent processes: melanoma growth (blue), inflammation and the body’s attempt to localize and destroy the tumor (red), and scar tissue formation (white).

There are four types of melanomas including superficial spreading, nodular, lentigo maligna, and acral lentiginous. **Superficial spreading melanoma** is characterized by a raised-edged nevus with lateral growth. It has a disorderly appearance in color and outline. This lesion tends to have biphasic growth, horizontally and vertically. It typically ulcerates and bleeds with growth. These lesions account for two thirds of all melanomas and are most prevalent in people who sunburn easily and have intermittent sun exposure. **Nodular melanomas**, which account for 15% of melanomas, are raised, dome-shaped lesions that can occur anywhere on the body, but most frequently on the trunk, head, and neck. They are commonly a uniform blue-black color and tend to look like blood blisters. Nodular melanomas tend to rapidly invade the dermis from the start, with no apparent horizontal growth phase. **Lentigo maligna melanomas**, which account for 5% of all melanomas, are slow-growing, flat nevi that occur primarily on sun-exposed areas of older adults. Untreated lentigo maligna tends to exhibit horizontal and radial growth for many years before it invades the dermis to become lentigo maligna melanoma. **Acral lentiginous melanoma**, which accounts for 10% of melanomas, occurs primarily on the palms, soles, nail beds, and mucous membranes. This melanoma has the worse prognosis of all of the melanomas but is not frequently seen. It has the appearance of lentigo maligna.

Detection and Diagnosis. Early detection is critical with malignant melanoma. Regular self-examination of the total skin surface in front of a well-lighted mirror provides a method for early detection. It requires that a person undress completely and examine all areas of the body using a full mirror, handheld mirror, and handheld hair dryer (to examine the scalp). An **ABCD** rule has been developed to aid in early diagnosis and timely treatment of malignant melanoma (Fig. 61.28) This acronym represents asymmetry, border irregularity, color variegation, and diameter greater than 6 mm (14 inch or pencil eraser size). People should be taught to watch for these changes in existing nevi or the development of new nevi, as well as other alterations such as bleeding or itching.

Diagnosis of melanoma is based on biopsy findings from a lesion. Consistent with other cancerous tumors, melanoma is commonly staged using the TNM (tumor, lymph node, and metastasis) staging system or the 2001 American Joint Committee on Cancer Staging System for Cutaneous Melanoma, in which the tumor is rated 0 to 4, with further subclassifications depending on numerous factors, including extent of tumor invasion, ulceration, and metastasis. Ulceration and invasion of the tumor into the deeper skin tissue result in a poorer prognosis.

Treatment. Treatment is usually surgical excision, the extent of which is determined by the thickness of the lesion, invasion into the deeper skin layers, and spread to the regional lymph nodes. When diagnosed in a premetastatic phase, melanoma is now treated in ambulatory settings, lessening the cost and inconvenience of care. Current capability allows for mapping lymph flow to a regional lymph node that receives lymphatic drainage from tumor sites on the skin. This lymph node, which is called the **sentinel lymph node**, is then sampled for biopsy. If tumor cells have spread from the primary tumor to the regional lymph nodes, the sentinel node will be the first node in which tumor cells appear. Therefore, sentinel node...
biopsy can be used to test for the presence of melanoma cells and determine if radical lymph node dissection is necessary.

Routine cancer treatment, such as chemotherapy, is indicated when the disease becomes systemic. Despite many interventions used over the years, efforts to cure melanoma in its later stages have been disappointing. However, there is promise in vaccine development or immunotherapy. Vaccines are targeted to prevent the recurrence of melanoma, especially in stages II and III.

**Basal Cell Carcinoma**

BCC, which is a neoplasm of the nonkeratinizing cells of the basal layer of the epidermis, is the most common skin cancer in light-skinned people (Fig. 61.29). Like other skin cancers,
BCC has increased in incidence over the past several decades. Fair-skinned people with a history of significant long-term sun exposure are more susceptible. Black- and brown-skinned people are affected occasionally. BCC usually occurs in people who were exposed to great amounts of sunlight. Of the 2,200,000 annually diagnosed skin cancers, the majority are BCCs.\(^1\)\(^4\)

BCC usually is a nonmetastasizing tumor that extends wide and deep if left untreated.\(^2\) These tumors are most frequently seen on the head and neck, most often occurring on skin that has hair. They also occur on skin surfaces unexposed to the sun, although less frequently. There are several histologic types of BCC, with many types being slow growing and many fast growing.\(^4\) Some of the more aggressive BCCs are called sclerosing, morpheaform, micronodular, and infiltrative BCC.\(^3\) Nodular ulcerative and superficial BCCs are the two most frequently occurring types. Nodular ulcerative BCC is the most common BCC and has a nodulocystic structure that manifests as a pinkish translucent papule, which grows larger over time. Telangiectatic vessels are often associated with nodular BCC. Over the years, a central depression forms that progresses to an ulcer surrounded by the original shiny, waxy border. BCC in darker-skinned people usually is darkly pigmented and frequently misdiagnosed as other skin diseases, including melanoma.

The second-most common form and less aggressive BCC is superficial BCC, which is seen most often on the chest or back.\(^3\) It begins as a flat, nonpalpable, erythematous plaque. The red, scaly areas slowly enlarge, with nodular borders and telangiectatic bases. Generally there is a thin, raised, white border that surrounds the BCC.\(^3\) This type of skin cancer is difficult to diagnose because it mimics other skin problems.

BCCs develop from basal keratinocytes of the epidermis.\(^2\) With the DNA damage from the UVB, the immunological response can be triggered to cause cancerous changes in the cells.\(^3\) Although the BCC does not usually metastasize via blood vessels or the lymph system, the BCC can enlarge slowly or rapidly, solely by extension.\(^3\)

Biopsies are obtained from all suspected BCCs for diagnosis. It is highly curable if detected and treated early. The treatment depends on the site and extent of the lesion. The most important treatment goal is complete elimination of the lesion. Also important is the maintenance of function and optimal cosmetic effect. Curettage with electrodesiccation, surgical excision, irradiation, laser, cryosurgery, and chemotherapy are effective in removing all cancerous cells. Immune therapy, gene therapy, and photodynamic therapy are emerging treatments. People should be checked at regular intervals for recurrences.

**Squamous Cell Carcinoma**

SCCs are the second-most common malignant tumors of the outer epidermis and account for 10% to 20% of all skin cancers.\(^3\)\(^5\)\(^4\) The increase in the incidence of SCCs is consistent with increased UVR exposure. There is also a strong occupational hazard link to the development of SCC. People exposed to arsenic (i.e., Bowen disease, which is also called SCC in situ), industrial tars, coal, and paraffin have an increased likelihood of contracting SCC. Men are twice as likely as women to have SCC. Dark-skinned people are rarely affected.

There are two types of SCC: intraepidermal and invasive. Intraepidermal SCC remains confined to the epidermis for a long time. However, at some unpredictable time, it penetrates the basement membrane to the dermis and metastasizes to the regional lymph nodes (Fig. 61.30). SCC has a significant risk for metastasis in contrast to BCC. It then converts to invasive SCC. The invasive type can develop from intraepidermal carcinoma or from a premalignant lesion (e.g., actinic keratoses). It may be slow growing or fast growing with metastasis.

SCC is a red-scaling, keratotic, slightly elevated lesion with an irregular border, usually with a shallow chronic ulcer. The lesions usually lack the pearly rolled border and superficial telangiectases found on BCCs. Later, lesions grow outward, show large ulcerations, and have persistent crusts and raised, erythematous borders. The SCC lesions occur on sun-exposed areas of the skin, particularly the nose, forehead, helix of the ear, lower lip, and back of the hand.

**Lauren** requests to see a physician regarding her keloid. She wants to be sure it is not skin cancer since she feels it might have been mistakenly diagnosed as a keloid. She feels it should be checked out and that a biopsy should be taken. She says it looks like a type of skin cancer she has seen on the Internet, and she is also worried because she has had previous sunburns on her face, including her ear. The physician reassures her it is a keloid and is a direct result of excessive formation of collagen corneum secondary to the ear piercing. Lauren finally accepts the diagnosis and vows never to have a piercing again. She also vows to always use sunscreen and to stay out of the sun as much as she can.
In dark-skinned black people, the lesions may appear as hyperpigmented nodules and occur more frequently on non-sun-exposed areas. Metastasis is more common with SCC than with BCC.37

Treatment measures are aimed at the removal of all cancerous tissue using methods such as electrosurgery, excision surgery, chemo surgery, or radiation therapy. After treatment, the person is observed for the remainder of his or her life for signs of recurrence.

**IN SUMMARY**

Nevi or moles usually are benign. Because they may undergo cancerous transformation, any mole that undergoes a change warrants immediate medical attention. There has been an alarming increase in skin cancers over the past few decades. Repeated exposure to the UV rays of the sun has been implicated as the principal cause of skin cancer. Neoplasms of the skin include malignant melanoma, BCC, and SCC.

Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. Clinically, malignant melanoma of the skin usually is asymptomatic. The most important clinical sign is the change in size, shape, and color of pigmented skin lesions, such as moles. As the result of increased public awareness, melanomas are being diagnosed earlier, when they can be cured surgically. SCC and BCC are of epidermal origin.

BCCs are the most common form of skin cancer among whites. They are slow-growing tumors that rarely metastasize. The two types of SCC are intraepidermal and invasive. Intraepidermal SCC remains confined to the epidermis for a long time. Invasive SCC can develop from intraepidermal carcinoma or from premalignant lesions such as actinic keratoses.

**Skin Manifestations of Infancy and Childhood**

**Skin Disorders of Infancy**

Infancy connotes the image of perfect, unblemished skin. For the most part, this is true. However, several congenital skin lesions, such as mongolian spots, hemangiomas, and nevi, are associated with the early neonatal period. There are also several acquired skin conditions, including diaper dermatitis, prickly heat, and cradle cap, that are relatively common in infants.

**Pigmented and Vascular Birthmarks.** Pigmented and vascular lesions comprise most birthmarks. Pigmented birthmarks represent abnormal migration or proliferation of melanocytes. For example, mongolian spots are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are seen commonly in Asian and dark-skinned people. Nevii or moles are small, tan to brown, uniformly pigmented solid macules. Nevocellular nevi are formed initially from aggregates of melanocytes and keratinocytes along the dermal–epidermal border. Congenital melanocytic nevi are collections of melanocytes that are present at birth or develop within the first year of life. They present as macular, papular, or plaque-like pigmented lesions of various shades of brown, with a black or blue focus. The texture of the lesions varies and they may be with or without hair. They usually are found on the hands, shoulders, buttocks, entire arm, or trunk of the body. Some involve large areas of the body in garment-like fashion. They usually grow proportionately with the child. Congenital melanocytic nevi are clinically significant because of their association with malignant melanoma.

Vascular birthmarks are cutaneous anomalies of angiogenesis and vascular development. Two types of vascular birthmarks commonly are seen in infants and small children: bright red, raised hemangiomas of infancy and flat, reddish-purple port-wine stains.

**Hemangiomas of infancy** are small, red lesions that are noticed shortly after birth. Hemangiomas of infancy are generally benign vascular tumors produced by proliferation of vascular endothelial cells4 (Fig. 61.31). A small proportion of these lesions are present at birth, and the remainder develop within a few weeks after birth.3 Girls are three times more likely to have hemangiomas than boys.3

Hemangiomas of infancy typically undergo an early period of a proliferation during which they enlarge, followed by a period of slow involution where the growth is reversed until complete resolution generally by 5 or 8 years of age.3 Hemangiomas of infancy can occur anywhere on the body. However, when they occur in the airway, they can be life-threatening. Ulceration, the most frequent complication, can be painful and carries the risk of infection, hemorrhage, and scarring. A small percentage of hemangiomas of infancy develop complications, such as infection or ulceration.3 Some hemangiomas of infancy are located in anatomic regions associated with other anomalies requiring careful monitoring and early intervention.

**AGE-RELATED SKIN MANIFESTATIONS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the distinguishing features of rashes associated with the following infectious childhood diseases: roseola infantum, rubella, rubella, and varicella.
- Characterize the physiologic changes of aging skin.
- Describe the appearance of skin tags, keratoses, lentigines, and vascular lesions that are commonly seen in older adults.

Many skin problems occur more commonly in certain age groups. Because of aging changes, infants, children, and older adults tend to have different skin problems.
malformations of the eye, resulting primarily in glaucoma, and other neurologic deficits (Sturge-Weber syndrome). Laser surgery has revolutionized the treatment of port-wine stains.

Diaper Dermatitis. Irritant diaper dermatitis, or diaper rash, is a form of contact dermatitis that results from an increased contact with a wet or soiled diaper. The wearing of diapers causes an increase in skin wetness and pH because of ammonia from urine. Prolonged wetness leads to softening and maceration of the skin, making it more susceptible to damage by friction from the surface of the diaper and local irritants. The contents of soiled diapers, if not changed frequently, can lead to contact dermatitis, bacterial infections, or other skin conditions. The proteases and lipases contained in feces are particularly irritating.

The appearance of diaper rash ranges from simple (i.e., widely distributed macules on the buttocks and anogenital areas) to severe (i.e., beefy, red, excoriated skin surfaces in the diaper area). Secondary infections with bacteria and yeasts are common; discomfort may be marked because of intense inflammation. Such conditions as contact dermatitis, seborrheic dermatitis, candidiasis, and atopic dermatitis should be considered when the eruption is persistent and recalcitrant to simple therapeutic measures.

Diaper dermatitis often responds to simple measures, including frequent diaper changes with careful cleansing of the irritated area to remove all waste products. Exposing the irritated area to air is helpful. It has been shown that application of a barrier ointment after each diaper change is a valuable component of therapy.

Selection of a barrier preparation is important. It is now clear that the barrier function of the skin is provided by the stratum corneum, whose main function is to minimize water loss and prevent inward penetration of toxic substances and microorganisms. Ideally, a barrier should mimic the skin’s natural function by forming a long-lasting barrier to increase protection against irritants and microorganisms and to maintain optimum moisture levels. Preparations should contain lipids similar to those naturally present in the stratum corneum.

Intractable and severe cases of diaper dermatitis should be seen by a health care provider for treatment of any secondary infections. Secondary candidal (i.e., yeast; Fig. 61.33) or other skin manifestations discussed in this chapter may occur in the diaper area. It is important to differentiate between normal diaper dermatitis and more serious skin problems.

Prickly Heat. Prickly heat or miliaria results from constant maceration of the skin because of prolonged exposure to a warm, humid environment. Maceration leads to mid-epidermal obstruction by blocking the eccrine glands and possible rupture of these sweat glands. It is possible that an infant could develop a fatal hyperpyrexia if the eccrine glands are congenitally absent. Although commonly seen during infancy, prickly heat may occur at any age. The treatment includes removing excessive clothing; cooling the skin with warm water baths; drying the skin with powders; and avoiding hot, humid environments.
Cradle Cap. Cradle cap is a greasy crust or scale formation on the scalp. It usually is attributed to infrequent and inadequate washing of the scalp. Cradle cap is treated using mild shampoo and gentle combing to remove the scales. Sometimes oil can be left on the head for minutes to several hours, softening the scales before scrubbing. Other emulsifying ointments or creams may be helpful in difficult cases. The scalp may need to be rubbed firmly to remove the buildup of keratinized cells. Recalcitrant cases need to be seen by a health care practitioner. Serious or chronic forms of seborrheic dermatitis may exist.

Skin Manifestations of Common Infectious Diseases

Infectious childhood diseases that produce rashes include exanthem subitum, rubella, rubeola, varicella, and scarlet fever. Although these diseases are seen less frequently because of successful immunization programs and the use of antibiotics, they still occur.

Roseola Infantum. Roseola infantum (exanthem subitum or sixth disease) is a contagious disease caused by HHV-6. Because HHV-6 is the etiologic agent, the condition is often referred to as sixth disease. Primary HHV-6 infection occurs early in life. The majority of cases of roseola occur in children between 6 months and 4 years of age. Transplacental antibodies likely protect most infants until 6 months of age. Roseola produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. The rash is preceded by a high fever (≤105°F) that occurs very suddenly, inflamed tympanic membranes, and coldlike symptoms usually lasting 3 to 4 days. These symptoms improve at approximately the same time the rash appears (Fig. 61.34). Because infants with roseola exhibit a unique constellation of symptoms over a short time, the infection may be confused with other childhood exanthems. Blood antibody titers may be taken to determine the actual diagnosis. In most cases, there are no long-term effects from this disease. Infants who spike high temperatures should be seen by their health care providers.

Rubella. Rubella (i.e., 3-day measles or German measles) is a childhood disease caused by the rubella virus (a togavirus). It is characterized by a diffuse, punctate, macular rash that begins on the trunk and spreads to the arms and legs. Mild febrile states occur (usually <100°F). Postauricular, suboccipital, and cervical lymph node adenopathy is common. Coldlike symptoms usually accompany the disease in the form of cough, congestion, and coryza (i.e., nasal discharge).

Rubella usually has no long-lasting sequelae. However, the transmission of the disease to pregnant women early in their gestation periods may result in congenital rubella syndrome. Among the clinical signs of congenital rubella syndrome are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects. Most states have laws requiring immunization to prevent transmission of rubella. Immunization is accomplished by live-virus injection and is generally 100% successful in immunizing children.

Rubeola. Rubeola (measles, hard measles, 7-day measles) is an acute, highly communicable viral disease caused by a morbillivirus. The characteristic rash is macular and blotchy; sometimes the macules become confluent. The rubeola rash usually begins on the face and spreads to the appendages. There are several accompanying symptoms: a fever of 100°F or greater, Koplik spots (i.e., small, irregular red spots with a bluish-white speck in the center) on the buccal mucosa, and mild to severe photosensitivity (Fig. 61.35). The patient commonly has coldlike symptoms, general malaise, and myalgia. In severe cases, the macules may hemorrhage into the skin tissue or onto the outer body surface. This form is called hemorrhagic measles. The course of measles is more severe in infants, adults, and malnourished children. There may be severe complications, including otitis media, pneumonia, and encephalitis. Antibody titers are determined for a conclusive diagnosis of rubeola.

Measles is a disease preventable by vaccine, and law in the United States requires immunization. Immunization is accomplished by the injection of a live-virus vaccine. Measles vaccination is generally 100% successful.
Varicella. Varicella (chickenpox) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which also is the agent in herpes zoster (shingles). The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab. The macular stage is characterized by development within hours of macules over the trunk, spreading to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctiva. During the second stage, the macules form vesicles with depressed centers. The vesicles break open and a scab forms during the third stage. Crops of lesions occur successively, so that all three forms of the lesion usually are visible by the third day of the illness.

Mild to extreme pruritus accompanies the lesions, which can lead to scratching and subsequent development of secondary bacterial infections. Chickenpox also is accompanied by coldlike symptoms, including cough, coryza, and sometimes photosensitivity. Mild febrile states usually occur, typically beginning 24 hours before lesion outbreak. Side effects, such as pneumonia, septic complications, and encephalitis, are rare.

Varicella in adults may be more severe, with a prolonged recovery rate and greater chances for development of varicella pneumonitis or encephalitis. Immunocompromised people may experience a chronic, painful form of the infection.

Skin Manifestations and Disorders in Older Adults

Older adults experience a variety of age-related skin disorders and exacerbations of earlier skin problems. Aging skin is believed to involve a complex process of actinic (solar) damage, normal aging, and hormonal influences. Actinic changes primarily involve increased occurrence of lesions on sun-exposed surfaces of the body.

Normal Age-Related Changes

Normal skin changes associated with aging are seen on areas of the body that have not been exposed to the sun. They include thinning of the dermis and the epidermis; diminution in subcutaneous tissue; a decrease and thickening of blood vessels; and a decrease in the number of melanocytes, Langerhans cells, and Merkel cells. The keratinocytes shrink, but the number of dead keratinized cells at the surface increases. This results in less padding and thinner skin, with color and elasticity changes. The skin also loses its resistance to environmental and mechanical trauma. Tissue repair takes longer.

With aging, there is also less hair and nail growth, and there is permanent hair pigment loss. Hormonally, there is less sebaceous gland activity, although the glands in the facial skin may increase in size. Hair growth reduction also may be hormonally influenced. Although the reason is poorly understood, the skin in most older adults becomes dry, rough, scaly, and itchy. When there is no underlying pathologic process, it is called senile pruritus. Itching and dryness become worse during the winter, when the need for home heating lowers the humidity.

The aging of skin, however, is not just a manifestation of age itself. Most skin changes associated with older adults are the result of cumulative actinic or environmental damage. For example, the wrinkled, leathery look of aged skin, as well as odd scars and ecchymotic spots, are due to solar elastotic degenerative change.

Skin Lesions Common Among Older Adults

The most common skin lesions in older adults are skin tags, keratoses, lentigines, and vascular lesions. Most are actinic manifestations, which means they occur as a result of exposure to sun and weather over the years.

Skin Tags. Skin tags are soft, brown or flesh-colored papules commonly seen in 25% of adults. They occur on any skin surface, but most frequently the neck, axilla, and intertriginous areas. They range in size from a pinhead to the size of a pea. Skin tags have the normal texture of the skin. They are benign and can be removed with scissors or electrodesiccation for cosmetic purposes.

Keratoses. A keratoses is a horny growth or an abnormal growth of the keratinocytes. A seborrheic keratoses (i.e., seborrheic wart) is a benign, sharply circumscribed, wartlike lesion that has a stuck-on appearance (Fig. 61.36). They vary in size up to several centimeters. They are usually round or oval, tan, brown, or black lesions. Less pigmented ones may appear yellow or pink. Keratoses can be found on the face or trunk, as a solitary lesion or sometimes by the hundreds. Seborrheic keratoses are benign, but they must be watched for changes in color, texture, or size, which may indicate malignant transformation.

Actinic keratoses are the most common premalignant skin lesions that develop on sun-exposed areas. The lesions usually are less than 1 cm in diameter and appear as dry, brown, scaly areas, often with a reddish tinge. Actinic keratoses often are multiple and more easily felt than seen. They often are indistinguishable from SCC without biopsy. Actinic keratoses may accumulate dense scale on the surface of the skin and become hyperkeratotic (i.e., developing cutaneous growths of fingernail-type tissue that grow into hornlike appendages). This form is more prominent and palpable. Often, there is a weathered appearance to the surrounding skin. Slight changes,
such as enlargement or ulceration, may indicate malignant transformation. Actinic keratoses are SCCs confined to the epidermis. Actinic keratoses are removed with cryosurgery, electrodesiccation, or lasers. When surgery is not indicated, they are treated with topical chemotherapy agents, like 5-fluorouracil or imiquimod creams, which erode the lesions.

**Lentigines.** A *lentigo* is a well-bordered, brown to black macule, usually less than 1 cm in diameter. *Solar lentigines* are tan to brown, benign spots on sun-exposed areas. Commonly referred to as *liver spots*, these lesions are considered risks for the development of skin cancers. Lentigines can be removed surgically (cryotherapy, laser therapy, liquid

(From Hall B. J., Hall J. C. (2010). *Sauer’s manual of skin diseases* (10th ed., p. 447). Philadelphia, PA: Lippincott Williams & Wilkins.)
Vascular Lesions. Vascular lesions include angiomas, telangiectases, and venous lakes. Cherry angiomas are smooth, cherry-red or purple, dome-shaped papules that occur in nearly all people older than 30 years of age. They usually are found on the trunk and are generally benign unless there is a sudden appearance of many cherry angiomas. Telangiectases are single dilated blood vessels, capillaries, or terminal arteries that appear on areas exposed to sun or harsh weather, such as the cheeks and the nose. They occur individually or in clusters, measure 1 cm or less, are nonpalpable, and easily blanch. They can become large and disfiguring. Pulsed dye lasers have been effective in removing them. Venous lakes are small, dark blue, slightly raised papules that have a lakelike appearance. They occur on exposed body parts, particularly the backs of the hands, ears, and lips. They are smooth and compressible. Venous lakes can be removed by electrotherapy, laser therapy, or surgical excision if a person desires. Careful monitoring for conversion to melanoma is important.

IN SUMMARY

Some skin problems occur in specific age groups. Common in infants are diaper rash, prickly heat, and cradle cap. Infectious childhood diseases that are characterized by rashes include roseola infantum, rubella, rubola, varicella, and scarlet fever. Vaccines are available to protect against rubella, rubola, and varicella.

With aging, there is thinning of the dermis and the epidermis, diminution in subcutaneous tissue, loss and thickening of blood vessels, and slowing of hair and nail growth. Dry skin is common among the elderly, becoming worse during the winter months. Among the skin lesions seen in older adults are skin tags, keratoses, lentigines, and vascular lesions.

REVIEW EXERCISES

1. The mother of a 7-year-old boy notices that he is scratching his head frequently. On close examination, she notices a grayish, round, and roughened area, where the hair has broken off. Examination by the child’s pediatrician produces a diagnosis of tinea capitis.

A. Explain the cause of the infection and propose possible mechanisms for spread of this infection in school-age children, particularly during winter months.
B. Explain the preference of the superficial mycoses (dermatophytooses) for the skin-covered areas of the body.
C. What methods are commonly used in the diagnosis of superficial fungal infections?

2. A 75-year-old woman presents with severe burning pain and a vesicular rash covering a strip over the rib cage on one side of the chest. She is diagnosed with herpes zoster or shingles.
A. What is the source of this woman’s rash and pain?
B. Explain the dermatomal distribution of the lesions.

3. Psoriasis is a chronically recurring papulosquamous skin disorder, characterized by circumscribed red, thickened plaques with an overlying silvery-white scale.
A. Explain the development of the plaques in terms of epidermal cell turnover.
B. Persons with psoriasis are instructed to refrain from rubbing or scratching the lesions. Explain the rationale for these instructions.
C. Among the methods used in the treatment of psoriasis are the use of topical keratolytic agents and corticosteroid skin preparations. Explain how these two different types of agents exert their effect on the plaque lesions.

4. During the past several decades, there has been an alarming increase in the incidence of skin cancers, including malignant melanoma, that has been attributed to increased sun exposure.
A. Explain the possible mechanisms whereby ultraviolet radiation promotes the development of malignant skin lesions.
B. Cite two important clinical signs that aid in distinguishing a dysplastic nevus from a malignant melanoma.

*Values may vary with laboratory. The values supplied by the laboratory performing the test should always be used since the ranges may be method specific.
†Laboratory and/or method specific.
‡Varies with age and muscle mass.
Abduction  The act of abducting (moving or spreading away from a position near the midline of the body or the axial line of a limb) or the state of being abducted.

Abrasion  The wearing or scraping away of a substance or structure, such as the skin, through an unusual or abnormal mechanical process.

Abscess  A collection of pus that is restricted to a specific area in tissues, organs, or confined spaces.

Accommodation  The adjustment of the lens (eye) to variations in distance.

Acromion  The lateral extension of the spine of the scapula, forming the highest point of the shoulder. (Adjective: acromial)

Acuity  The clearness or sharpness of perception, especially of vision.

Adaptation  The adjustment of an organism to its environment, physical or psychological, through changes and responses to stress of any kind.

Adduction  The act of adducting (moving or drawing toward a position near the midline of the body or the axial line of a limb) or the state of being adducted.

Adhesin  The molecular components of the bacterial cell wall that are involved in adhesion processes.

Adrenergic  Activated by or characteristic of the sympathetic nervous system or its neurotransmitters (i.e., epinephrine and norepinephrine).

Aerobic  Growing, living, or occurring only in the presence of air or oxygen.

Afferent  Bearing or conducting inward or toward a center, as an afferent neuron.

Agglutination  The clumping together of particles, microorganisms, or blood cells in response to an antigen–antibody reaction.

Agonist  A muscle whose action is opposed by another muscle (antagonist) with which it is paired, or a drug or other chemical substance that has affinity for or stimulates a predictable physiologic function.

Anomaly  An abnormal condition characterized by the total lack of oxygen.

Antagonist  A muscle whose action directly opposes that of another muscle (agonist) with which it is paired, or a drug or other chemical substance that can diminish or nullify the action of a neuromediator or body function.

Anterior  Pertaining to a surface or part that is situated near or toward the front.

Antigen  A substance that generates an immune response by causing the formation of an antibody or reacting with antibodies or T-cell receptors.

Apex  The uppermost point, the narrowed or pointed end, or the highest point of a structure, such as an organ.

Aphagia  A condition characterized by the refusal or the loss of ability to swallow.

Aplasia  The absence of an organ or tissue due to a developmental failure.

Apnea  The absence of spontaneous respiration.

Ampulla  A saclike dilatation of a duct, canal, or any other tubular structure.

Anabolism  A constructive metabolic process characterized by the conversion of simple substances into larger, complex molecules.

Anaerobic  Growing, living, or occurring only in the absence of air or oxygen.

Analog  A part, organ, or chemical having the same function or appearance but differing in respect to a certain component, such as origin or development.

Anaplasia  A change in the structure of cells and in their orientation to each other that is characterized by a loss of cell differentiation, as in cancerous cell growth.

Anastomosis  The connection or joining between two vessels; or an opening created by surgical, traumatic, or pathologic means.

Androgen  Any substance, such as a male sex hormone, that increases male characteristics.

Anencephaly  Any state of absent or diminished reaction to an antigen or group of antigens.

Aneuploidy  A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

Anaplasia  A change in the structure of cells and in their orientation to each other that is characterized by a loss of cell differentiation, as in cancerous cell growth.

Anemia  A condition of vision impairment without a detectable organic lesion of the eye.
Apoptosis A mechanism of programmed cell death, marked by shrinkage of the cell, condensation of chromatin, formation of cytoplasmic blebs, and fragmentation of the cell into membrane-bound bodies eliminated by phagocytosis.

Apraxia Loss of the ability to carry out familiar, purposeful acts or to manipulate objects in the absence of paralysis or other motor or sensory impairment.

Articulation The place of connection or junction between two or more bones of a skeletal joint.

Ascites An abnormal accumulation of serous fluid in the peritoneal cavity.

Asepsis The condition of being free or freed from pathogenic microorganisms.

Astereognosis A neurologic disorder characterized by an inability to identify objects by touch.

Asterixis A motor disturbance characterized by a hand-flapping tremor, which results when the prolonged contraction of groups of muscles lapses intermittently.

Ataxia An abnormal condition characterized by an inability to coordinate voluntary muscular movement.

Athetosis A neuromuscular condition characterized by the continuous occurrence of slow, sinuous, writhing movements that are performed involuntarily. (Adjective: athetoid)

Atony Genetic predisposition toward the development of a hypersensitivity or an allergic reaction to common environmental allergens.

Atresia The absence or closure of a normal body orifice or tubular organ, such as the esophagus.

Atrophy A wasting or diminution of size, often accompanied by a decrease in function, of a cell, tissue, or organ.

Autocrine A mode of hormone action in which a chemical messenger acts on the same cell that secretes it.

Autophagy Segregation of part of the cell’s own damaged cytoplasmic material within a vacuole and its disposal.

Autosome Any chromosome other than a sex chromosome.

Axillary Of or pertaining to the axilla, or armpit.

Bacteremia The presence of bacteria in the blood.

Bactericide An agent that destroys bacteria. (Adjective: bactericidal)

Bacteriostat An agent that inhibits bacterial growth. (Adjective: bacteriostatic)

Ballismus An abnormal condition characterized by violent flailing motions of the arms and, occasionally, the head, resulting from injury to or destruction of the subthalamic nucleus or its fiber connections.

Baroreceptor A type of sensory nerve ending such as those found in the aorta and the carotid sinus that is stimulated by changes in pressure.

Basal Pertaining to, situated at, or forming the base, or the fundamental or the basic.

Benign Not malignant or of the character that does not threaten health or life.

Bipolar neuron A nerve cell that has a process at each end—an afferent process and an efferent process.

Bolus A rounded mass of food ready to swallow or such a mass passing through the gastrointestinal tract, or a concentrated mass of medicinal material or other pharmaceutical preparation injected all at once intravenously for diagnostic purposes.

Borborygmus The rumbling, gurgling, or tinkling noise produced by the propulsion of gas through the intestine.

Bruit A sound or murmur heard while auscultating an organ or blood vessel, especially an abnormal one.

Buccal Pertaining to or directed toward the inside of the cheek.

Buffer A substance or group of substances that prevents change in the concentration of another chemical substance.

Bulla A thin-walled blister of the skin or mucous membranes greater than 5 mm in diameter containing serous or seropurulent fluid.

Bursa A fluid-filled sac or saclike cavity situated in places in the tissues at which friction would otherwise develop, such as between certain tendons and the bones beneath them.

Cachexia A condition of general ill health and malnutrition, marked by weakness and emaciation.

Calculus A stony mass formed within body tissues, usually composed of mineral salts.

Capsid The protein shell that envelops and protects the nucleic acid of a virus.

Carcinogen Any substance or agent that causes the development or increases the incidence of cancer.

Carpal Of or pertaining to the carpus, or wrist.

Caseation A form of tissue necrosis in which the tissue is changed into a dry, amorphous mass resembling crumbly cheese.

Catabolism A metabolic process through which living organisms break down complex substances to simple compounds, liberating energy for use in work, energy storage, or heat production.

Catalyst A substance that increases the velocity of a chemical reaction without being consumed by the process.

Catecholamines Any one of a group of biogenic amines having a sympathomimetic action and composed of a catechol molecule and the aliphatic portion of an amine.

Caudal Signifying an inferior position, toward the distal end of the spine.

Cellulitis An acute, diffuse, spreading, edematous inflammation of the deep subcutaneous tissues and sometimes muscle, characterized most commonly by an area of heat, redness, pain, and swelling, and occasionally by fever, malaise, chills, and headache.

Cephalic Of or pertaining to the head, or to the head end of the body.

Cerumen The waxlike secretion produced by vestigial apocrine sweat glands in the external ear canal.
**Cheilosis** A noninflammatory disorder of the lips and mouth characterized by chapping and fissuring.

**Chelate** A chemical compound composed of a central metal ion and an organic molecule with multiple bonds, arranged in ring formation, used especially in treatment of metal poisoning.

**Chemoreceptor** A sensory nerve cell activated by chemical stimuli, as a chemoreceptor in the carotid artery that is sensitive to changes in the oxygen content in the blood and reflexly increases or decreases respiration and blood pressure.

**Chemotaxis** A response involving cell orientation or cell movement that is either toward (positive chemotaxis) or away from (negative chemotaxis) a chemical stimulus.

**Chimeric** Relating to, derived from, or being an individual possessing one’s own immunologic characteristics and that of another individual; a phenomenon that can occur as the result of procedures such as a bone marrow graft.

**Chondrocyte** Any one of the mature polymorphic cells that form the cartilage of the body.

**Chromatid** One of the paired threadlike chromosome filaments, joined at the centromere, that makes up a metaphase chromosome.

**Chromosome** Any one of the structures in the nucleus of a cell containing a linear thread of DNA, which functions in the transmission of genetic information.

**Chyme** The creamy, viscous, semifluid material produced during digestion of a meal that is expelled by the stomach into the duodenum.

**Cilia** A minute, hairlike process projecting from a cell, composed of nine microtubules arrayed around a single pair. Cilia beat rhythmically to move the cell around in its environment or they move mucus or fluids over the surface.

**Circadian** Being, having, pertaining to, or occurring in a period or cycle of approximately 24 hours.

**Circumduction** The active or passive circular movement of a limb or of the eye.

**Cisterna** An enclosed space, such as a cavity, that serves as a reservoir for lymph or other body fluids.

**Clone** One or a group of genetically identical cells or organisms derived from a single parent.

**Coagulation** The process of transforming a liquid into a semisolid mass, especially of blood clot formation.

**Coarctation** A condition of stricture or contraction of the walls of a vessel.

**Cofactor** A substance that must unite with another substance in order to function.

**Colic** Sharp, intermittent abdominal pain localized in a hollow or tubular organ, resulting from torsion, obstruction, or smooth muscle spasm. (Adjective: colicky)

**Collagen** The protein substance of the white, glistening, inelastic fibers of the skin, tendons, bone, cartilage, and all other connective tissue.

**Collateral** Secondary or accessory rather than direct or immediate, or a small branch, as of a blood vessel or nerve.

**Complement** Any one of the complex, enzymatic serum proteins that are involved in physiologic reactions, including antigen–antibody reaction and anaphylaxis.

**Confluent** Flowing or coming together, not discrete.

**Congenital** Present at, and usually before, birth.

**Conjugate** To pair and fuse in conjugation, or a form of sexual reproduction seen in unicellular organisms in which genetic material is exchanged during the temporary fusion of two cells.

**Contiguous** In contact or nearly so in an unbroken sequence along a boundary or at a point.

**Contralateral** Affecting, pertaining to, or originating in the opposite side of a point or reference.

**Contusion** An injury of a part without a break in the skin, characterized by swelling, discoloration, and pain.

**Convolution** An elevation or tortuous winding, such as one of the irregular ridges on the surface of the brain, formed by a structure being infolded upon itself.

**Corpuscle** Any small mass, cell, or body, such as a red or white blood cell.

**Costal** Pertainning to a rib or ribs.

**Crepitus** A sound or sensation that resembles a crackling or grating noise.

**Cutaneous** Pertainning to the skin.

**Cyanosis** A bluish discoloration, especially of the skin and mucous membranes, caused by an excess of deoxygenated hemoglobin in the blood.

**Cytokine** Any of a class of polypeptide immunoregulatory substances that are secreted by cells, usually of the immune system, that affect other cells.

**Cytology** The study of cells, including their origin, structure, function, and pathology.

**Cytosol** Cytoplasm exclusive of membranous components (e.g., mitochondria, endoplasmic reticulum) and non-membranous insoluble components.

**Decibel** A unit for expressing the relative power intensity of electric or acoustic signal power that is equal to one tenth of a bel.

**Defecation** The evacuation of feces from the digestive tract through the rectum.

**Deformation** The process of adapting in form or shape; also the product of such alteration.

**Degeneration** The deterioration of a normal cell, tissue, or organ to a less functionally active form. (Adjective: degenerative)

**Deglutition** The act or process of swallowing.

**Degradation** The reduction of a chemical compound to a compound less complex, usually by splitting off one or more groups.

**Dehydration** The condition that results from excessive loss of water from the body tissues.
Delirium An acute, reversible organic mental syndrome characterized by confusion, disorientation, restlessness, incoherence, fear, and often illusions.

Dendrite One of the branching processes that extends and transmits impulses toward a cell body of a neuron. (Adjective: dendritic)

Depolarization The reduction of a cell membrane potential to a less negative value than that of the potential outside the cell.

Dermatome The area of the skin supplied with afferent nerve fibers of a single dorsal root of a spinal nerve.

Desmosome A small, circular, dense area within the intercellular bridge that forms the site of adhesion between intermediate filaments and cell membranes.

Desquamation A normal process in which the cornified layer of the epidermis is shed in fine scales or sheets.

Dialysis The process of separating colloids and crystalline substances in solution, which involves the two distinct physical processes of diffusion and ultrafiltration, or a medical procedure for the removal of urea and other elements from the blood or lymph.

Diapedesis The outward passage of red or white blood corpuscles through the intact walls of the vessels.

Diaphoresis Perspiration, especially the profuse perspiration associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress.

Diathesis A specialized articulation that permits, to some extent, free joint movement. (Adjective: diarthrodial)

Diastole The dilatation of the heart, or the period of dilatation, which is the interval between the second and the first heart sound and is the time during which blood enters the relaxed chambers of the heart from the systemic circulation and the lungs.

Differentiation The act or process in development in which unspecialized cells or tissues acquire more specialized characteristics, including those of physical form, physiologic function, and chemical properties.

Diffusion The process of becoming widely spread, as in the spontaneous movement of molecules or other particles in solution from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid.

Dimer A compound or unit formed by the combination of two identical molecules or radicals of a simpler compound. (Adjective: dimeric)

Diopter A unit of measurement of the refractive power of lenses equal to the reciprocal of the focal length in meters.

Diploid Pertaining to an individual, organism, strain, or cell that has two full sets of homologous chromosomes.

Disseminate To scatter or distribute over a considerable area.

Distal Away from or being the farthest from a point of reference.

Diurnal Of, relating to, or occurring in the daytime.

Diverticulum A pouch or sac of variable size occurring naturally or through herniation of the muscular wall of a tubular organ.

Dorsum The back or posterior. (Adjective: dorsal)

Dysgenesis Defective or abnormal development of an organ or part, typically occurring during embryonic development. (Also called dysgenesis.)

Dyslexia A disturbance in the ability to read, spell, and write words.

Dyspepsia The impairment of the power or function of digestion, especially epigastric discomfort following eating.

Dysphagia A difficulty in swallowing.

Dysphonia Any impairment of the voice that is experienced as a difficulty in speaking.

Dysplasia The alteration in size, shape, and organization of adult cell types.

Eburnation The conversion of bone or cartilage, through thinning or loss, into a hard and dense mass with a worn, polished, ivory-like surface.

Ecchymosis A small hemorrhagic spot, larger than a petechia, in the skin or mucous membrane caused by the extravasation of blood into the subcutaneous tissues.

Ectoderm The outermost of the three primary germ layers of the embryo, and from which the epidermis and epidermal tissues, such as nails, hair, and glands of the skin, develop.

Ectopic Relating to or characterized by an object or organ being situated in an unusual place, away from its normal location.

Edema The presence of an abnormal accumulation of fluid in interstitial spaces of tissues. (Adjective: edematous)

Efferent Conveyed or directed away from a center.

Effusion The escape of fluid from blood vessels into a part or tissue, as an exudation or a transudation.

Embolus A mass of clotted blood or other formed elements, such as bubbles of air, calcium fragments, or a bit of tissue or tumor, that circulates in the bloodstream until it becomes lodged in a vessel, obstructing the circulation. (Plural: emboli)

Empyema An accumulation of pus in a cavity of the body, especially the pleural space.

Emulsify To disperse one liquid throughout the body of another liquid, making a colloidal suspension, or emulsion.

Endocytosis The uptake or incorporation of substances into a cell by invagination of its plasma membrane, as in the processes of phagocytosis and pinocytosis.

Endoderm The innermost of the three primary germ layers of the embryo, and from which epithelium arises.

Endogenous Growing within the body, or developing or originating from within the body or produced from internal causes.

Endoscopy The visualization of any cavity of the body with an endoscope.
Enteropathic  Relating to any disease of the intestinal tract.
Enzyme  A protein molecule produced by living cells that catalyzes chemical reactions of other organic substances without itself being destroyed or altered.
Epiphyseal The expanded articular end of a long bone (head) that is separated from the shaft of the bone by the epiphyseal plate until the bone stops growing, the plate is obliterated, and the shaft and the head become united.
Epithelium  The covering of the internal and the external surfaces of the body, including the lining of vessels and other small cavities.
Epitope  The simplest form of an antigenic determinant that combines with an antibody or a T-cell receptor to cause a specific reaction by an immunoglobulin.
Erectile  Capable of being erected or raised to an erect position.
Erythema  The redness or inflammation of the skin or mucous membranes produced by the congestion of superficial capillaries. (Adjective: erythematous)
Etiology  The study or theory of all factors that may be involved in the development of a disease, including susceptibility of an individual, the nature of the disease agent, and the way in which an individual’s body is invaded by the agent, or the cause of a disease.
Eukaryotic  Pertaining to an organism with cells having a true nucleus; that is, a highly complex, organized nucleus surrounded by a nuclear membrane containing organelles and exhibiting mitosis.
Euploid  Pertaining to an individual, organism, strain, or cell with a balanced set or sets of chromosomes, in any number, that is an exact multiple of the normal, basic haploid number characteristic of the species; or such an individual, organism, strain, or cell.
Evisceration  The removal of the viscera from the abdominal cavity or disembowelment, or the extrusion of an internal organ through a wound or surgical incision.
Exacerbation  An increase in the severity of a disease as marked by greater intensity in any of its signs and symptoms.
Exfoliation Peeling and sloughing off of tissue cells in scales or layers. (Adjective: exfoliative)
Exocytosis  The discharge of cell particles, which are normally occurring and pathologic, found in or on an organ.
Fascia  A sheet or band of fibrous connective tissue that may be separated from other specifically organized structures, as the tendons, the aponeuroses, and the ligaments.
Fibrin  A stringy, insoluble protein formed by the action of thrombin on fibrinogen during the clotting process.
Fibrosis  The formation of fibrous connective tissue, as in the repair or replacement of parenchymatous elements.
Filtration  The process of passing a liquid through or as if through a filter, which is accomplished by gravity, pressure, or vacuum.
Fimbria  Any structure that forms a fringe, border, or edge or the processes that resemble such a structure.
Fissure  A cleft or a groove, normal or otherwise, on the surface of an organ or a bony structure.
Fistula  An abnormal passage or communication from an internal organ to the body surface or between two internal organs.
Flaccid  Weak, soft, and lax; lacking normal muscle tone.
Flatus  Air or gas in the intestinal tract that is expelled through the anus. (Adjective: flatulent)
Flexion  A movement that allows the two elements of any jointed part to be brought together, decreasing the angle between them, as bending the elbow.
Flora  The microorganisms, such as bacteria and fungi, both normally occurring and pathologic, found in or on an organ.
Focal  Relating to, having, or occupying a focus.
Follicle  A sac or pouchlike depression or cavity.
Fontanel  A membrane-covered opening in bones or between bones, such as the soft spot covered by tough membranes between the bones of an infant’s incompletely ossified skull.
Foramen  A natural opening or aperture in a membranous structure or bone.
Fossa  A hollow or depressed area, especially on the surface of the end of a bone.
Fovea  A small pit or depression in the surface of a structure or an organ.
Fundus  The base or bottom of an organ or the portion farthest from the mouth of an organ.
Ganglion One of the nerve cell bodies, chiefly collected in groups outside the central nervous system. (Plural: ganglia)

Genotype The entire genetic constitution of an individual, as determined by the particular combination and location of the genes on the chromosomes, or the alleles present at one or more sites on homologous chromosomes.

Glia The neuroglia, or supporting structure of nervous tissue.

Globulin One of a broad group of proteins classified by solubility, electrophoretic mobility, and size.

Gluconeogenesis The formation of glucose from any of the substances of glycolysis other than carbohydrates.

Glycolysis A series of enzymatically catalyzed reactions, occurring within cells, by which glucose is converted to adenosine triphosphate (ATP) and pyruvic acid during aerobic metabolism.

Gonad A gamete-producing gland, as an ovary or a testis.

Gradient The rate of increase or decrease of a measurable phenomenon expressed as a function of a second, or the visual representation of such a change.

Granuloma A small mass of nodular granulation tissue resulting from chronic inflammation, injury, or infection. (Adjective: granulomatous)

Hapten A small, nonproteinaceous substance that is not antigenic by itself but that can act as an antigen when combined with a larger molecule.

Hastrum A structure resembling a recess or sacculcation. (Plural: haustra)

Hematoma A localized collection of extravasated blood trapped in an organ, space, or tissue, resulting from a break in the wall of a blood vessel.

Hematopoiesis The normal formation and development of blood cells.

Hemianopia Defective vision or blindness in half of the visual field of one or both eyes.

Heterogeneous Consisting of or composed of dissimilar elements or parts, or not having a uniform quality throughout. (Noun: heterogeneity)

Heterophagy The taking into the cell of an exogenous substance by phagocytosis or pinocytosis and the subsequent digestion of the newly formed vacuole by a lysosome.

Heterozygous Having two different alleles at corresponding loci on homologous chromosomes.

Histology The branch of anatomy that deals with the minute (microscopic) structure, composition, and function of cells and tissue. (Adjective: histologic)

Homolog Any organ or part corresponding in function, position, origin, and structure to another organ or part, as the flippers of a seal that correspond to human hands. (Adjective: homologous)

Homozygous Having two identical alleles at corresponding loci on homologous chromosomes.

Humoral Relating to elements dissolved in the blood or body fluids.

Hybridoma A tumor of hybrid cells produced by fusion of normal lymphocytes and tumor cells.

Hydrolysis The chemical alteration or decomposition of a compound into fragments by the addition of water.

Hypercapnia Excess amount of carbon dioxide in the blood.

Hyperemia An excess or engorgement of blood in a part of the body.

Hyperesthesia An unusual or pathologic increase in sensitivity of a part, especially the skin, or of a particular sense.

Hyperplasia An abnormal multiplication or increase in the number of normal cells of a body part.

Hypertonic A solution having a greater concentration of solute than another solution with which it is compared, hence exerting more osmotic pressure than that solution.

Hypertrophy The enlargement or overgrowth of an organ that is due to an increase in the size of its cells rather than the number of its cells.

Hyposthesia An abnormal decrease of sensation in response to stimulation of the sensory nerves. (Also called hypoesthesia.)

Hypocapnia A deficiency of carbon dioxide in the blood.

Hypotonic A solution having a lesser concentration of solute than another solution with which it is compared, hence exerting less osmotic pressure than that solution.

Hypoxia An inadequate supply of oxygen to tissue that is below physiologic levels despite adequate perfusion of the tissue by blood.

Iatrogenic Induced inadvertently through the activity of a physician or by medical treatment or diagnostic procedures.

Idiopathic Arising spontaneously or from an unknown cause.

Idiosyncrasy A physical or behavioral characteristic or manner that is unique to an individual or to a group. (Adjective: idiosyncratic)

Incidence The rate at which a certain event occurs (e.g., the number of new cases of a specific disease during a particular period of time in a population at risk).

Inclusion The act of enclosing or the condition of being enclosed, or anything that is enclosed.

Indigenous Native, or natural, to the particular country or region where found.

Infarction Necrosis or death of tissues due to local ischemia resulting from obstruction of blood flow.

Inotropic Influencing the force or energy of muscular contractions.

In situ In the natural or normal place, or something, such as cancer, that is confined to its place of origin and has not invaded neighboring tissues.

Interferon Any one of a group of small glycoproteins (cytokines) produced in response to viral infection and which inhibit viral replication.
Interleukin Any of several multifunctional cytokines produced by a variety of lymphoid and nonlymphoid cells, including immune cells, that stimulate or otherwise affect the function of lymphopoietic and other cells and systems in the body.

Interstitial Relating to or situated between parts or in the interspaces of a tissue.

Intramural Situated or occurring within the wall of an organ.

Intrinsic Pertaining exclusively to a part or situated entirely within an organ or tissue.

In vitro A biologic reaction occurring in an artificial environment, such as a test tube.

In vivo A biologic reaction occurring within the living body.

Involution The act or instance of enfolding, entangling, or turning inward.

Ionize To separate or change into ions.

Ipsilateral Situated on, pertaining to, or affecting the same side of the body.

Ischemia Decreased blood supply to a body organ or part, usually due to functional constriction or actual obstruction of a blood vessel.

Juxta-articular Situated near a joint or in the region of a joint.

Juxtaglomerular Near to or adjoining a glomerulus of the kidney.

Karyotype The total chromosomal characteristics of a cell, or the micrograph of chromosomes arranged in pairs in descending order of size.

Keratin A fibrous, sulfur-containing protein that is the primary component of the epidermis, hair, and horny tissues. (Adjective: keratinous)

Keratosis Any skin condition in which there is overgrowth and thickening of the cornified epithelium.

Ketosis A condition characterized by the abnormal accumulation of ketones (organic compounds with a carboxyl group attached to two carbon atoms) in the body tissues and fluid.

Kinesthesia The sense of movement, weight, tension, and position of body parts mediated by input from joint and muscle receptors and hair cells. (Adjective: kinesthetic)

Kyphosis An abnormal condition of the vertebral column, characterized by increased convexity in the curvature of the thoracic spine as viewed from the side.

Lacuna A small pit or cavity within a structure, especially bony tissue, or a defect or gap, as in the field of vision.

Lateral A position farther from the median plane or midline of the body or a structure, or situated on, coming from, or directed toward the side.

Lesion Any wound, injury, or pathologic change in body tissue.

Lethargy The lowered level of consciousness characterized by listlessness, drowsiness, and apathy, or a state of indifference.

Ligament One of many predominantly white, shiny, flexible bands of fibrous tissue that binds joints together and connects bones or cartilages.

Ligand A group, ion, or molecule that binds to the central atom or molecule in a chemical complex.

Lipid Any of the group of fats and fatlike substances characterized by being insoluble in water and soluble in nonpolar organic solvents, such as chloroform and ether.

Lipoprotein Any one of the conjugated proteins that is a complex of protein and lipid.

Lobule A small lobe.

Lordosis The anterior concavity in the curvature of the lumbar and cervical spine as observed from the side.

Lumen A cavity or the channel within a tube or tubular organ of the body.

Luteal Of or pertaining to or having the properties of the corpus luteum.

Lysis Destruction or dissolution of a cell or molecule through the action of a specific agent.

Maceration Softening of tissue by soaking, especially in acidic solutions.

Macroscopic Large enough to be visible with the unaided eye or without the microscope.

Macula A small, flat blemish, thickening, or discoloration that is flush with the skin surface. (Adjective: macular)

Malaise A vague feeling of bodily fatigue and discomfort.

Manometry The measurement of tension or pressure of a liquid or gas using a device called a manometer.

Marasmus A condition of extreme protein-calorie malnutrition that is characterized by growth retardation and progressive wasting of subcutaneous tissue and muscle, and occurs chiefly during the first year of life.

Matrix The intracellular substance of a tissue or the basic substance from which a specific organ or kind of tissue develops.

Meatus An opening or passage through any body part.

Medial Pertaining to the middle, or situated or oriented toward the midline of the body.

Mediastinum The mass of tissues and organs in the middle of the thorax, separating the pleural sacs containing the two lungs.

Meiosis The division of a sex cell as it matures, so that each daughter nucleus receives one half of the number of chromosomes characteristic of the somatic cells of the species.

Mesoderm The middle layer of the three primary germ layers of the developing embryo, lying between the ectoderm and the endoderm.

Metabolism The sum of all the physical and chemical processes by which living organisms are produced and maintained, and also the transformation by which energy is provided for vital processes and activities.

Metaplasia Change in type of adult cells in a tissue to a form that is not normal for that tissue.
Metastasis The transfer of disease (e.g., cancer) from one organ or part to another not directly connected with it. (Adjective: metastatic)

Miosis Contraction of the pupil of the eye.

Mitosis A type of indirect cell division that occurs in somatic cells and results in the formation of two daughter nuclei containing the identical complements of the number of chromosomes characteristic of the somatic cells of the species.

Molecule The smallest mass of matter that exhibits the properties of an element or compound.

Morbidity A diseased condition or state; the relative incidence of a disease or of all diseases in a population.

Morphology The study of the physical form and structure of an organism, or the form and structure of a particular organism. (Adjective: morphologic)

Mosaicism In genetics, the presence in an individual or in an organism of cell cultures having two or more cell lines that differ in genetic constitution but are derived from a single zygote.

Mutagen Any chemical or physical agent that induces a genetic mutation (an unusual change in form, quality, or some other characteristic) or increases the mutation rate by causing changes in DNA.

Mydriasis Physiologic dilatation of the pupil of the eye.

Myoclonus A spasm of a portion of a muscle, an entire muscle, or a group of muscles.

Myoglobin The oxygen-transporting pigment of muscle consisting of one heme molecule containing one iron molecule attached to a single globin chain.

Myopathy Any disease or abnormal condition of skeletal muscle, usually characterized by muscle weakness, wasting, and histologic changes within muscle tissue.

Myotome The muscle plate or portion of an embryonic somite that develops into a voluntary muscle, or a group of muscles innervated by a single spinal segment.

Necrosis Localized tissue death that occurs in groups of cells or part of a structure or an organ in response to disease or injury.

Neutropenia An abnormal decrease in the number of neutrophil leukocytes in the blood.

Nidus The point where a morbid process originates, develops, or is located.

Nociception The reception of painful stimuli from the physical or mechanical injury to body tissues by nociceptors (receptors usually found in either the skin or the walls of the visera).

Nosocomial Pertaining to or originating in a hospital, such as a nosocomial infection: an infection acquired during hospitalization.

Nystagmus Involuntary, rapid, rhythmic movements of the eyeball.

Oncogene A gene that is capable of causing the initial and continuing conversion of normal cells into cancer cells.

Oncotic Relating to, caused by, or marked by edema or any swelling.

Oocyte A primordial or incompletely developed ovum.

Oogenesis The process of the growth and maturation of the female gametes or ova.

Opsonization The process of making cells, such as bacteria, more susceptible to the action of phagocytes.

Organelle Any one of the various membrane-bound particles of distinctive morphology and function present within most cells, as the mitochondria, the Golgi complex, and the lysosomes.

Orthopnea An abnormal condition in which a person must be in an upright position in order to breathe deeply or comfortably.

Orthesis An external orthopedic appliance or apparatus, as a brace or splint, used to support, align, prevent or correct deformities, or to improve the function of movable parts of the body.

Osmolality The concentration of osmotically active particles in solution expressed in osmol or milliosmols per kilogram of solvent.

Osmolarity The concentration of osmotically active particles in solution expressed in osmol or milliosmols per liter of solution.

Osmosis The movement or passage of a pure solvent, such as water, through a semipermeable membrane from a solution that has a lower solute concentration to one that has a higher solute concentration.

Osteophyte A bony projection or outgrowth.

Palpable Perceptible by touch.

Papilla A small nipple-shaped projection, elevation, or structure, as the conoid papillae of the tongue.

Papule A small, circumscribed, solid elevation of the skin less than 1 cm in diameter. (Adjective: papular)

Paracrine A mode of hormone action in which a chemical messenger that is synthesized and released from a cell acts on nearby cells of a different type and affects their function.

Paralysis An abnormal condition characterized by the impairment or loss of motor function due to a lesion of the neural or muscular mechanism.

Paraneoplastic Relating to alterations produced in tissue remote from a tumor or its metastases.

Parenchyma The basic tissue or elements of an organ as distinguished from supporting or connective tissue or elements. (Adjective: parenchymal)

Paresis Slight or partial paralysis.

Paresthesia Any abnormal touch sensation, which can be experienced as numbness, tingling, or a “pins and needles” feeling, often in the absence of external stimuli.

Parietal Pertaining to the outer wall of a cavity or organ, or pertaining to the parietal bone of the skull or the parietal lobe of the brain.

Parous Having borne one or more viable offspring.

Pathogen Any microorganism capable of producing disease.
**Pedigree** A systematic presentation, such as in a table, chart, or list, of an individual’s ancestors that is used in human genetics in the analysis of inheritance.

**Peptide** Any of a class of molecular chain compounds composed of two or more amino acids joined by peptide bonds.

**Perfusion** The process or act of pouring over or through, especially the passage of a fluid through a specific organ or an area of the body.

**Peripheral** Pertaining to the outside, surface, or surrounding area of an organ or other structure, or located away from a center or central structure.

**Permeable** A condition of being pervious or permitting passage, so that fluids and certain other substances can pass through, as a permeable membrane.

**Pervasive** Pertaining to something that becomes diffused throughout every part.

**Petechia** A tiny, perfectly round, purplish red spot that appears on the skin as a result of minute intradermal or submucous hemorrhage. (Plural: petechiae)

**Phagocytosis** The process by which certain cells engulf and consume foreign material and cell debris.

**Phalanx** Any one of the bones composing the fingers of each hand and the toes of each foot.

**Phenotype** The complete physical, biochemical, and physiologic makeup of an individual, as determined by the interaction of both genetic makeup and environmental factors.

**Pheresis** A procedure in which blood is withdrawn from a donor, a portion (plasma, leukocytes, etc.) is separated and retained, and the remainder is reperfused into the donor. It includes plasmapheresis and leukapheresis.

**Pili** Hair, or in microbiology, the minute filamentous appendages of certain bacteria. (Singular: pilus)

**Plasmapheresis** Relating to an excess of any of the body fluids, especially blood; the term used to describe the beefy red coloration of a newborn.

**Plexus** A network of intersecting nerves, blood vessels, or lymphatic vessels.

**Polygene** Any of a group of nonallelic genes that interact to influence the same character in the same way so that the effect is cumulative, usually of a quantitative nature, as size, weight, or skin pigmentation. (Adjective: polygenic)

**Polymorph** One of several, or many, forms of an organism or cell. (Adjective: polymorphic)

**Polyp** A small, tumor-like growth that protrudes from a mucous membrane surface.

**Polypeptide** A molecular chain of more than two amino acids joined by peptide bonds.

**Presbyopia** A visual condition (farsightedness) that commonly develops with advancing years or old age in which the lens loses elasticity causing defective accommodation and inability to focus sharply for near vision.

**Prevalence** The number of new and old cases of a disease that is present in a population at a given time, or occurrences of an event during a particular period of time.

**Prodrome** An early symptom indicating the onset of a condition or disease. (Adjective: prodromal)

**Prokaryotic** Pertaining to an organism, such as bacterium, with cells lacking a true nucleus and nuclear membrane that reproduces through simple fission.

**Protrusion** The falling down, sinking, or sliding of an organ from its normal position or location in the body.

**Proliferation** The reproduction or multiplication of similar forms, especially cells.

**Pronation** Assumption of a position in which the ventral, or front, surface of the body or part of the body faces downward. (Adjective: prone)

**Propagation** The act or action of reproduction.

**Propriocception** The reception of stimuli originating from within the body regarding body position and muscular activity by proprioceptors (sensory nerve endings found in muscles, tendons, joints).

**Prosthesis** An artificial replacement for a missing body part, or a device designed and applied to improve function, such as a hearing aid.

**Proteoglycans** Any one of a group of polysaccharide-protein conjugates occurring primarily in the matrix of connective tissue and cartilage.

**Proto-oncogene** A normal cellular gene that with alteration, such as by mutation, becomes an active oncogene.

**Proximal** Closer to a point of reference, usually the trunk of the body, than other parts of the body.

**Pruritus** The symptom of itching, an uncomfortable sensation leading to the urge to rub or scratch the skin to obtain relief. (Adjective: pruritic)

**Purpura** A small hemorrhage, up to about 1 cm in diameter, in the skin, mucous membrane, or serosal surface, or any of several bleeding disorders characterized by the presence of purpuric lesions.

**Purulent** Producing or containing pus.

**Quiescent** Quiet, causing no disturbance, activity, or symptoms.

**Reflux** An abnormal backward or return flow of a fluid, such as stomach contents, blood, or urine.

**Regurgitation** A flow of material that is in the opposite direction from normal, as in the return of swallowed food into the mouth or the backward flow of blood through a defective heart valve.

**Remission** The partial or complete disappearance of the symptoms of a chronic or malignant disease, or the period of time during which the abatement of symptoms occurs.

**Resorption** The loss of substance or bone by physiologic or pathologic means, for example, the loss of dentin and cementum of a tooth.

**Retrograde** Moving backward or against the usual direction of flow, reverting to an earlier state or worse condition (degenerating), catabolic.
Retroversion A condition in which an entire organ is tipped backward or in a posterior direction, usually without flexion or other distortion.

Rhabdomyolysis Destruction or degeneration of muscle, associated with myoglobinuria (excretion of myoglobin in the urine).

Rostral Situated near a beak (oral or nasal region).

Sacroiliitis Inflammation in the sacroiliac joint.

Sclerosis A condition characterized by induration or hardening of tissue resulting from any of several causes, including inflammation, diseases of the interstitial substance, and increased formation of connective tissues.

Scotopic vision Describes vision, especially night vision, when the eye is dark adapted.

Semipermeable Partially but not wholly permeable, especially a membrane that permits the passage of some (usually small) molecules but not of other (usually larger) particles.

Senescence The process or condition of aging or growing old.

Sepsis The presence in the blood or other tissues of pathogenic microorganisms or their toxins, or the condition resulting from the spread of microorganisms or their products. (Adjective: septic)

Serous Relating to or resembling serum, or containing or producing serum, such as a serous gland.

Shunt To divert or bypass bodily fluid from one channel, path, or part to another; a passage or anastomosis between two natural channels, especially between blood vessels, established by surgery or occurring as an abnormality.

Soma The body of an organism as distinguished from the mind; all of an organ, excluding germ cells; the body of a cell.

Spasticity The condition characterized by spasms or other uncontrolled contractions of the skeletal muscles. (Adjective: spastic)

Spatial Relating to, having the character of, or occupying space.

Sphincter A ringlike band of muscle fibers that constricts a passage or closes a natural orifice of the body.

Stenosis An abnormal condition characterized by the narrowing or stricture of a duct or canal.

Stochastic Involving a random process.

Stria A streak or a linear scarlike lesion that often results from rapidly developing tension in the skin, or a narrow bandlike structure, especially the longitudinal collections of nerve fibers in the brain.

Stricture An abnormal temporary or permanent narrowing of the lumen of a duct, canal, or other passage, as the esophagus, because of inflammation, external pressure, or scarring.

Stroma The supporting tissue or the matrix of an organ as distinguished from its functional element or parenchyma.

Stupor A lowered level of consciousness characterized by lethargy and unresponsiveness in which a person seems unaware of his or her surroundings.

Subchondral Beneath a cartilage.

Subcutaneous Beneath the skin.

Subluxation An incomplete or partial dislocation in which the relationship between joint surfaces is altered, but contact remains.

Sulcus A shallow groove, depression, or furrow on the surface of an organ, as a sulcus on the surface of the brain, separating the gyri.

Supination Assuming the position of lying horizontally on the back or with the face upward. (Adjective: supine)

Suppuration The formation of pus or purulent matter.

Symbiosis Mode of living characterized by close association between organisms of different species, usually in a mutually beneficial relationship.

Sympathomimetic An agent or substance that produces stimulating effects on organs and structures similar to those produced by the sympathetic nervous system.

Syncope A brief lapse of consciousness due to generalized cerebral ischemia.

Syncytium A multinucleate mass of protoplasm produced by the merging of a group of cells.

Syndrome A complex of signs and symptoms that occur together to present a clinical picture of a disease or inherited abnormality.

Synergist An organ, agent, or substance that aids or cooperates with another organ, agent, or substance.

Synthesis An integration or combination of various parts or elements to create a unified whole.

Systemic Pertaining to the whole body rather than to a localized area or regional portion of the body.

Systole The contraction, or period of contraction, of the heart that drives the blood onward into the aorta and pulmonary arteries.

Tamponade Stoppage of the flow of blood to an organ or a part of the body by pathologic compression, such as the compression of the heart by an accumulation of pericardial fluid.

Teratogen Any agent or factor that induces or increases the incidence of developmental abnormalities in the fetus.

Thrombus A stationary mass of clotted blood or other formed elements that remains attached to its place of origin along the wall of a blood vessel, frequently obstructing the circulation. (Plural: thrombi)

Tinnitus A tinkling, buzzing, or ringing noise heard in one or both ears.

Tophus A chalky deposit containing sodium urate that most often develops in periarticular fibrous tissue, typically in individuals with gout. (Plural: tophi)

Torsion The act or process of twisting in either a positive (clockwise) or negative (counterclockwise) direction.
Trabecula A supporting or anchoring stand of connective tissue, such as the delicate fibrous threads connecting the inner surface of the arachnoid to the pia mater.

Transmural Situated or occurring through the wall of an organ.

Transudate A fluid substance passed through a membrane or extruded from the blood.

Tremor Involuntary quivering or trembling movements caused by the alternating contraction and relaxation of opposing groups of skeletal muscles.

Trigone A triangular-shaped area.

Ubiquitous The condition or state of existing or being everywhere at the same time.

Ulcer A circumscribed excavation of the surface of an organ or tissue, which results from necrosis that accompanies some inflammatory, infectious, or malignant processes. (Adjective: ulcerative)

Urticaria A pruritic skin eruption of the upper dermis, usually transient, characterized by wheals (hives) of various shapes and sizes.

Uveitis An inflammation of all or part of the uveal tract of the eye.

Vector An invertebrate animal (e.g., tick, mite, mosquito) that serves as a carrier, transferring an infective agent from one vertebrate host to another.

Ventral Pertaining to a position toward the belly of the body, or situated or oriented toward the front or anterior of the body.

Vertigo An illusory sensation that the environment or one’s own body is revolving.

Vesicle A small bladder or sac, as a small, thin-walled, raised skin lesion, containing liquid.

Visceral Pertaining to the viscera or internal organs of the body.

Viscosity Pertaining to the physical property of fluids, caused by the adhesion of adjacent molecules, that determines the internal resistance to shear forces.

Zoonosis A disease of animals that may be transmitted to humans from its primary animal host under natural conditions.

inflammation, 310
in inflammation, 312
headache, 446
edema of, in neonates, 23
vagina, 1335–1336, 1335f, 1336f
edema of, in neonates, 23
vagina, 1335–1336, 1335f, 1336f
Selective immunoglobulin A deficiency, 333
Selective serotonin reuptake inhibitors, 54
Selenium, for Parkinson disease, 475
Selenium sulfate, for tinea versicolor, 1545
Self-renewal, of cells, 165
Self-tolerance, 353, 357
Selye, Hans, on stress response, 202, 205
Senescent, 125, 177
Senescence, cellular, 115, 177
Senile pruriitis, 1581
Senility, 55
Sennetsu fever, 260
Sensitivity, of test results, 6
Sensitivity, of pain perception, 434
Sequestrum, 1463
Sequestra, 1463
Sequelae, of disease, 5
Septum secundum, 830f, 831
Septum primum, 830f, 831
Septoplasty, for sleep apnea, 538
Septoplasty, for sleep apnea, 538
Sepsis, 1570
Sepsis and septicemia, 264, 318
Septal valves, 722
Sentinel lymph nodes, 171–172, 1409
Serous fluid, in small intestine, 1164, 1198
Serous, in small intestine, 1164, 1198
Serrata, in pneumonia, 936
Sertoli cells
damage of, 1342
physiology of, 1338, 1339f, 1340, 1341f
Serum, 638
Set-point, for body temperature, 218
Sevelamer, 1056
Severe acute respiratory syndrome (SARS), 274
Severe combined immunodeficiency disorder, 336
Sex
determination of, 1334–1335
developmental disorders of, 1347
Sex chromosomes, 127, 128f
disorders of, 148–150, 148f, 149f, 150t
in sex determination, 1334
Sex hormones
abnormalities of, in liver failure, 1231
in adaptation, 201–211
adrenal, 1294
asthma and, 970
for cancer treatment, 194
in stress response, 208
Sexual activity
in adolescents, 35–36
in older adults, 49
Sexual behavior, 35–36
Sexual dysfunction
in chronic kidney disease, 1123–1124
in spinal cord injury, 485
Sexually associated reactive arthritis (Reiter syndrome), 1425
Sexually transmitted infections (STIs), 1416–1429
epididymitis in, 1354–1355
external genitalia infection chancroid, 1420–1421
treponema pallidum, 1417–1418
genital herpes, 1418–1420
granuloma inguinale, 1421
lymphogranuloma venereum, 1421
molluscum contagiosum, 1420
HIV transmission risk in, 363
incidence, 1416
infection agents, 1416
prevalence, 1416
spread, 1416
systemic, 1424–1428, 1425f–1428f
transmission of, 262
vaginal infections, 1422–1424, 1422f, 1423f
bacterial vaginosis, 1423–1424
candidiasis, 1423
trichomoniasis, 1422
vaginal-urogenital-systemic infections
chlamydial infections, 1424–1425
gonorhea, 1425–1427
syphilis, 1427–1428
Shear stress, on endothelium, 730
Shell shock (post-traumatic stress disorder), 213
Shiga toxins, 266
Shigellosis, in enterocolitis, 1190
Shingles, 1549, 1549f
keratitis in, 583
neuralgia after, 444
Shivering in hypothermia, 227–228
in infants, 19
physiology of, 218t, 219, 221, 222f
Shock
anaphylactic, 434, 887–888
blood vessel collapse in, 718
cardiogenic, 881–885
circulatory, 867–895
complications of, 890–891
disseminated intravascular coagulation in, 662f, 663, 663c
distributive, 887–889
endotoxic, 266
neurogenic, 887
normovolemic (distributive), 887
obstructive, 889–890
renal failure in, 1113, 1113c
septic, 888–889
spinal, 480, 887
Shoes, for diabetes mellitus, 1329
Short QT syndrome, 816
Short stature, 1281–1282, 1282f
Shoulder
arm motion, 1447
articulations, 1447
clavicle, 1447
humerus, 1447
injuries of, 1447–1448, 1448f
overuse and degenerative disorder, 1447–1448
physical examination, 1448
scapula, 1447
stability, 1447
subacromial bursae, 1447
Shoulder impingement syndrome, 1448
Shunts (shunting)
left-to-right, 833
portosystemic, 1230–1231, 1231f
in pulmonary circulation, 918
right-to-left, 833
Shy-Drager syndrome, 788
Sick sinus syndrome, 854–855
Sickle cell disease, 675–677, 675f, 676f
Sigmoidoscopy
in colorectal cancer, 1203
in Crohn disease, 1187
Signal-averaged electrocardiography, 801, 860
Signs, of disease, 4
Sildenafil
for erectile dysfunction, 1350
for pulmonary hypertension, 987
Silicosis, pneumoconiosis in, 981–982
Silver sulfadiazine, for burns, 1570
Simple epithelium, 91
Sims-Huhner test, 1411–1412
Single nucleotide polymorphisms, 134
Single photon emission computed tomography (SPECT), 546, 802
Single-breath test, for diffusing capacity, 919
Single-gene disorder(s)
arthrogryposis multiplex congenital, 139–142, 140f,
140t, 141f
autosomal recessive, 140t, 142–144, 142f, 143f
Single-gene trait, 131, 132f
Single-ventricle anatomy, 839, 840f
Sinusoidal node
dysfunction of, 846
function of, 845–846
Sinus arrest, 854
Sinus bradycardia, 854
Sinus (es), cerebral, 409f
Sinus rhythm, 853
Sinus tachycardia, 854
Sinusitis, 931
Sinusoids, 1210, 1211f
Sitaalp, for diabetes mellitus, 1318f, 1319t,
1320
Sixth disease, 1580
Sjogren syndrome, 578
Skeletal disorders
in chronic kidney disease, 1121–1122
congenital, 1481–1484, 1482f–1484f
Skin

Skin disorders, 1541–1583
dermatomes of, 424, 424f, 425f
damage, UV rays, 1566–1567
characteristics of, 1545
basal cell carcinoma, 1574–1576, 1575f
incidence, 1574
malignant melanoma, 1559–1562, 1560f, 1562f
pigmentary, 1542–1543
rosacea, 1554–1555
in spinal cord injury, 486
in systemic lupus erythematosus, 1506
viral, 3105–3108, 3106f, 3107f
Skinfold thickness, measurement of, 1258
Skip lesions, in Crohn disease, 1184, 1185f
Skull

Skin of adolescents, 31
effects on, 43–44
appendages
hair, 1533, 1533f
nails, 1534
sebaceous glands, 1533
sweat glands, 1533
barrier function of, 282–283
bed rest effects on, 247
blood supply of, 1534

cancer
basal cell carcinoma, 1576–1577, 1576f
incidence, 1574
malignant melanoma, 1575–1576, 1576f
squamous cell carcinoma, 1577–1578
characteristics of, 1545
damage, UV rays, 1566–1567
dermatomes of, 424, 424f, 425f
diseases of. See Skin disorders
dry, 1539
emotional state reflected in, 1541
functions, 1534
graft, burn, 1567–1568

Ventricular bigeminy, 858
Ventricular assist devices, for heart failure
Vestibular system, 628–630, 628f, 629f
Vestibular nuclei, 630
Vestibular neuronitis, acute, 632
Vesicle(s)
Vertigo, 630–631, 631t
Ventricular septum, 830f, 831
Ventricular diastole, 723
Ventricular fibrillation
in acute coronary syndromes, 807
Ventricular assist devices, for heart failure
Vestibular system, 628–630, 628f, 629f
Vasopressin.
Antidiuretic hormone (ADH,
White blood cells, 640–643, 641f, 642f. See also specific type
deficiency of (leukopenia), in inflammation, 318
development of, 689
disorders of
infectious mononucleosis, 696
leukemias. See Leukemia(s)
lymphoma. See Lymphoma(s)
neutropenia. See Neutropenia
excess of (leukocytosis), in inflammation, 309, 309f, 310, 318
in inflammation, 309–311, 311f
maturation of, 645f
number of, 689
types of, 689
White heads, 1550
White matter, 384
of cerebellum, 405
layers of, 396, 399f, 399t
of spinal cord, 400, 401f
White pupil reflex, 602, 602f
Whole blood buffer base, 1069
Wide-dynamic-range neurons, 433
Wild-type alleles, 139
Williams syndrome, heart defects in, 832
Willis, circle of, 506f, 507, 510, 510f
Wilson disease, 583, 1228
Window period
in hepatitis B, 1222
in HIV infection, 363
Windup, in pain transmission, 433
Wiskott-Aldrich syndrome, 337
Withdrawal reflex, 402, 403f, 429
Wolbachia, 260
Wolffian ducts, 1335
Wolff-Parkinson-White syndrome, 853, 856
Women’s Health Initiative, hormone therapy and,
1376–1377
Wood light, for fungal detection, 1543
Work of breathing, 915–916, 971
World Health Organization
analgescic ladder of, 439
health definition of, 3
Hodgkin lymphoma classification of, 689
lymphoma classification of, 689
obesity classification of, 1252
Worms (helminths), 261
Wound(s)
bite, 325
separation of, 325
Wound botulism, 464
Wound healing, 321–326
connective tissue repair in, 321
factors affecting, 324–325
by primary intention, 322, 322f
proliferative phase of, 321, 323
regeneration in, 319
remodeling phase of, 322, 322f, 323
by secondary intention, 322, 322f, 432f
wound separation and, 325
Woven bone, 1436
Wrinkles, 1581
Wrist
fractures of, 52
sprain, 1446, 1447, 1447f
Wrist actigraphy, in sleep evaluation, 531
X chromosomes, 127, 128f
X-linked disorders
agammaglobulinemia, 322f, 332–333
chronic granulomatous disease, 339
color blindness, 595
immunodeficiency with hyper-IgM, 335
muscular dystrophy, 461–463, 462f
severe combined immunodeficiency, 336
vitamin D-resistant rickets, 1494
Wiskott-Aldrich syndrome, 337
Y-linked recessive disorders, 143, 143f
XXY male (Klinefelter syndrome), 149–150, 149f
Y chromosomes, 127, 128f
Y chromosomal disorders of, 149–150, 149f
in sex differentiation, 1335
Yeast, 254t, 260, 261, 1543
Yeast infection. See Candidiasis, vaginal
Yersinia pestis, 273
Yolk sac tumors, of testis, 1356
Z chromosomes, 127, 128f
ZAP-70 protein, in leukemia, 705
Zidovudine, for HIV infection, 375, 377
Zinc, dietary, 1250t
Z-line, of sarcomere, 94, 95f
Zollinger-Ellison syndrome, 1182
Zona fasciculata, 1293f, 1294
Zona glomerulosa, 1293f, 1294
Zona pellucida, 1373, 1374f
Zona reticularis, 1293f, 1294
Zonules, 589
Zoonoses, 263
Zoster, 1549, 1549f
keratitis in, 583
postherpetic pain in, 444
Zygote, 14, 14f, 119
Zygote intrafallopian transfer, 1412–1413
